WE are constantly referred by the writers above alluded to, to the usages of France as fit objects of imitation, and as contrasting strongly with our institutions here. What will our readers think when we inform them, that, by recent decrees, the privilege of conducting dissections is limited to two establishments (*viz.* le Clamart(?) and the Ecole de Médecine;) while, with regard to autopsies, the physicians to the hospitals *are prohibited from opening more than one body out of every three!* a pretty pattern for imitation, truly.

FRENCH MEDICAL GRADE AND THE *CONCOURS*.

CIRCUMSTANCES have just occurred in Paris, which place in a strong light at once the jealous distinction of grade, and the warm feeling in favour of the

concoirs, entertained by the most distinguished professional men in that metropolis. The place of surgeon in one of the hospitals having become vacant, a physician in the same establishment was exerting his interest to obtain the nomination; but the surgeons of the Central Bureau immediately protested against the proceeding, and petitioned the Minister of the Interior on the subject. "It is contrary to all precedent," they say, "that titles should thus be transformed;" and they quote the law which allows medical men to be transferred from one appointment to another, but only *in the same quality*: the physician, in fact, even though he be a Doctor of Surgery, must still remain a physician, while attached to the same hospital: by the concours alone can he obtain a surgeoncy.

The protest against violating the law of the concours is signed by MM. Dupuytren, Berard, Dubois, J. Cloquet, Roux, Breschet, Velpeau, Richerand, &c.; and we must say, that we have seldom observed a measure, emanating from our Parisian brethren, more unanimously or more respectfully supported.

FATAL INADVERTENCE IN PRESCRIBING.

A CASE was tried last week before the Correctional Chamber of Paris, involving a serious charge of homicide by imprudence. A medical man was called in to a child, three years and a half old, who was suffering under fever. A prescription was written, in which it was intended to order for a lavement eight grains of *sulphate of quinine*, with a few drops of laudanum. But the prescriber having just previously been engaged in a warm conversation with a medical friend concerning *acetate of morphine*, inadvertently wrote down that potent drug, instead of the quinine, in the prescription. The apothecary who dispensed it did nothing towards rectifying the error, except reducing the quantity to five grains. Scarcely was the lavement administered when the

child experienced a sinking sensation; the skin became of a violet hue, and was covered with large drops of perspiration. Convulsions ensued, and death with great agony in a few hours. The Court severely censured the conduct of the apothecary for making up a prescription so palpably incorrect; but, owing to the mitigatory circumstances, the accused prescriber was let off with a fine of 600 francs, and costs.

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

VIII.—*The Voluntary Muscles—Tendons—Bursæ Mucosæ—Filamentous Tissue—Aponeuroses—Adipose Tissue.*

I. *Of the voluntary muscles.*—The higher endowments of the voluntary muscles open a new field in pathology: we have to study in them, not only the changes of structure which their tissue displays, but the alterations or modifications of their properties and functions, which are liable to occur without any visible deterioration of texture.

The voluntary muscles are liable to palsy, which may affect, either their sensibility, or their motion, or both. The first case is termed *anæsthesia*. When met with (and that is rare) it is combined with loss of cutaneous sensation, and is confined to the extremities. The second case is of more frequent occurrence: it is met with, for instance, in the paralysis which attacks one side of the face. The combination of the two is frequent, and occurs of every degree, from numbness and weakness to total insensibility and powerlessness. The voluntary muscles are liable to be the seat of pain: thus, in cancer of the breast, muscular pain is often felt at the insertion of the deltoid, at the elbow, and in the back. The voluntary muscles are liable to be thrown into involuntary action. This state is called *cramp*, or *spasm*: its duration is either instantaneous, or of longer continuance. Ordinary cramp of the gastrocnemii and of the muscles of the great toe, bears the latter character; so does the spasm in locked-jaw, tetanus, cholera. Of the former kind of spasm I recollect a remarkable instance: a workman had struck a chisel through the lower tendon of the rectus; three or four days afterwards, spasms began, which in a short time recurred once or twice in a minute;

in them the leg was suddenly raised, with the knee straightened.

The affections which I have thus enumerated belong, however, rather to the nerves than to the muscles; not the pain only, but the spasmodic action likewise. When tetanus has been produced in animals by affecting them with strychnine, the spasm is found to be temporarily suspended upon making pressure upon the spinal marrow.

The transition from these affections to changes of structure in muscle, is found in the permanent and rigid contraction of the sterno-mastoid, which causes and constitutes wry-neck.

The alterations, which the texture of voluntary muscles is liable to undergo, are the following:—

a. When a muscle has been divided, it may reunite in one or other of two ways—according as the skin covering it is torn and remains ununited, or otherwise. In the first case, the reparation of the muscle is preceded by inflammation and suppuration: from the inflamed surfaces lymph is poured out, which coagulates, and, adhering to it, becomes organized, and forms granulations. The latter growing by fresh exudation of lymph, fill the vacancy caused by the retraction of the torn fibres. The organized medium of union subsequently contracts, and the divided ends of the muscle are drawn towards each other, and finally become directly reunited. In the second case—namely, when the skin is entire, and inflammation, suppuration, and granulation do not take place—the medium of union is infiltration of the cellular tissue surrounding the torn muscle with lymph, which forms a kind of callus that becomes organized, and finally contracts, like the uniting substance that proceeds from inflammation. The soft texture of muscle is easily cut through, or lacerated. It has been ruptured by its own action, and, in the instance of the abdominal muscles, by a bruise which has not torn the skin.

b. The voluntary muscles are liable to hypertrophy. I saw in a young woman the tongue enlarged to five or six times its natural size, which, projecting permanently from the mouth, had caused the corners of the mouth to ulcerate.

c. The voluntary muscles are liable to atrophy. This proceeds either from age or from disuse. In the first case, the muscular fibre becomes paler, and thin layers of fat are often found deposited in the interstices of the fasciculi. In the latter case, as upon the disuse of a limb from disease of a principal joint, the muscles become thinner and paler, and lose their firmness. One remark, which deserves to be borne in mind in surgical operations, I have made upon the extent of retraction

upon division in extenuated muscles: it is considerably greater in these than in the firm and well-developed muscles of a strong adult.

d. There is a degeneration of muscle, which is called *steatosis*: it is somewhat different from atrophy. Without losing its volume or its fibrous character entirely, the affected muscle becomes of a lighter colour, and greasy, and seems to be in process of conversion into firm lamellated fat. This change is sometimes attended with great pain of the muscle affected.

e. The voluntary muscles are susceptible of inflammation, abscess, sloughing.

In the arm of a subject in which death appeared to have been occasioned by phlegmonous erysipelas, I found the muscles of the fore-arm and upper-arm full of small abscesses.

In a case of ulcer of the leg, which spread rapidly, without any general taint of the system, the aponeurosis of the anterior muscles sloughed; when a singular tumor and protrusion took place of the unsupported and inflamed and granulating muscle, which, for a time, conveyed to some who witnessed it the impression that it was a malignant growth.

Acute rheumatism is said sometimes to be attended with the effusion of a jelly-like fluid in and upon the muscles attacked.

Gouty inflammation of muscular texture is occasionally followed by the deposit of lithate of soda between the fasciculi.

Muscle is liable to be involved in or to be the seat of all the malignant growths.

The liability of muscle to ossification has been already mentioned.

One species of entozoa [*cysticercus cellulosus*] has been found in human muscles.

II. Of tendons.—Tendon is the seat of the following changes:—

a. When torn, its reunion takes place in this manner, which I have verified by experiment. The adjacent cellular membrane swells through an infiltration with lymph. The torn ends of the tendon, which have been drawn apart by the tone of the muscle, are at first imbedded in the thickened mass of infiltrated cellular tissue, without having any strong adhesion to it; in the progress of restoration, the infiltrated membrane becomes a firm callus, cohering with the sides and ends of the tendon, with which it at last becomes inseparably joined; at the same time it becomes denser, whiter, firmer; and shrinking in volume as it gains strength, it approaches more and more to the character of the tendon which it unites.

b. Tendons are susceptible of inflammation. In acute rheumatism, the tendinous structure is certainly involved;

and in gout, the gouty concretion is found deposited in tendon. In the tendo Achillis, and probably in other tendons, small painful swellings occasionally take place in persons who take much and irregular walking exercise: these swellings become less, and cease to be painful, when less exercise is taken.

III. The *bursæ mucosæ* are the joints of tendons. When tendons play over periosteum, or ligament, or cartilage, sacs of synovial membrane are interposed between the surfaces which move on each other. Similar sacs of synovial membrane are met with between the skin and tendinous, ligamentous, or periosteal surfaces, over which the skin has much motion; and what is very singular, similar sacs are liable to be produced in places where they naturally have no existence, upon unusual pressure being made there. Thus ganglions are often met with on the wrist, produced between the skin and the posterior annular ligament.

a. The affections of the synovial sheaths of tendons are no less troublesome than simple. As far as I have seen, they are limited to two varieties of subacute inflammation; one in which the inflamed membrane contains an increased quantity of synovia only; the other in which small portions of lymph, generally smooth and of an irregular shape, are contained in the increased synovia.

A young woman has recently left the Middlesex Hospital, who was under my care for the first of these affections. She had a painful swelling behind and below the outer ankle-joint, which evidently consisted of fluid in the sheath of the tendons of the peronei. With rest, as had happened on former occasions, the pain and tenderness of the ankle went away; and I succeeded, by applying irritants to the skin, in producing absorption of part of the fluid.

The second of these affections I have twice seen in the fore-arm. In one case the swelling was towards the wrist, and I entertained no doubt as to its nature. It was attended with no pain or increase of sensibility; and it mended, and seemed disposed to get well, upon repeated puncturing; when I lost sight of the patient. In the other case the fore-arm was generally and greatly enlarged, and I was not without my fears that it was affected with malignant disease; but on puncturing the swelling, synovia, with portions of lymph floating in it, escaped, and the intermuscular swelling diminished. I punctured the swelling twice, when the patient being better left the hospital, and I heard no more of him.

The subcutaneous bursæ present the following features under disease:—

α, Without thickening or pain, or with very trifling pain, there may be increased secretion of synovia. This affection is most frequent in the subcutaneous bursa of the patella. The appropriate treatment for it is rest, with the application of some irritant to the skin. If this method fails, in alternation with it, simple and repeated puncturing may be used. It often happens that the fluid thus once let out does not re-collect.

β, Great thickening and induration of the synovial membrane, with slight effusion of fluid. The best practice in this case is the excision of the subcutaneous bursa. I have cut out thickened bursæ both on the wrist, and at the outside of the head of the tibia; they were in each case, I believe, synovial sacs, that had been developed from pressure; for, in general, no bursæ are met with at the points where these occurred.

γ, With considerable thickening great effusion of fluid. A middle-aged woman was admitted into the Middlesex Hospital, with a large tumor in front of the knee-joint, with which I could satisfy myself that it had no connexion. Upon puncturing it, eight ounces of a dark-brown viscid liquid escaped. The cyst then inflamed and suppurated, producing a considerable degree of fever, which lessened upon making three or four openings half an inch in extent, at the different corners of the suppurating synovial membrane, and the patient recovered.

δ, Without thickening or effusion previously observed, sudden inflammation, with swelling of the parts around, and redness of the skin. This is not uncommon in men as well as women at the subcutaneous bursa of the patella: it appears to involve the knee joint, but it does not. Upon opening the bursa, which in such an attack suppurates early, the inflammation subsides, and the synovial cavity, in the process of healing, becomes obliterated.

IV. *The filamentous tissue.*—The filamentous tissue, or cellular membrane, in one of its relations, forms the joints of the voluntary muscles; viewed in another, the slender and almost mucous threads of which it is composed with the cellular interstices between them, constitute a channel, through which the whole frame may be rapidly traversed by any fluid that has been introduced or produced at a single point.

a. It is in the last relation that the filamentous tissue will be first considered.

1. *Emphysema.*—The filamentous tissue may be distended with air, which causes

a uniform swelling, erepitating, or emitting a crackling sound, when pressed. The situations in which this swelling may begin, vary with the cause by which it is produced. It may take place spontaneously, when it is commonly general, and is supposed to be a product of secretion. It may arise from rupture or laceration of the mucous membrane of the larynx or wind-pipe, when the swelling appears chiefly over the face, neck, and upper part of the chest. It may succeed a broken rib, or any injury of the lungs, when it appears sometimes over the neck, face, and chest; sometimes over the chest and side only. It may arise from rupture of the bronchial membrane during violent efforts; and in this manner emphysema happens in puerperal women. Lastly, it may appear as an effect of gangrenous inflammation and mortification, when it is confined solely to the affected limb. In the latter case, air is produced by the decomposition of the serum of the blood in the morbid parts*. In examining the body of a person who died after injury of the lungs, with emphysema, on dissecting back the integuments and adipose tissue of the chest and abdomen, the cellular membrane appeared like bubbles upon the muscles, from which, when pressed, the air partly passed on into the adjacent cells, partly escaped.

2. *Serous infiltration, edema, anasarca.*—Under the operation of various causes, of which the commonest is delay of the circulation from disease of the valves of the heart, the quantity of serous fluid in the filamentous tissue may be considerably increased; and this increase gives rise to a pale, white, or wan-coloured and cold swelling of the skin, which is distinguished by receiving the impression of the finger, or any other substance forcibly applied. When this swelling arises from a cause of such general influence as obstruction in the heart, the effect is necessarily general likewise; but from the free communication of the cells of the filamentous tissue, the fluid gravitates to the lower part of the person.

3. There are occasions on which the fluid with which the filamentous tissue is infiltrated is not simple serum, but has an acrid and stimulating quality. This is observed in the fluids of the cellular membrane adjoining a part bitten by a venomous serpent; or in the swelling which, in unwholesome constitutions, rapidly follows a severe injury, such as a compound fracture; or in phlegmonous erysipelas.

There is nothing more formidable in

surgery than the second case to which I have adverted. An instance is now before me. A labourer, of a full gross habit, yesterday morning early was thrown down by a waggon, the wheel of which passed over his knee, causing a compound fracture of the inner condyle of the femur, and opening the knee-joint. He refused to have the limb amputated. At this time, thirty hours after the accident, the thigh, nearly to the hip, is swollen to nearly double its natural size, the veins full, and the skin mottled with large patches of red: the ordinary hue of the skin which attends this form of swelling, when its progress is something less rapid, is a pale coppery tint.

In the third case, a modified practice, founded upon that of Mr. Copland Hutchison and of Mr. Lawrence, is peculiarly useful. The most striking instance of its efficacy which I recollect is the following. A medical student, then an assistant at the Marylebone Infirmary, had poisoned a wound on his finger in examining a body. The worst form of symptoms supervened; he was attacked with shivering, with fever of a low character, and nervous irritability; there was no affection of the lymphatic system, but some tumefaction of the arm, and a large swelling upon one side of the body. Sir Benjamin Brodie had seen this patient, but being out of town, I happened at the moment to be sent for. The patient's breathing was oppressed; the cellular membrane on the side was swollen, without fluctuation; the skin was hard, brawny, and of a dark red colour. I made an incision through the skin and the thickened subjacent membrane; some serum and about six ounces of blood escaped; the tension of the side was thus lessened, and the patient mechanically relieved. From that period he mended, and finally recovered; but such had been the diffusion of acrid humour through the cellular tissue, that abscess formed not only in the shoulder and on the side which I had opened, but below the pectoral muscle, and the integuments of almost the whole back.

b. The cellular membrane, when divided, readily unites. I have already adverted to its efficiency in uniting other parts. In the restoration of a broken bone, a divided fibro-cartilage, a ruptured ligament, a divided tendon, muscle, or nerve, it is the surrounding cellular tissue, which, becoming infiltrated with lymph, forms the firm glue-like capsule, in which the divided parts are contained, and the process of organized reparation commenced.

c. The cellular membrane in phlegmonous erysipelas constitutes a medium along which an acrid humour rapidly finds its way, the presence of which contributes

* The observations in this paragraph, and in the next, are taken, nearly word for word, from Craigie's Elements of General and Pathological Anatomy—a very excellent treatise.

to excite suppuration and sloughing. The cellular membrane is no less the ordinary seat of common phlegmon. Phlegmonous or circumscribed inflammations often occur immediately below the integuments of the arm, and of the thigh. The same often form in the nates, and about the anus. A common boil is a small phlegmon, with a central slough of cellular membrane,—a carbuncle, a large and virulent boil.

d. Chronic abscesses have their seat in the cellular membrane, both below the skin and in the intermuscular and interfascicular spaces, the muscular fibre being absorbed to make room for the enlarging abscess. Such abscesses forming without pain, contain vast collections of fluid, which is commonly serum, containing flakes of lymph. Sometimes the serum is deeply tinged with blood. Abscesses of this kind are met with in the thigh; and with proper care, they commonly do well. It has been mentioned, that the chronic abscesses which form in the loins, and which usually point above the posterior part of the crest of the ilium, or below Poupart's ligament, are commonly connected with disease of the vertebral column. In that case, as far as my recollection serves me, the fluid of the abscess has more of a puriform character.

e. Another kind of abscess, which I suppose is the apostema frigidum of authors, occurs in the cellular membrane. The two following cases may serve to exemplify this disorder. In the first of the two, the inguinal lymphatic glands participated in the disease.

A middle-aged man had had for several months a tumor in the groin, which had formed very slowly; it was about the size of two half oranges, but presented three or four rounded elevations; he had experienced little pain in it. Shortly before his admission into the Middlesex Hospital, the skin had become red and softer at one part of the tumor. The swelling had greatly the appearance of malignant disease. The soft and red integument now threatened to slough; I punctured it, when a little air and fetid ichor escaped. The integument, by sloughing and ulceration, in a few days gaped for some extent, and nodular granulating masses were seen within. No further unpleasant feature, however, presented itself; and without any great quantity of discharge taking place, the swelling slowly subsided, and the part healed.

There is a middle-aged man now in the Middlesex Hospital, who was admitted eight weeks ago, with the calf of the leg immensely swollen, the skin of a dark red, with a small hole in the middle, through which some thin pus found vent. Some

months before, he had been kicked by a horse on the calf of the leg, to which he attributed the swelling. Placed in bed, and the leg poulticed, the swelling diminished at first rapidly; the discharge, however, was very inconsiderable in quantity. A probe being introduced, passed below the gastrocnemii; the external wound was enlarged a little; the abscess got well. But at the same time this patient shewed me a swelling on the back of the fore-arm, as large as, and much of the figure of, two half walnuts; it had been a year forming, and latterly had become painful; it adhered to the periosteum covering the posterior edge of the ulna and to the aponeurosis. My attention was now drawn to the general health of the patient, and I found that he had had for many months a scaly eruption upon the skin; and he said that a year before, a tumor like the present, only less, had formed at the corresponding part of the other arm. I gave him, upon this, the decoction of sarsaparilla, with the oxymuriate of mercury: his health began to improve, and the scaly eruption to die away; but the lump below the elbow increased in size. I therefore punctured it with a lancet in three places, where it was most elastic; it bled freely, and at one part small fragments of lymph escaped with the blood. The swelling was poulticed, and is now beginning to suppurate, and lessens daily.

f. The various morbid deposits and the different forms of encysted tumors, are met with in the cellular tissue.

V. Of aponeuroses and fasciæ.—The principal part which these textures play in disease is mechanical; they are tense, strong, and unyielding; they bind the flesh of the limbs; but what is salutary support in the healthy condition of a limb, is liable to become painful and mischievous tension and confinement in disease. This the surgeon can easily relieve. I shall describe two especial affections of the aponeuroses.

The first is simple inflammation; it is the most frequent untoward consequence of ordinary bleeding. The wound festers; the arm and fore-arm adjacent to the elbow are swollen, painful, and the skin has a slight blush upon it. Rest, cooling medicines, fomenting, and a raised position of the limb, in a few days relieve the inflammation.

The second case is rarer; it is a part of lues. I have seen, in connexion with syphilitic periosteal inflammation and suppuration on the tibia, inflammations with suppuration on the aponeuroses of the arm and leg, bearing a close affinity to the periosteal nodes.

VI. Of the adipose tissue.—The most re-

markable circumstance with which I am acquainted respecting this texture, is its increase in animals after the removal of the spleen. This increase begins in dogs (upon two I made the experiment), as soon as they have recovered from the abdominal wound. The duration of the obesity is temporary: before a year is passed, the animal returns to its former weight and degree of sparseness.

The adipose tissue readily unites when divided; and if the wound heal by granulation, presents, in the process of restoration, granulations as florid as those of the adjacent muscle.

The adipose tissue is liable to general or partial hypertrophy.

Common fatty tumors result from partial hypertrophy of this texture. They require to be removed by an operation; which occupies very little time, and is easily performed, if the surgeon begin by opening the sac of cellular membrane that immediately contains the tumor. Fatty tumors consist of large lobulated masses of coarse adipose membrane and fat. They often acquire a large size. The largest which I have removed weighed 13 pounds 2 ounces.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Meetings, and Papers read.

THE ordinary meetings of the Society for 1834-5, commenced the 11th of last month, at the house of the President. The whole of the time of the meeting on the 11th of November was consumed in the consideration of matters arising out of the grant of a charter by the Crown, a copy of which we gave in a recent number.

Dr. Philip on the Sympathies.—The next meeting took place on the 25th, when, after some private business, a paper was read from the pen of Dr. Wilson Philip, "On the Influence of the Sympathies of the more perfect Animals in determining the Nature and Progress of Disease." The abstract nature of the subject, and the unavoidable absence of new facts, rendered the paper somewhat barren of general interest, notwithstanding the hard-earned and well-deserved reputation of its author: these considerations, joined to the pressure of "metal more attractive," compels us to abstain from analysing it.

Mr. Key on Ulceration in the Joints.—Another meeting was held, *hora locoq. solitis*, on the 9th of the current month, when a paper was read from Mr. Key, on ulceration in joints. The principal feature in the paper appeared to us an ingenious at-

tempt to prove that ulcerative erosion, or thinning of cartilage, is in many cases not the effect of absorption, so much as of ramollissement or breaking down of the tissue, which would appear to be a return *pro tanto* to the theory of suppuration maintained before the discoveries of Hunter. We have not space for a detailed analysis of it: the author illustrated his views by interesting preparations.

Mr. Cock on the Anatomy of Congenital Deafness.—On the same evening was read a short but important paper, by Mr. Cock, on the anatomy of congenital deafness. In this paper the author gave details and observations made in the examination of several cases of congenital deafness, all agreeing in having the semicircular canals more or less imperfect. The inference of the author was, that the deafness was owing to the defective structure or development of the canals.

Dr. Seymour on the Use of Morphia in Lunacy.—On the 23d ult. the fourth ordinary meeting of the session was held in Conduit-Street, when a paper by Dr. Seymour, of St. George's Hospital, was read, on the use of morphia in lunacy. In this paper the author gives details of three cases, in which the acetate of morphia, generally in grain doses, and aided by constant refrigeration of the head and by mild aperients, appeared to produce very satisfactory results. He mentions having prescribed it nightly for several consecutive months with excellent effects. The practice, which is rather at variance, we believe, with ideas very generally received as to the properties of opium as a remedy for insanity, was suggested, the author stated, by the experience of the great asylum of Bethnal Green, with the results of which he had been made acquainted some years since. The class of cases for which Dr. S. considers the remedy especially advisable, are the melancholic.

Yet another meeting is, we understand, likely to be held at the house of the president. It is not expected, if we are not misinformed, that the apartments taken by the Society in Berners-street will be fully ready before the middle of January.

PASTILLES (*de Lepère*) FOR COLDS AND CATARRHS.

No. 1.—Acetate of morphia, 1 *gros*; gum tragacanth, 3 *onces*; sugar, 18 *livres*; water, q. s. To be made into pastilles, a *demigros* each.

No. 2.—Sulphate of quinine, 1 *once*; saffron powdered, 3 *gros*, 54 *grains*; liquorice powdered, 2 *livres*, 4 *onces*; gum tragacanth, 3 *onces*; sugar, 18 *livres*; water, q. s. Make as before, pastilles, a *demigros* each.

No. 3.—Acetate of morphia, 1 *gros*; camphor, 1 *once*, 1 *gros*; chloruret of lime, 2 *onces*, 2 *gros*; gum tragacanth, 3 *onces*; sugar, 18 *lires*; water, q. s. Pastilles of this description to weigh 8 grains each.—*Gaz. des Hôpitaux*.

EFFECTS OF IODINE ON THE EPIDERMIS AND HAIR.

By M. STEDMAN.

THE author relates, that in the winter of 1831, having amputated the foot of a person affected with scrofulous disease of the instep, he was for a long time unable to obtain a cure of some scrofulous ulcers situated on the tibia. Wishing to act on the constitution, and to combat the diarrhoea, which seemed to keep up the disease, he prescribed iodine. Before the appearance of the ulcer had been modified, and about a fortnight after the patient had commenced the use of the iodine, he remarked that the scalp, which for a long time had been covered with scales and filth, was completely freed from them, and that the hair which had been formerly dry and filthy, had become soft, and had acquired a bright gloss.

The observation of these change directed the attention of Mr. Stedman to other scrofulous patients, under the same medical treatment. Similar changes occurred. One thing is remarkable, that while the hair and scalp experienced this improvement, the tumors or scrofulous ulcers, against which the medicine was specially directed, remained in the same state. All the patients were kept to a milk diet, and the iodine was administered according to the following formula of M. Lugol:—

R. Iodini, gr. v.

Pot Hydriodat. gr. x.

Aq. Distill. ζ iv.

Capt. gutt. vi. bis in die; dose aucta gradatim ad gutt. xl.—*Boston Medical Mag.*

INSECT PARASITES.

M. VALLOT, of Dijon, writes to the Académie des Sciences, that, in September last, he observed, on the female flax, some larvæ of the *notua persicariæ* which were visibly preyed upon by intestinal worms. The worms pierce the skin of the *notua* readily, are white, glistening, and ovoidal in shape. They appear to have a tail, but it is owing to the gluey nature of their dejections. A larva of this species, on quitting the *notua* at whose expense it has been nourished, changes at once its integument: the chrysalis is well formed, and

in the course of twenty-four hours becomes of a shining black colour. It adheres by the back to the place of its support, and presents its abdomen to the observer. At the end of a fortnight the perfect insect is developed: it is the *Eulophus*, with branched antennæ.

BONE SOUP.—(*Soupe à la Gelatine.*)

THIS economical and nutritious substance has now been tried for five years, at the Hospital St. Louis, Paris, with the most complete success. It appears that more than a million and a half of portions of the soup have been distributed, within that period, to above 45,000 persons. The portion is a *demi-litre*; and it is calculated, that, all expenses included, the cost of each *litre* (about 1½ pint English) is not more than 18 cent. 3 mill. (about 1½d. of our money.)

ORNITHORYNCHUS PARADOXUS.

A COMMUNICATION from Mr. Richard OWEN, of the College of Surgeons, London, was read in the Académie des Sciences on the 3d ult. It was on the subject of the *mammiferous* organization of the *ornithorynchus*.—*Journal Hebdomadaire*.

REPUTED ANTIDOTE FOR ARSENIC.

M. ORFILA, at a late sitting of the Académie de Médecine, gave an account of M. Lesueur's experiments on the properties of the hydrated tritoxide of iron, as an antidote for arsenious acid. When an animal has the power of vomiting (said M. Orfila) this poison may be expelled wholly, or in part, from the stomach, and recovery take place: so that if a reputed counterpoison be administered in these circumstances, to it may be attributed the effects which really belong to the vomiting. Now M. Lesueur, in order to avoid this objection, took care to tie the œsophagus immediately after the introduction of the deleterious substance.

In his first experiment, he gave a strong dog nine grains of arsenious acid, and, immediately after, three ounces two gros of the hydrated tritoxide of iron. The œsophagus was tied. No accident resulted: the dog still lives—seventy hours after the experiment. The same was tried on other dogs, with the same result.

In a second experiment, the tritoxide was not given till half an hour after the ar-

senic: the dog died with all the symptoms of poisoning. Now, as it is known (said M. Orfila) that arsenious acid does not kill by local inflammation, but by absorption, we must infer that, in this second experiment, the absorption had actually taken place—for which there was abundant time.

The conclusions stated by M. Orfila are, that the hydrated tritoxide of iron is an effective counter-poison for arsenic; but that the anhydrous tritoxide has not the same virtues. He imagines that an arsenite of iron is formed in the stomach, and that this substance is not poisonous.

It was suggested by M. Duval, that Navier had long ago recommended the salts of iron by way of antidote for arsenic, and that writing-ink had even been employed for the purpose.

M. Chevallier, it is said, is engaged at present in ascertaining the efficacy of large doses of the protoxide of iron. — *Journal Hebdomadaire*.

[We have little faith in the properties of the new *antidote*, so confidently lauded by M. Orfila. It is pretty evident, from the large quantities of it required, that it must act chiefly by mechanically protecting the coats of the stomach: but we refer our readers to Mr. Brett's ingenious experiments on the subject, in a late number of this journal. See p. 220, *ante*.]

OFFICIAL CONTRADICTION OF THE MISSTATEMENTS IN THE LANCET,

REGARDING THE SCHOOL OF PHYSIC IN
IRELAND.

To the Editor of the Medical Gazette.

SIR,

HAVING seen in the *Lancet* of Saturday last a statement that the classes of the School of Physic in Ireland have declined to one-third of the usual number since the late Parliamentary inquiry, I am directed by the governors of this hospital to communicate, through the medium of your journal, that the clinical class of the School of Physic is more numerous, and better attended this season, than for several previous years.

I have the honour to be, sir,

Your obedient humble servant,

S. C. HOPE COOPER, *Reg.*

Sir Patrick Dun's Hospital, Dublin,
Dec. 23, 1834.

NEW WORKS.

An Essay on the Use of the Liquor Potassæ and Liquor Alkalinus, in the Treatment of Malignant Cholera: with Notes and Cases. By H. W. Dodd, M.R.C.S.

IN THE PRESS.—Remarks on the Electric and Galvanic Influence, in the Cure of Acute and Chronic Diseases. By M. La Beaume, Esq. Medical Galvanist, &c. to the King, F.R.S. &c.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CERTIFICATES DEC. 24, 1834.

George Henry Bore, Ryde, Isle of Wight.
William Phillips, Brockton Grange, Salop.
Robert Ellison Gorst, Cheshire.
James Shaw, Manchester.
John Thomas Harland, Ashbourne, Derbyshire.
William Harris Green, Woburn, Bedfordshire.

NOTICES.

“An Unsuccessful Competitor” states no new facts, and we have no desire to open our pages to mere matter of opinion on the subject.

Mr. Robertson's paper has been received: the suggestions accompanying it shall be attended to.

We are informed by Dr. Turner, that the report relating to his evidence in the case of alleged poisoning, which we noticed in our last number, was incorrectly given in the newspapers. We are obliged to postpone Dr. T.'s letter, which, although dated the 22d, did not reach us till the evening of the 24th; before which time, owing to Christmas falling on the Thursday, we had been obliged to make up the number.

We cannot insert the anonymous letter about the Marylebone Infirmary election.

W. WILSON, Printer, 57, Skinner-Street, London.

WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

SATURDAY, JANUARY 3, 1835.

LECTURES
ON THE
DISEASES OF THE CHEST,

In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

—
LECTURE XIV.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

ASTHMA.

WE now proceed, gentlemen, to the consideration of one of the most complicated affections of the pulmonary system—I mean Asthma.

Asthma is a disorder which until lately has been but little understood; firstly, because the organic changes of the different tissues composing the cardiac, and especially the pulmonary structures, have been but little known; secondly, because the signs derived from auscultation have been but recently discovered, and are not yet sufficiently appreciated; and lastly, because we have long been in the habit of considering signs as diseases themselves, and not as their representatives—a gross error, indeed, since the same sign may be common to a variety of lesions, each of a very different nature, and each requiring a very different mode of treatment. To give you proofs of this, the older nosologists created a class of diseases under the name of *dolores*, or *pains*. Now pain is not in itself a disease; it is a symptom which be-

comes a sign of a certain condition of parts, which condition is the disease.—*Tussis*, or *cough*, has been established as a genus, but it is a sign only of a variety of lesions of the pulmonary structure, which lesions constitute the diseases, and not the signs. Cullen formed a genus under the appellation of *dyspnoea*, or difficulty of breathing; but this again is but the denomination of a sign—a sign, too, representing every change of the organs contained in the chest, when arrived at a certain intensity. The same objection may be applied to the term *asthma*, or difficulty of breathing, occurring at intervals, without fever, for this state is only a sign of certain anomalous conditions of the pulmonary or cardiac organs, which conditions ought to be considered as the diseases, which we shall soon see are very various, and require different modes of treatment, although their effect may be the same in producing the common sign.

Definition of asthma.—Asthma is defined to be a difficulty of breathing, occurring at intervals, without fever. I object not to the term, or the definition, so long as we recollect their true value, namely, that asthma is a mere symptom, or sign, of various changes producing the common effect of intermittent dyspnoea.

According, however, to the vulgar acceptance, the word asthma is applied to every continued difficulty of breathing as summing a chronic form. To understand this subject, it will therefore be necessary to examine, firstly, the various causes which induce continued and chronic difficulty of breathing; and secondly, those which produce an intermittent difficulty. In the hopes of elucidating this very complicated subject, I offer the following tabular view, and beg you will constantly refer to it as I proceed.

Chronic Difficulty of Breathing.

Species 1st, Continued—Dyspnœa of Cullen.

Causes, are Catarrhs $\left\{ \begin{array}{l} \text{Mucous.} \\ \text{Pituitous, with } \text{œdema Pulmonum.} \\ \text{Dry, with Emphysema and } \text{œdema Pulmonum.} \end{array} \right.$

Species 2d, *Intermittent*, or occurring at intervals, without fever—Asthma of Cullen, &c.

Causes $\left\{ \begin{array}{l} 1. \text{ Organic—Catarrhs } \left\{ \begin{array}{l} \text{Mucous.} \\ \text{Pituitous, with } \text{œdema Pulmonum.} \\ \text{Dry, with Emphysema and } \text{œdema Pulmonum.} \end{array} \right. \\ 2. \text{ Nervous. } \left\{ \begin{array}{l} \text{Asthma, with Puerile Respiration.} \\ \text{Asthma, spasmodic.} \end{array} \right. \\ 3. \text{ Complication of Organic and Nervous Causes.} \end{array} \right.$

You perceive, gentlemen, that I head this table with the phrase “chronic difficulty of breathing,” an expression which requires no definition. I divide this into two classes; 1st, that which is *continued*, having no intermission, and existing with greater or less intensity, and which answers in general to the *dyspnœa* of Cullen; 2d, that which is *intermittent*, or occurring at intervals, which corresponds to the *asthma* of the same author. I then proceed to examine the causes, or real diseases, which effect these aberrations in the functions of respiration.

Causes of continued difficulty of breathing.—These causes may very easily be understood; indeed, I have already described them, and shall therefore be very brief in their detail, since you can refer to what I have already said relating to them; they consist of the various forms of chronic catarrh, of emphysema, and œdema pulmonum.

Chronic mucous catarrh consists in chronic inflammation, or gleet, of the mucous membrane lining the ærian passages, and having for its result a yellow secretion. This disease is usually trifling at first, but by the reiteration of its external causes may extend from point to point of the mucous lining, until the whole becomes at last affected. In proportion to the extent of the disease the patient is troubled with dyspnœa; at first it may be slight, requiring, perhaps, unusual movement to excite it, but gradually the difficulty becomes more and more permanent, till it terminates, as old age advances, in suffocative catarrh.

Chronic pituitous catarrh.—The same observations precisely apply to this disease as the preceding, the principal difference consisting only in the nature of the secretion, which in this case is clear and colourless. The two forms of catarrh are not infrequently combined. *œdema* of the lungs often co-exists with chronic mucous and pituitous catarrhs, especially the latter; and in proportion to the quantity of

serum infiltrating the organ, so must the difficulty of breathing be increased, since that fluid occupies the space which should be filled by air.

Chronic dry catarrh.—You will recollect that this affection is so named, not because there is no secretion, but because there is infinitely less than in the two preceding forms of catarrh. The mucous membrane is here habitually reddened and swollen, and the disease has a very strong tendency to become chronic, and extend gradually through the whole of the bronchial tubes. Constant dyspnœa is always the result, its degree being proportionate to the number of tubes affected. *Vesicular emphysema* is a frequent consequence of this form of catarrh, and when present, adds to the difficulty of respiration, by preventing the free entrance and exit of the atmospheric air to and from the lungs. *œdema* is also occasionally superadded.

Chronic hepatization and gangrene of the lungs, the presence of tubercles, or other adventitious deposits, chronic effusions into the pleuritic cavities, might be enumerated as causes of continued chronic dyspnœa; but these diseases are of slight duration compared to catarrhs, since the latter may last for many years, and the former run their course much more rapidly.

Such are the causes of continued chronic difficulty of breathing; we will now investigate those which produce the intermittent form.

Asthma, or Intermittent Dyspnœa.

The causes of asthma, or intermittent dyspnœa, may be referred to three heads: the first I have called *organic*, the second *nervous*, the third consists of a *complication* of both.

1st, *Organic causes.*—These causes are precisely the same as of continued chronic dyspnœa, which are, chronic mucous, pituitous, and dry catarrhs, with their combinations of emphysema and œdema pulmonum.

Chronic mucous catarrh.—It not unfre-

quently happens, that when this disease has lasted for a considerable time, especially in aged persons, that a fresh catarrh is grafted upon the bronchial mucous membrane, and a great increase of mucus suddenly takes place, so great and so sudden, that some of the larger bronchial tubes become filled by it, so as totally to prevent the passage of air down them; the result is, that the habitual dyspnœa becomes suddenly increased, the patient breathes with great difficulty, and he is only relieved by a large expectoration of mucus, after which he returns to his usual state. This fit is often repeated. In consequence of the copious expectoration which terminates the paroxysm, this form has been called *humid asthma*.

Chronic pituitous catarrh.—The same observations exactly apply to this catarrh, the difference being only in the colour of the secretion, and in its being accompanied more frequently by œdema of the lung, rendering the paroxysm more severe. It is also a case of *humid asthma*.

Chronic dry catarrh is also an organic cause of asthma; it occurs from the sudden engrafting of a fresh catarrh. I have so fully already explained the symptoms of this disease, that I need only refer you to it. In consequence of the slight quantity of expectoration terminating the paroxysm, it may be considered as an instance of *dry asthma*.

Paroxysm of humid asthma.—Although I have previously described the symptoms of catarrh, yet it may be necessary to throw into one point of view those by which increased temporary difficulty of breathing is accompanied.

Humid asthma more commonly attacks men than women, more frequently old persons than young. It is generally preceded by nausea and unpleasant eructations, by sensations of flatulent distention of the stomach and bowels, by loss of appetite and the general symptoms of dyspepsia, and often by drowsiness—this state continuing two, three, or four days before the attack. At last, towards the evening, the patient complains of tightness, or a sense of stricture or straightness about the chest, particularly in the direction of the sternum; the dyspnœa gradually increases, and becomes very great; there is often considerable wheezing and desire for fresh air. The cough is usually slight at first, and the expectoration is but trifling. The paroxysm thus formed may now continue for some hours, generally until the approach of morning. Finally, the cough increases, and the patient becomes relieved by a copious expectoration of mucous or pituitous matter, by which the bronchial tubes become emptied: the paroxysm then ceases, and the sufferer re-

turns to his usual state of habitual but slighter dyspnœa.

If the chest be examined during the fit, it will be found that a good sound may be elicited by percussion. The respiratory murmur is often lost in many points of the lungs, in consequence of the obturation of the bronchial tubes; in others it becomes puerile here and there. All the different species of wheezings may be heard in the same patient. Thus in the beginning of the paroxysm you will find the sibilating or sonorous sounds, but towards its termination they become intermixed with the mucous rattle. When œdema of the lungs occurs, it is indicated by the rhonchus crepitans.

A paroxysm of humid asthma is frequently renewed in three, four, or five days, especially in damp or cold weather; occasionally it does not return for many months. In aged persons it sometimes happens that the power of expectorating is lost, or so extremely diminished that the secretion accumulates. The fit in that case will continue for many days; the dyspnœa increases; the face becomes bloated and livid; coma, from which the patient is with difficulty roused, supervenes; the mucus still continues to increase; the catarrh becomes suffocative; and the scene closes in death.

2d, Nervous causes.—It sometimes occurs, that individuals are attacked with severe and sudden dyspnœa, without any apparent organic cause whatever; we then attribute them to some peculiar condition of the nervous system. Pure nervous asthmas are somewhat rare, for, as we shall hereafter see, they are most commonly combined with organic lesions; but I have seen them in their purest forms, in which it was impossible to discover any of the species of catarrh, emphysema, or œdema.

Laennec has divided asthma from nervous causes into two varieties. 1st, Asthma from increased necessity for respiration, or with puerile respiration. 2d, Spasmodic asthma.

1st, Asthma from increased necessity for respiration, or with puerile respiration.—The expression “increased necessity for respiration,” requires explanation, or it will be impossible to understand what is meant by this form of asthma.

The elucidation of the following proposition will demonstrate what is meant by the term.

The loudness of the respiratory murmur is always proportionate to the necessity for respiration, so that it becomes a measure of that necessity.

Thus, if you examine the respiratory murmur of an infant (if the breathing be going on calmly and without interruption), you will find it very distinct and loud;

every air cell seems to expand with vigour and force. The necessity for respiration in a child is great, because all its organic functions are in high activity; it requires to be fed frequently; its digestion is extremely active; the chyle is carried with a more rapid current into the blood; the heart is more active and frequent in its movements; the blood requires a greater proportionate quantity of air, and the function of respiration is carried on with increased force; or, in other words, the necessity for respiration is great, and the loudness of the sound of the respiratory murmur is at once the proof and the measure of it.

Examine the chest of a youth: the sound of the respiratory murmur, although perfectly audible, is less so than in the infant; because, at the adolescent period, the extreme energy of the functions of nutrition and sanguification are diminished, and the blood requires proportionately less air. The necessity for respiration is now diminished, as well as the loudness of the sound of the murmur.

Apply the stethoscope to the chest of an old person, and in many the respiratory murmur is scarcely to be heard at all; it is always less loud, because all the vital functions become less energetic; the digestion is slower, the circulation less frequent, and less air is needed: the necessity for the respiratory act is consequently diminished, and the sound of the murmur is almost lost.

I may add here, that we see in the organization of the bones and cartilages of the chest, at different ages, a beautiful adaptation to the necessity for respiration. In infancy, the chest admits of free dilatation in all its diameters, in consequence of its flexibility; as age advances, its mobility becomes less; the octogenarian scarcely moves his ribs at all, but breathes by the diaphragm alone.

The necessity for respiration not only varies at different periods of life, but it varies also in different individuals. Thus you will find that the respiration of persons of certain temperaments, as of hypochondriacs or hysterical women, produces a much louder sound than that of individuals of an opposite or phlegmatic disposition. The function of respiration is commonly more active in women than in men.

It is a curious fact, that the necessity for respiration is commonly less during sleep than in the waking state. It is for this reason you will find that patients who are labouring under considerable dyspnoea during the day, when awake, will at night, whilst sleeping, respire with comparative ease and freedom.

But not only may the necessity vary ac-

cording to age, sex, temperament, and the states of sleeping and waking, but it may vary in the different parts of the same lung. If the lung of one side be hepaticized, or compressed by fluid in the pleuritic cavity, the function of the opposite lung will become doubly energetic to make up for the deficiency, and the murmur of the healthy organ will become as loud as that of a child; from whence it is called *puerile respiration*. Nay, if a portion of the lung of one side alone be affected, the healthy part of it will act with increased force, and give the puerile sound.

If I have been sufficiently clear in explaining the doctrine of *increased necessity for respiration*, you will have no difficulty in understanding what is meant by asthma from this cause. Thus you may be called to a patient labouring under great and sudden dyspnoea, who is endeavouring to expand his chest in every direction, grasping surrounding objects for the purpose of obtaining fixed points from whence he may effect that expansion; whose face is turgid, livid, or slate coloured, from venous congestion;—you examine the local signs, expecting to find an absence of the respiratory murmur, or at least the presence of catarrhal signs, but you find, to your great surprise, the lungs acting with great force, and the respiratory murmur extremely loud at every point. The paroxysm may last for many hours, but it is not terminated by expectoration, nor does the patient relapse into continued dyspnoea afterwards, as in asthma from organic causes. This is another form of *dry asthma*.

This disease in the pure state is rare. In ten years, I have seen but three cases; all of them were in females, and none were fatal. The paroxysms were frequently repeated.

2. *Spasmodic Asthma*.—In the infancy of morbid anatomy, every sudden dyspnoea unconnected with inflammation was attributed to spasm; since that science has made such great progress, the existence of spasm has been denied, and all sudden difficulties of respiration have been supposed to depend upon organic lesions.

I will not deny—nay, I am fully disposed to believe—that organic changes must be the immediate causes of all symptoms; for it is difficult to conceive how a function can be altered, without supposing some material change to be effected in the organ performing that function, or in the vessels and nerves supplying it. It is very true that the scalpel of the anatomist, or the test of the chemist, cannot always shew the nature of the lesion or change; but may not this arise from the imperfection of our means, or may not these alterations be so fugacious or microscopic as to elude our research? I would freely admit,

therefore, in the cases of spasmodic asthma, the probability of the nervous system being temporarily affected organically, although there be no other proofs than the aberration of its functions; I assert only, that spasmodic asthma may occur without the evidence of any lesion of the lungs.

But spasms of the bronchial tubes and air-vessels has been affirmed by some, and denied by others, to exist. Let us examine the question.

Spasm is defined to be an involuntary contraction of a contractile organ. It has been divided into two species:—1. *Tonic*, or continued contraction, as in tetanus; 2. *Clonic*, a sudden contraction, followed by as sudden a relaxation—as in chorea, convulsio, hysteria, &c.

If, as is supposed, spasm can only affect muscular fibre, it will be necessary to search whether such fibre can be found in the bronchial tubes. Reissessen has demonstrated their existence in bronchial vessels of a very small caliber, and Laennec says he has traced them to tubes of one line in diameter. The former author infers their presence in the air-vessels themselves, but such is their minuteness that we can have no ocular proofs of this, although the facts I am about to detail would lead us to coincide in that opinion.

Admitting, then, gentlemen, the existence of muscular fibres in the bronchial tubes, we must admit also that they are subject to the same pathological laws as the muscular fibres of the rest of the body—that is, they may be affected by spasm and relaxation.

We shall first examine whether there are any stethoscopic proofs of spasm of the bronchial tubes, and then describe spasmodic asthma; and finally proceed to offer you evidences of muscular relaxation, by which asthma from increased necessity of respiration will be still further elucidated.

Stethoscopic proofs of spasm of the bronchial tubes.—In describing whooping-cough, I mentioned that after the violent and repeated respirations were made, a deep and convulsive inspiration followed (producing the whooping sound). It might be supposed that the air entered the lungs during this apparent inspiration, but it does not; for, during this period, the respiratory murmur is inaudible; the dilatation of the cells, therefore, does not take place. Why is this? It can only arise from occlusion of the tubes or air cells; and what can close them but a spasmodic constriction? It cannot be from any organic cause, for that would be permanent; but the respiratory murmur immediately returns upon the cessation of the paroxysm.

Sobbing consists in a rapid succession of short inspirations and expirations; *gaping*,

in a very deep inspiration, followed by a shorter expiration. In both these cases you will often hear no respiratory murmur. What prevents the air entering into the cells in these cases? There certainly must be some obstruction, which is explicable by a temporary spasmodic state alone.

If you examine persons in a state of anhelation from running, you will usually find that their respiratory murmur becomes gradually evident as the dyspnoea diminishes, but it is not heard at all during its intensity. Here, then, is another instance in which the temporary occlusion of the cells is only attributable to spasmodic constriction.

No respiratory murmur can be heard, or at least but very little, during an attack of spasmodic asthma: desire a patient, during a paroxysm, to read as loud and as long as he can in one breath; you will then find the puerile respiration form in one or more points of the lungs. Why was the murmur not heard at first?—because the obstructing spasm prevented the admission of the air. Why was the puerile respiration heard during the reading?—because you threw the patient into still greater dyspnoea, and thereby occasioned so great a necessity for respiration as to overcome the spasm: it was a greater force overpowering a less.

If, then, these facts be true (and I have often enough proved them to satisfy myself that they are so), we shall not be accused of an insufficient enumeration of causes in attributing them to spasm alone, for they occur during the absence of organic lesions, and the disappearance of the respiratory murmur is so sudden that I think it impossible they can arise from any other source.

Supposing, then, gentlemen, that spasm of the muscular fibres of the bronchial tubes may occur, you may readily conceive it to be of the tonic form, or persistent for some hours, and that the patient, during that time, would be thrown into great distress from difficulty of breathing. This state constitutes what is called *spasmodic asthma*.

Symptoms of spasmodic asthma.—The functional and general symptoms of this affection are precisely the same as those of asthma from increased necessity for respiration; the dyspnoea is equally sudden, equally great; the face becomes swollen and livid, and the brain the seat of sanguineous congestions; there is the same desire for fresh air. The fit will sometimes last for hours; sometimes the patient, as I have seen, expires in a moment, in a state of asphyxia. The pathognomonic sign arises from the absence of the respiratory murmur almost all over the chest. The fits do not terminate by any expecto-

ration, nor does the dyspnœa return between them. This is another form of *dry asthma*.

Having thus, gentlemen, proved to you (I hope satisfactorily) that spasm may affect the ærian passages, I now proceed to examine the subject of *relaxation* of the muscular fibres of these tubes. To prove a relaxation of muscular fibre after its contraction were unnecessary, it is self-evident; but a question has arisen, particularly relative to the hollow muscles, whether it is always a passive movement, or whether the opposite state to contraction is not effected by an active force—a strong expansion, rather than a mere relaxation.

Upon opening the chest of a large living animal, and embracing its heart with your hands, you will instantly, I think, satisfy yourselves that the dilatation of the ventricles is effected by a most active expansion of their parietes; for you will find it extremely difficult, by pressure, to prevent their dilatation. It may be said that this expansive force arises from the impulse given by the blood entering these cavities; but separate the heart entirely from the body, so that no blood can pass into it, still the expansion will continue for a time, so as to afford resistance to pressure. It appears to me an abuse of terms to say that that is a passive relaxation which a compressing force cannot prevent.

If one hollow muscle can dilate with an active force, it is fair to infer that another may do so. Do the muscular fibres of the bronchial tubes and of the air-cells (if the latter exist) dilate by an active or passive movement? Are the movements of the lungs mere consequences of the movements of the chest; or do they contract and dilate by a power inherent in themselves?

There can be no doubt that the movements of the chest and diaphragm strongly influence the capacity of the lungs; but I think there are quite sufficient proofs that the pulmonary organs are not passive in these changes, and are not to be considered as inert.

To obtain a direct proof of the active resiliency of the lungs, I have four or five times examined their movements by opening the chests of living animals. I have twice thought only that I had seen the independent movements of these organs; but I confess myself not satisfied with these experiments. But the moment we expose the pleuritic surfaces of the lungs

to the atmospheric air, we submit them to a pressure which may prevent their expansion: the animal, too, is in a struggling and expiring state. We should not forget the advice given by Laennec, that before we draw our conclusions from experiments on living animals, we should always defalcate the anomalies arising from the agonies of death.

But we have sufficient proofs from auscultation of the active expansion of the lungs without resorting to experiments, which, however necessary for the advancement of physiological science, are always performed with reluctance. Thus the most active voluntary movements of the chest can never so dilate the air cells as to induce puerile respiration; shewing clearly that that condition does not depend upon external movements, but upon the active expansion of the lungs themselves. Again, if any portion of a lung be impermeable to air, puerile respiration will arise in some other portion, even when the movements of the chest are not perceptibly increased.

I may state here that asthma from increased necessity for respiration consists in too active an expansion of the air-cells—a state exactly opposed to asthma from spasm, but both evidently arising from some peculiar condition of the nervous system, of the nature of which we are at present totally ignorant.

Asthma, from combinations of Organic and Nervous Causes.

It is somewhat rare to meet with purely nervous asthmas, but those from combined causes are very frequent. It is impossible for me to enter into the details of these combinations, as it would lead me far beyond the limits which a course of lectures like this permits; but if you have well understood what I have said, you will have no difficulty, by a little reflection, in anticipating these complications, since you are now acquainted with all the elements from which they are formed. Thus—

Asthma with puerile respiration may be combined with all the forms of catarrh, with emphysema and œdema of the lungs.

Spasmodic asthma may have precisely the same complications: so that if you would extend the tabular view I have already given, it might be formed in the following manner:—

Asthmas from organic and nervous causes	{ Asthma from increased necessity for respiration, combined with	{ Chronic mucous catarrh } { Chronic pituitous catarrh } { Dry catarrh.—Emphysema pulmonum.	{ Œdema Pulmonum.
	{ Spasmodic asthma, combined with	{ Chronic mucous catarrh } { Chronic pituitous catarrh } { Dry catarrh.—Emphysema pulmonum.	{ Œdema Pulmonum.

The pathognomonic signs of these varieties will of course depend upon the nature of the complication. In asthma from increased necessity for respiration, the puerile respiratory murmur will be the essential sign; if it be combined with chronic mucous, or pituitous catarrh, the local signs of these affections will be present also—as the sibilating sound, the deep sonorous wheeze, or the mucous rattle. The yellow or white expectoration will determine which species of catarrh it is. If *ardema* co-exist, then its sign of rhonchus crepitans will be distinctly heard; and these would be forms of humid asthma. When dry catarrh is the complication, then sibilating or sonorous wheezing will be present; and the expectoration at the termination of the fit consists of a few pearly sputa, mixed with a small quantity of diffluent pituitous matter. This constitutes a form of *dry asthma*.

Spasmodic asthmas are still more commonly complicated with organic changes than the preceding. In these cases, superadded to the almost general absence of the respiratory murmur, the various species of rhonchus may be heard at different parts of the chest; and the appearance of the expectoration will shew the character of the complicating catarrh.

Percussion elicits a good sound in all the forms of asthma, simple or combined, since in asthma, from increased necessity for respiration, there is an excessive quantity of air in the lung; and in spasmodic asthma some air is always confined below the obstructing cause. An emphysematous complication renders the sound upon percussion much louder.

Relative to the signs, I should also state, that there are other essential differences between the simple nervous, and the organic and complicated asthmas. In the simple nervous forms, no dyspnoea or local signs of organic pulmonary lesion remain after the paroxysm is over; whilst in the organic and combined, the patient is always affected with more or less difficulty of breathing; and there constantly exists afterwards some local sign indicating a material change in the bronchial or parenchymatous structure of the lungs.

After repeated attacks of nervous asthma, some organic pulmonary or cardiac lesion, or both, most frequently supervenes. Dry catarrh is the most common consequence, although the other forms of catarrh are not unfrequent. If the asthma has been of long duration, emphysema of the lungs is an inevitable result. The cardiac lesions we shall advert to when we arrive at the description of diseases of the heart.

Remote Causes of Asthma.

The remote causes of organic asthmas are precisely those of catarrhs. I refer you to that subject.

The remote causes of nervous asthmas are evidently those which are considered to act upon the nervous system. The disease attacks peculiarly persons of a nervous or irritable temperament. The principal causes are as follow:—Emotions of the mind, venereal excesses, the presence of a strong light, or the absence of light. A paroxysm of asthma has often been induced by certain odours—as of the tuberose, the heliotrope, of masses of apples, the smoke arising from the snuff of a candle. If a body be moved before the face of some persons, they will immediately feel a sense of closeness and suffocation. A very opposite cause will bring on the attack occasionally. Lænnec mentions the case of a gentleman who, in riding on horseback, arrived at an extensive plain; as he proceeded upon it, gradually a sense of suffocation came on; he returned, and the sensation went off. He again attempted to proceed on his journey, and the dyspnoea again returned. He finally was obliged to give up all thoughts of proceeding onwards. A young friend of mine cannot touch ipecacuanha without being thrown into a violent paroxysm of asthma. Certain associations often produce the fit. Dr. Bree, in his excellent work on this disease, states, that after having suffered a severe asthmatic attack on a certain spot, he could never pass it without experiencing its renewal. I have met with similar instances. I have known strong green tea to produce the disease violently. I knew, also, two clergymen, on whom the paroxysm was arrested by active mental exertion; for in ascending the pulpit, the dyspnoea gradually disappeared, and they improved in voice as they warmed with their subject.

Treatment. — Continued Chronic Difficulty of Breathing.

I need not allude to the treatment of continued chronic dyspnoea, since I have already described it in speaking of the various diseases which produce that effect.

Asthma, or Intermittent Difficulty of Breathing.

1. *Asthma from organic causes.*—The treatment in these cases must be directed to the paroxysms, and to the intervals between them.

Chronic mucous, or pituitous catarrhs.—As the paroxysm of asthma from these causes depends upon a sudden accumulation of secretions in the bronchial tubes and air cells, our indication is to promote as free

an expulsion of them as possible. Emetics, by the succession they afford to the lungs, will often effect this object. Ammoniacum, squills, antimony, and ipecacuanha, are also used as expectorants, and frequently with success. Inhalations of the vapour of water, or of vinegar and water, often succeed in loosening the viscid phlegm, and occasion its easy expectoration. Bleeding is rarely of advantage in these cases; for it is our object to preserve the strength of the patient as much as possible: if he be strong and plethoric, it may be used with some advantage; but the application of leeches, or the scarificator, are safer remedies. Counter-irritants may always be applied—as blisters, or, what are more immediate in their effects, mustard cataplasms, or stimulant liniments.

I would strongly recommend you to avoid the use of opium, particularly in old persons, for there is generally a great tendency to coma already; and if the patient sleeps profoundly, the accumulation of mucous or pituitous matter increases; he loses the power of expelling so great a quantity, and dies of suffocative catarrh. I have seen instances of this.

Dry catarrh.—Asthma from this cause requires a different treatment from the preceding species. This disease consists of a sudden engrafting of a fresh inflammation upon the chronic state, by which the mucous membrane becomes additionally swollen, and more completely obstructs the bronchial tubes. General bleeding may now be used with less caution; still it is rarely necessary; the application of leeches, or the cupping-glasses, are usually sufficient: the use of ipecacuanha and tartar emetic, in nauseating doses, frequently dissipates the paroxysm.

The treatment of the intervals between the paroxysms in the organic forms of asthma is precisely the same as I have described for the various species of catarrh, œdema, or emphysema of the lungs.

2. *Asthma from nervous causes.*—*Asthma from increased necessity for respiration* is so infrequent an affection, as to have afforded but little experience of the mode in which it should be treated; but as we find that the necessity for respiration is less during sleep, it is fair to infer that narcotics might be used with advantage. I have administered opiates in all the cases I have seen, and I think with good effect. Various other means have been used with this view, as the belladonna, stramonium, aconite, colchicum, tobacco, conium maculatum, hyoscyamus, nux vomica, boletus suaveolens, narcissus pseudo-narcissus; also certain irritants, as the tincture of cantharides, Fowler's solution of arsenic, arsenic in vapour, sulphate of zinc, and

muriate of barytes. Laennec, after having given this list, gives the preference to narcotics, and then to the distilled laurel-water, or hydrocyanic acid.

Asthma from spasm.—Most of the above remedies answer as well for this species as the preceding. To the above list may be added, the foetid gums, æther, musk, castor, camphor, myrrh, ammoniacum. I have tried the lobelia inflata pretty frequently, but I cannot say I have met with all the advantages which have been attributed to its use. Very strong and clear-made coffee often produces an excellent effect. The inhalation of oxygen gas, recommended by Fourcroy and Beddoes, has fallen into total desuetude: I have no experience of its value.

Electricity and galvanism have not produced the effects anticipated from them. Mineral magnetism has also been proposed. I have lately, as you are aware, been making some experiments with it upon the neuralgiæ, and with a certain degree of success, but not sufficient to warrant as yet a safe conclusion.

Combined forms of asthma.—The treatment of these cases must consist of a combination of that of the organic and nervous forms of asthma.

After all the remedies I have mentioned, it must be admitted, gentlemen, that their effects are extremely uncertain upon the paroxysm of any form of asthma: one medicament seems to suit one person, another a second, and none a third. You may form this conclusion—that whenever you find a great number of means proposed for the cure of any disease, it is an affection of an intractable nature.

Although therapeutics offer but little certain in the treatment of the asthmatic paroxysms, yet much may be done to prevent them by a judicious treatment of the intervals between. Thus you will find asthmatics very subject to dyspepsia: you should obviate that affection by a close attention to the stomach and bowels, which may be done by the occasional administration of the warmer purgatives combined with antacids, as the rhubarb and magnesia; and these may be followed by tonics, as gentian, cinchona, and above all, the carbonate of iron.

The diet should be light, yet nutritious; the patient should clothe himself according to the season, and let his own feelings of comfort be the guide to the quantity of vestments. He should not expose himself to sudden changes of temperature: a change of air is often highly advantageous, but you must often be directed in this by the experience of the invalids themselves, for some feel better in the country, others in town. Some, too, breathe most freely

at a high elevation, and others on a low plain.

Habitude, no doubt, has a considerable effect in producing the paroxysm; in that case, a total change of position and employment should be recommended, where practicable.

ON THE ORIGIN AND NATURE OF HYSTERIA.

By JOHN ROBERTON, Esq.

Surgeon to the Manchester Lying-in Hospital.

INSTEAD of attempting a definition of hysteria, I prefer the easier task of detailing a case, to illustrate its character in one of its most ordinary forms. A healthy girl suffers some unlooked-for grief or disappointment; soon after it is noticed that she is become pensive and languid, and that her complexion has undergone a change, being no longer natural, but sallow. Her bowels *work*, which means that they are filling with air, and are agitated with spasmodic contractions. She seems to be repressing a violent disposition to weep: suddenly she falls back in her chair, slightly convulsed, particularly in the arms and limbs; a handful of cold water is thrown in her face, she opens her eyes, gives a stupified stare, and relapses into her convulsions again. She is put to bed, where she has repeated returns of the convulsive motion, with intervals of consciousness, during which she presses her hand on her stomach, eructates with a loud noise, and struggles to eructate more. The convulsions now subside into a kind of stupor, the stupor by degrees into natural sleep, and the girl in a few hours is quite well, saving only an unusual languor, and that she voids once, or oftener, a large quantity of limpid urine.

This is a mild instance of spasmodic hysteria; but the disease assumes a greater number of forms, almost, than we have terms to designate them by. The following forms and varieties, with two or three exceptions, I have myself repeatedly witnessed in practice. Two or more of these, however, are sometimes so blended together, and the more notable symptoms of the present hour so unexpectedly give place to fresh trains, as to constitute the most perplexing series of morbid phenomena imaginable, which

the patient and experienced observer alone can unravel and refer to their true cause.

1. SPASMODIC HYSTERIA.—Besides the regular hysterical paroxysm, of which the case above described is an instance, this form of the disease is exhibited in the following varieties, in each of which some one symptom is chief and predominant.

Hysterical cough.—Dry, perpetually barking; with or without difficulty of breathing.

Hysterical hiccup.—Sometimes violent, beyond the common singultus.

Hysterical exclamation.—Sighing, agitation, with the utterance of some such exclamation, at regular intervals, as heigh-ho! heigh ho!

Hysterical sighing.—Recurrers in paroxysms after irregular intervals, consisting in convulsive inspirations, loud, exhausting, distressing to hear.

Hysterical dyspnoea.—May continue for several days, and with a severity which, if originating in any other cause, would destroy life.

Hysterical dysphagia.—Proceeding apparently from dread of suffocation.

Hysterical lock-jaw.—Stiff neck; motion of jaw impaired or suspended; other local hysterical affections, as a pain in one of the breasts, or between the shoulders.

Hysterical rigidity of other muscles.—Such affections have been known to recur monthly; contraction of the muscles of one half of the face, or of the muscles of one hand, or of the flexors of one of the larger joints.

Hysterical palpitation.—A degree of palpitation is usual in various forms of hysteria, but in certain instances it constitutes the prominent symptom, every pulsation violently shaking the whole frame, and producing the appearance of alarming exhaustion.

2. HYSTERIC PALSY.—Generally commencing or combined with spasmodic symptoms, which lead to the detection of its real nature.

Hysterical paraplegia. (palsy of one symmetrical half of the body), attended generally with palpitations, flutterings, partial headache, and the like.

There are various minor varieties of this form.

3. HYSTERIC DISTURBANCE OF MIND.—Often variable and fugitive, but sometimes chronic.

Hysteric delirium. — Commencing with obvious signs of hysteria; of uncertain duration, from a few hours to many days; ought to be discriminated from true mania, in which hysteric symptoms rarely occur, even in those who have previously been liable to the disease.

Other varieties of this exist, as obstinate valetudinarianism and despondency, combined with hysteric symptoms.

4. *HYSTERIC Sopor.* — Apparent insensibility to external objects; inaudible respiration; resembles death. The patient may be roused by completely closing the lips and nostrils.

5. *HYSTERIC PAINS.* — Often imitate inflammation of an important organ or texture; generally other hysteric symptoms present; also leucorrhœa, or derangement of the menstrual function. Some great incongruity in the symptoms leads to the detection of the real nature of the affection, more particularly absence of that peculiar depression of countenance which characterizes inflammation of some important internal organ.

Hysteria imitating pleurisy. — Pain most acute, generally under the left breast, increased on pressure; respiration panting; pulse rapid, variable.

The following well-marked case will serve, in some degree, to illustrate this form of hysteria in all its varieties:— Miss D.'s servant, aged 22, a healthy delicately formed Irish girl, possessing a face and mien that would have graced a higher station. During the catamenia, which had always been regular, was obliged to sit up a whole night attending on her mistress, who was affected with violent hysterics; in the morning went to the wash-tub, caught cold, and suddenly ceased being unwell. The following day I was requested to see her, when I found her in bed slightly feverish, panting rather than breathing, complaining of acute pain under the left breast, to which place she kept her hand constantly applied. Pressing the part with my finger appeared to cause exquisite pain. The pulse was rapid, and the tongue furred; there was a degree of tremor of the hand as I was feeling the pulse, and her manner was restless. Blood was drawn to the amount of sixteen ounces, which produced faintness, and appeared to give relief. On the following morning I found all the symptoms aggravated; the

pain in the side intense, and respiration performed with great action of the chest. At my entrance the pulse was rapid; but on feeling again, before leaving the room, the frequency was greatly lessened. A blister to the side was ordered. The following day she was better, and had had a return of the catamenia. On the fourth day of my attendance she had an hysteric fit in the evening. The day following that, the pain shifted to under the right breast, and was so intense that an attendant was obliged constantly to press the hand on the part. The respiration was violent panting, the pulse was rapid and variable, and the hand tremulous. A smart purgative was ordered, and to be followed by frequent small doses of carbonate of ammonia. I had no sooner left the room than she was seized with violent hysterics. Next morning every distressing symptom had entirely vanished.

Although I should not have felt justified in omitting venesection in this case, I question whether it was beneficial. It certainly sometimes happens that inflammation of an important organ and hysteria co-exist. The practitioner ought, therefore, always to act on the safe side; never forgetting, however, that a constitution disposed to hysteria is comparatively little liable to inflammatory affections.

Hysteria imitating hepatitis. — Pain and acute tenderness on the right side; attack sudden; pulse may be quick, but is not hard.

Hysteria imitating peritonitis. — Seizure not gradual but sudden; tenderness most acute, particularly on a light degree of pressure.

Hysteria imitating hysteritis. — Pain in the uterine region extreme; greatly increased on light pressure; patient more restless and active than in true hysteritis.

Hysteria imitating pericranitis. — Excruciating pain of scalp, with extreme tenderness; vomiting; intolerance of light; pain variable, and frequently confined to one spot.

Hysteria imitating arthritis. — Wrist may be the seat; commences with slight swelling and great pain, which may continue long; the wrist becomes drawn and rigid, the hand wasted, the surface exquisitely tender. If in the knee, it is semi-flexed, and there is slight tumidity, acute pain, exquisite sensibility; generally the joint may be moved in sleep

without producing evidence of painful sensation.

6. HYSTERIA THAT IS VOLUNTARY.—A power, possessed in rare instances, of bringing on at will a paroxysm of spasmodic hysteria.

7. HYSTERIA IN THE MALE.—Chiefly of an irregular kind, as flatulent suffocation, palpitation, mental excitement, with *globus*, and limpid urine, &c., seldom reaching to convulsive action of the voluntary muscles, *i. e.* to a regular fit*.

It may very naturally be asked, how the practitioner is, in all instances, to distinguish between symptoms that are hysterical, and such diseases as epilepsy, tetanus, trismus, hydrophobia, mania, chorea, palsy, catalepsy? The reply is, that the task of diagnosis, although generally easy, is occasionally difficult, and sometimes, perhaps, impossible; nevertheless, it is to be performed somewhat in the same way as the naturalist proceeds to distinguish animals from each other that are of the same order and family,—as, for example, the dog in all its varieties from the fox, the wolf, the jackal,—viz. by observation, and patiently noting and comparing the traits of individual character, by which it is at length discovered in what traits there is agreement, and in what, essential difference.

It is admitted on all hands that some are more liable than others to the hysterical affection, although, I believe, it is likewise commonly assumed that *all women*, without exception, may become its subjects, if they are only sufficiently long exposed to the exciting causes. This is an opinion that I do not entertain; on the contrary, I hope to be able to prove, that liability to hysteria is confined to a certain proportion of the sex, the remainder not being, under any circumstances, susceptible of it. But waving this question, to which I shall have occasion to return, let us give a moment's attention to the peculiarities of constitution which distinguish such as are *known* to be liable to hysteria. It would be little less than impertinent were I to attempt a sketch of these peculiarities, since it has been drawn with so free,

bold, and vigorous a hand, by Burton, in his *Anatomy of Melancholy*. His pencil, it is true, is not the most delicate, but we are to remember his delineation is intended for the *manifestly hysterical*, and not for the fainter, more evanescent, traits discovered in such as are rarely affected, and then only when subjected to powerful exciting causes. Women given to be hysterical, he remarks, “complain many times of a great pain in their heads, about their hearts, and hypochondries; and so likewise in their breasts, which are often sore. Sometimes ready to swoon, their faces are inflamed and red; they are dry, thirsty, suddenly hot, much troubled with wind, cannot sleep; and from hence proceed a brutish kind of dotage, troublesome sleep, terrible dreams in the night, a foolish kind of bashfulness in some, perverse conceits and opinions, dejection of mind, much discontent, preposterous judgment. They are apt to loathe, dislike, disdain, to be weary of every object; each thing almost is tedious to them. They pine away, void of counsel, apt to weep and tremble; timorous, fearful, sad, and out of all hope of better fortunes. They take delight in nothing for the time, but love to be alone and solitary, though that do them more harm; and thus they are affected so long as this vapour lasteth; but by and by as pleasant and merry as ever they were in their lives; they sing, discourse, and laugh, in any good company, upon all occasions; and so, by fits, it takes them now and then, except the malady be inveterate, and then it is more frequent, vehement, and continue; many of them cannot tell how to express themselves in words, or how it holds them, and what ails them; you cannot understand them, or well tell what to make of their sayings.”

These “sayings,” and other indications of hysteria, are manifested in very different degrees in different women. In some they are seldom to be perceived, while in others they are rarely ever wanting in all their intensity. In the most robust and muscular they are witnessed, as well as in the slender and delicate, though doubtless oftenest in the latter. The moral disposition, too, of this portion of the sex is extremely varied, a number being of feeble capacity, while the generality are of lively parts, but, perhaps, wanting in steady

* The reader who takes the trouble to consult Dr. Pommé's “*Traité des Affections Vapeureuses des deux Sexes*,” will be astonished at the great number of forms of disease to which, even in his day, the title “hysterical” was annexed.

application. Many, however, possess singular vigour of intellect, brilliancy of imagination, great ardour of affection, and a susceptibility of the most generous emotions; gentleness being the only estimable quality in which there is deficiency; and even the latter remark is not without exceptions. That in not a few the temper is wayward, fickle, capricious, irritable, impetuous, unamiable, and the spirits in most exceedingly variable, must be conceded; nor can it be denied, that nearly all the most famous impostors of the female sex have manifested symptoms of the hysterical constitution.

If we are to believe the ancients, the whole variety of symptoms classed under the title hysteria originate in a morbid condition of the female generative system. This notion is embraced by Dr. Cullen, who asserts that physicians have at all times judged rightly in considering this disease as an affection of the uterus, and other parts of the genital system. Writers since his time have affirmed that the uterus alone is the seat of hysteria; in other words, that it depends on some form of derangement of the menstrual function. Several regard the disease as "an affection of the brain;" and Professor Burris ascribes it to excitement of the nerves at their origins, produced directly, or by sympathy, from irritation at their extremities. Doubtless it is desirable both to know, and to make known, the causes of things, whenever we can; but vague conjecture is a poor resource in science. These opinions cannot all be correct; and probably they are all equally unfounded. They have apparently originated in a partial and very limited view of the phenomena of hysteria—in the common error, I may say, of regarding one or more symptoms, ordinarily present in a disease, as essentially characteristic, and indicating its nature and origin. In a majority of hysterical attacks, there can be no question that the menstrual function is either deranged or suspended; but then in many other instances this is not the case; and in others, again, derangement of that function is impossible, as the menstrual period is either not yet attained, or is terminated. Besides, there is another class of facts that ought not to be overlooked; every variety of diseased menstruation occurs without producing hysteria, producing in some

women little serious disturbance of the health, and in others chorea, epilepsy, or mania, according to individual predisposition.

But it may be said, if hysteria does not depend on the uterine system, how happens the disease (as is commonly taken for granted) to be confined to the female sex? The proper reply is, that hysteria, though chiefly, is not altogether a disease of women. Several well-marked instances I have myself seen in males, as, for example—

1st. A gentleman, whose sister is highly hysterical, was unexpectedly plunged in a sea of business-trials, which laid him up with an intensely painful affection of the head, that excited fears for his life, it being imagined that the meninges of the brain were inflamed. At times he could not so much as bear the scalp to be touched, and often felt a most acute pain darting through the head, from one parietal protuberance to the other, as if a nail were driven. Meanwhile there was great despondency, and apprehension of death; a feeling of distension at the præcordia, and a sensation of sinking; distinct *globus*, excessive flatulence, and deranged bowels. The pain of the head occurred in paroxysms, preceded by a peculiar feeling in the stomach; and the accession of the paroxysm could generally be prevented by taking food. Relaxation from business, purgatives, quinine, and change of air, ultimately effected a cure. These symptoms in a female would have been considered hysterical.

2d. Mr. B., 22 years of age, of puny stature and pallid face, by trade a watchmaker, complains of all kinds of pains, and is a regular grumbler; fancies now and then he shall tumble over as he sits at his work; the appetite is variable, and the bowels constipated. At times he has marked *globus hystericus*, which seizes him sometimes in the street, and then he feels as if he must be suffocated. At the periods of these attacks he voids large quantities of limpid urine. His aunt, who is strongly predisposed to hysteria, says (justly, I think) that her nephew is troubled with the "family complaint."

Other cases I might relate, as several equally well marked have come under my notice; and it would be easy to quote a great number of unexceptionable

examples from the works of writers perfectly worthy of credit. However, the following statement of Dr. Trotter, which occurs in his *Medicina Nautica*, will suffice in proof of the existence of *hysteria masculina*. "We found," says Dr. T., "not a few of the cases sent to the hospital-ships subject to very frequent fits of hysteria, and, where this singular affection occurred, with as much violence of convulsions as we have ever marked it in female habits, attended with globus, dysphagia, immoderate risibility, weeping, and delirium*."

Were hysteria, however, a disease of women alone, this would furnish no decided argument for its origin being in the uterine system; for surely the conformation and temperament of the sexes are sufficiently dissimilar to warrant our belief that there may be diseases peculiar to each. It cannot be doubted that the nervous system exercises a far more marked influence in the female than in the male: hence the former is susceptible of a thousand impressions which the other sex, if not exempt from (and this, of course, cannot be predicated), generally receives with little manifestation of feeling. In a mixed assembly, subjected to the moving tones of oratorical declamation, particularly if the tenderer emotions, or those of a religious kind, are powerfully addressed, how different the effect! Among the females there will probably be sobbing, or even fainting, when nothing of this is perceivable in the men. The words of the declaimer fall, it might seem, on two distinct classes of intelligent beings, whose moral and physical susceptibilities, although not radically different, differ strangely in degree. Were hysteria, therefore, a disease solely of females, there are other grounds on which its existence might be explained, without needing to suppose that it always originates in a morbid condition of the generative system†.

That hysteria is "an affection of the brain," is a no less untenable opinion, yet having this in its favour, that it is exceedingly vague; and as an eminent writer has well remarked, no opinion is so incontrovertible as that which is un-

intelligible. From whatever *causes* hysteria may be supposed to proceed (and surely they are manifold), there has never, that I know, been any dispute in regard to its *seat* being the nervous system; for it is manifestly a disease of mere sensations and disordered functions. The brain, therefore, is doubtless occasionally affected in common with the other organs; and often the brain would appear to be chiefly affected. But in frequent instances the function of this organ is very little impaired; while the stomach, the larynx, the pleura, the peritoneum, the liver, the kidneys, or perhaps a remote joint of an extremity, is the part that suffers.

It will aid us in perceiving how readily other parts of the nervous system, besides the brain, may become the seat of the hysterical affection, to remark, that we have reason to believe that, in different individuals, the nervous system differs in regard to the situations of its weak points, some persons being liable to painful sensation, or impaired function, in *this*, and others in *that*, point; just as happens with respect to the other systems—the glandular, for example. Exposure to cold, we know, will in one affect the tonsils, in another the liver, in a third the sub-lingual and sub-maxillary glands. After the same manner, a piece of unpleasant news will produce, in one person, pain at the precordia; in a second, looseness; in a third, tumor and palpitation of the heart; in a fourth, a stitch; in a fifth, headache. Some, on seeing a ghastly wound, or a formidable cutting instrument, as a newly-whetted scythe, feel an acute pain in the perineum, in the line of the urethra; a disgusting object or idea, in some, excites the stomach to vomit; a discordant sound causes the teeth to ache; an indigestible meal temporarily paralyzes the optic nerve, or produces *tie douloureux*, or pain and tenderness of the calves of the legs. The "natural history" of bashfulness, to employ a modish phrase, affords us abundant examples: in one the larynx is the weak point, and we have stammering; in another it is the lips that are unmanageable, and then there is mispronunciation; in a third, the demon lurks in the optic nerve, and there is the abashed averted eye; in a fourth he prefers the legs, and then the gait is the dance of St. Vitus; in a fifth the brain is his throne, and now the wise man is thrice

* See an interesting case of Hysterical Loss of Voice in a Male, in which the above extract from Dr. Trotter is given, by Mr. Watson, *Edinburgh Medical and Surgical Journal*, vol. ii. p. 303.

† See article "Imitation," *Rees's Cyclopædia*, and the *Edinburgh Medical and Surgical Journal*, vol. iii.

a fool. Facts of a similar description, tending to illustrate the pathology of the nervous system, are almost infinite in number and variety; they appear to indicate distinct local affections of that system; and more than this, I apprehend, we may not venture to affirm. Our knowledge of the functions of the different parts of the nervous system, in a state of health, is inexpressibly limited and imperfect; more so, if possible, is our knowledge of the morbid conditions.

The hypothesis of Dr. Burns calls for little remark. In hysteric females there is often tenderness on pressure in the course of the spine, as well as pain at the nape of the neck, and over the occiput, indicating, perhaps, what the Professor calls excitement of the nerves at their origins; but in how many cases are there the same tenderness in the spine, and the same kind of headache, without the presence of hysteria; whilst there are many instances of this disease without there being the slightest evidence of the existence of irritation of the nerves at their origins.

If I am asked what is the seat and origin of hysteria, I find it convenient, in return, to put a similar question in reference to scrofula; because a reply to the latter query, which refers to a less complex and more palpable disease, will assist me in explaining my views of the nature of hysteria. The term scrofula is applied to an indammatory affection, characterized by tolerably well defined features, seated sometimes in the skin, sometimes in the subcutaneous tissue, or in the lymphatic glands,—in the bones, cartilages, ligaments,—which, in fact, has been discovered affecting every organ and texture of the body. I further find, that this disease is thought to appear only in certain constitutions; and consequently, that the causes which produce it in one class of persons fail to produce it in another class, even although they may operate on the health, to the production of some disease of a different kind. Hence arises the notion of individual predisposition; in other words, that certain persons possess a conformation of the whole body, or of certain organs only, tending, under the influence of particular exciting causes, to originate scrofulous disease; and this notion is further strengthened by observation, which has discovered, in such as were already affected, certain physical

peculiarities, that enable us frequently to detect the same predisposition in those in whom the disease may never have appeared. More than this of the origin and nature of scrofula we cannot, I apprehend, ever know. We cannot tell, for example, why that particular conformation, called the strumous, leads to scrofula rather than to gout: we know the fact from observation, and farther than observation guides we cannot proceed. No doubt; if we will, *we may conjecture*.

The same line of reasoning will, in a measure, apply to hysteria, which, however, is a totally different kind of disease, being in its nature, as I have already said, purely functional; meaning by that term that it is to be detected only in the living body, and never produces changes of structure discernible by post-mortem dissection, whilst scrofula is, essentially, a disease of structure, always changing or destroying the textures it affects. In the diversity of organs and parts in which it fixes its seat, as well as in the diversity of its character, hysteria equals or surpasses scrofula. That the former also can occur only in *certain constitutions*, is, I think, capable of the strongest proof; for I find from diligent observation, that those causes which are found to excite hysteria in certain women, entirely fail to excite it in others. Not only so (for this might be owing merely to difference in the degree of predisposition respectively possessed), but we shall witness the latter class exposed again and again, for years, to the most powerful exciting causes—grief, disappointment, extreme fatigue—and not without injurious effects; the effects, however, in no instance partaking of the nature of hysteria. Such a view, it may be said, admits of presumptive proof only. Be it so: the same may as justly be said with respect to the proofs in favour of a peculiar predisposition to scrofula. If it be affirmed of certain women who have always resisted the ordinary causes of hysteria, that they, nevertheless, are susceptible of the disease were they only for a sufficient period exposed to the influence of the most powerful causes, it would only be needful to reply, that this is to beg the question. Many women, to my knowledge, have suffered intensely, both in mind and body, from those very influences which are known the most readily to produce hysteria;

and have yet, at no period of their lives, exhibited a single hysteric symptom. This fact I regard as sufficient evidence of their not possessing *that peculiar kind of physical conformation* (be it what it may) which predisposes to hysteria: precisely as I should with confidence infer, if a number of young persons had been greatly, and for years, exposed to the ordinary causes of scrofula—humidity, filth, confinement, and poor diet—without that malady appearing, that they were free from predisposition to it.

[To be concluded in our next.]

CASES IN MIDWIFERY.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think that the enclosed cases may interest any of your obstetric readers, I shall feel obliged by your inserting them.—I am, sir,

Your obedient servant,

JAMES REID.

10, Bloomsbury-Square,
Dec. 22, 1834.

1. — *Case resembling Rupture of the Uterus.*

I was called in, by one of the midwives attached to the Parochial Infirmary of St. Giles and St. George, Bloomsbury, to visit Mrs. O'Keefe, æt. 37, residing in Smart's Buildings, Holborn. The following is the history of her case:—

May 31st.—She has nearly gone her full time, and has enjoyed good health throughout her pregnancy. This morning, about 10 o'clock, she carried a heavy pitcher down stairs, in order to fill it with water, and, before returning, visited the water-closet in the yard, her bowels having, the previous night, been much deranged, owing to her partaking of some fat broth at dinner. This frequent action of the bowels was accompanied by great pain, and the child had been particularly strong in its movements during the whole of yesterday.

Whilst straining, she suddenly felt most acute pain in the abdomen and back, and thinks that she must have fainted away for some time. She then became very sick, and soon after was assisted up stairs with much difficulty.

The midwife, on her arrival, found her in a very low state, with pallid countenance (although naturally of a florid complexion) and feeble pulse, and administered cordials, but with no benefit.

I visited her at 7 P.M. and found her complaining of severe pain in the abdomen (especially on pressure), and likewise in the back; it resembles labour-pain (she says) somewhat, but with no intermission. She vomits whatever her urgent thirst compels her frequently to drink; complains of pain and vertigo in the head; a great degree of faintness coming over her at intervals, attended by cold clammy perspiration. Her pulse varies, being sometimes extremely feeble, at others approaching somewhat nearer to the natural standard. She is very restless; her extremities cold, and an expression of great anxiety depicted in her countenance; respiration oppressed. She has passed very little water within the last twelve hours, and she has not felt the child move since last night. On examining the os uteri, I found it high up and very little dilated. No part of the child could be distinguished, neither could I, on attentively examining the abdomen, discern any projecting part of the infant through the parietes. A catheter was passed, by which a small portion of urine was evacuated, and a turpentine enema produced little or no effect on the bowels.

9 P.M.—The patient continues in almost the same state. I now caused her to be placed on her back, her knees to be raised and separated far apart, in order that I might more freely examine the state of the womb. I could thus distinguish the os uteri rather more dilated than before, and the membranes tense, as we find them in ordinary cases during regular pains; which latter, however, were here absent. As the woman still complained as much as before, and the attendants thought her sinking, I judged it proper to rupture the membranes with my nail; which I accordingly did, and an immense gush of liquor amnii followed; to the extent, I should think, of three or four pints. She was immediately relieved of the sickness and pain in the abdomen, and revived much in the course of a few minutes. I gave her ℥ss. of vin. opii, and as I now expected, contrary to my former opinion, that the case would terminate well, I left her in the charge of the midwife. Regular pains came on,

after a short time had elapsed; at two o'clock in the morning she was delivered of a dead child, and did very well afterwards.

I have never seen any case which resembled one of rupture of the uterus more closely than the foregoing. A medical friend, who accompanied me on my second visit, had no doubt of the fact; and I must confess that I could hardly, at the time, give any satisfactory reason for not concurring in this opinion, unless it was that the pulse occasionally seemed to rally a little. I had another reason for doubting it, however, on finding the membranes tense, as I should naturally have expected them to have been otherwise, supposing the uterus to have been lacerated; in which case it would have been most probable that they had shared in this rupture, and that their contents had escaped into the abdomen. The fibres of the uterus seem to have been unable to exert any contractile efforts, until the over-distension was removed by the escape of the liquor amnii. The friends of the patient felt quite assured that she was dying, and the Catholic priest had arrived to administer extreme unction, which he deferred doing, however, until I had given an opinion that she could not possibly survive: this I hesitated to offer, and eventually had reason not to regret having thus acted. I find in my note-book, a case that occurred in our Infirmary, in which the progress of labour was impeded by the large quantity of liquor amnii contained within the uterus (far greater, indeed, than in the present one), but in which none of the above symptoms were present.

2.—*Case of Tubal Fecundation.*

The following is a case to which I was called during the absence of my neighbour, Mr. Walker; by whose permission I insert it.

March 22, 1834.—Mrs. H—, æt. 35, of delicate constitution, has already borne two children, the younger of whom is now 7 years old. She has lately suffered much from occasional spasmodic pains in the abdomen, but has generally been relieved by aperients. Has not been regular for the two last periods, but is uncertain whether she is pregnant or not.

I was called to her this morning, at three o'clock, and found her suffering from violent pains at the lower part of

the abdomen (apparently spasmodic). They were partially relieved by fomentations, cataplasms, and an opiate; but I was again called up to her at 6 A.M. as they had returned with increased violence. A stronger opiate draught than the last much relieved her. Twelve leeches were afterwards applied to the part, when Mr. W. on his return took charge of her. Castor-oil was administered, and by the following day the patient felt tolerably well, and free from pain.

24th.—Was attacked by violent pains in the head, attended with fever, for which twelve leeches were applied to the temples, and an aperient medicine given.

25th. — Vesic. Nuchæ. Rep. Haust. Aper.

She was now much relieved; gradually became better; sat up, but still kept her room, flatulency being the only symptom which troubled her.

April 3d.—Much annoyed by an irritable state of the bladder, accompanied by ardor urine; the latter fluid being passed in very small quantities. Tragacanth and sp. æther. nitr. mitigated these disagreeable symptoms, but they were followed, on the 5th, by very acute pains in the left iliac region, for which she took tr. opii, ʒss. every hour: it required a third draught before they were relieved. A dose of castor-oil was administered the next day, but on the 9th the pain recurred, although in a less degree, and was removed by tinct. opii, ℥v. taken every four hours. As these unpleasant symptoms recurred so frequently, Mr. W. properly deemed it requisite that Dr. Spurgin should visit her with him, and a consultation took place on the 10th; but as the case still presented symptoms similar to those usually found in colic, it was concluded that they depended upon an unhealthy state of the alvine secretions, and a powder of rhubarb combined with magnesia, hydrarg. c. cret. and hyoscyam. produced very copious evacuations, after which she felt better.

16th.—She suffered from another similar attack, but more violent still than the former ones. She was again relieved by large doses of opium, but as her friends felt very anxious about her safety, Sir C. Clarke saw her on the 17th. After a careful examination, during which little or no tenderness was

felt on pressing the abdomen, he was likewise of opinion that the prognosis was favourable, judged it most probable that she was encephalic, and recommended the combination of tonics with the medicines she was already taking.

18th.—At 7 p.m. seized with bearing-down pains (especially in the back) resembling labour, attended with much faintness. She feels sure that the waters have escaped, as she felt something burst, followed by a warm sensation internally. On examination, the os uteri is found quite closed.

10 A.M.—Pulse becoming very weak; on which account cordials were administered.

2 P.M.—Patient still more languid; pains continuing; and Mr. W. advised that Dr. Spurgin should again see her, fearing that if abortion should supervene she might sink under it.

3 P.M.—Dr. S., on visiting her, advised cupping-glasses to be applied to the loins, but no blood could be obtained. Though cordials were still administered, she gradually sunk, and at 4 p.m. was evidently moribund. She retained her senses to nearly the last, and at 5 o'clock expired.

Autopsy.—April 21st, I was requested by Mr. W. to examine the body, which I did in the presence of Dr. Spurgin and himself. From the symptoms immediately preceding death, we were led to expect that some internal hæmorrhage had taken place; and as it was most probable that she was pregnant, a rupture of the fallopian tube was casually mentioned as not unlikely to be found.

The body was not emaciated, but the abdomen was much swollen, and evidently contained fluid: the uterus could not be felt through its parietes. The mammae were not enlarged, nor was there any areola round the nipples. On opening the abdomen, the omentum was found to present a greenish muddy colour, and it had formed many adhesions, principally to the pelvic viscera, which it required a little force to separate. The intestines presented the same greenish dull hue, with large patches of effused and organized lymph upon them, especially on the lower ones. A large quantity of dark blood and clots, to the amount of three pints, was found in the abdominal, but principally in the pelvic cavity. After removing this, and on

detaching the adhesions of the omentum in the pelvis, a small portion of the left fallopian tube was torn away with them, and a fetus, about the tenth or eleventh week, found in the abdomen. The uterus was rather enlarged; and on making a longitudinal section through it, a distinct creamy semi-solid coat was found lining its cavity throughout, small blood-vessels shooting through various points of it. The ruptured fallopian tube contained coagulated blood. The cervix uteri was much harder than usual, the mouth a little opened, and containing a glairy fluid. No aperture could be discovered connecting the cavity of the uterus with the ruptured fallopian tube.

Although the above case is not a very rare one, still it may serve as a warning to us, how difficult the diagnosis will prove occasionally in similar cases. It will be allowed that it is hardly possible to discover the presence of this dilatation of the tube until rupture has taken place, and symptoms of internal hæmorrhage are observable. Still the friends will be (as in the present case they were at first) dissatisfied with the judgment even of the most experienced practitioner who prognosticates a happy issue of the case the day before death occurs. A post-mortem examination had the good effect of entirely dissipating this unpleasant feeling, by pointing out that the most correct knowledge of what was going on internally could not possibly have saved the patient. I forgot to mention that that part of the uterus adjoining the dilated tube was increased in volume, as it was on this circumstance formerly that Mauriceau founded his idea of its being simple hernia of the uterus.

3.—*Instrumental Labour—Accidents—Recovery.*

The following case is inserted chiefly to shew what a succession of untoward symptoms a puerperal patient will sometimes surmount, though at others we find her sink rapidly, under circumstances which would not by any means lead us to suspect a fatal termination.

M. Davis, æt. 32, residing in Church-lane, was taken in labour with her first child on Sunday, September 29, 1833. The pains continued strong all that day, I understand, and on the succeeding one likewise: no advance of the

head had taken place, however, although the os uteri was fully dilated; yet the pains having gradually worn off, I was requested by our principal midwife to visit the patient.

Oct. 1st, at noon.—On examination I found the rami of the pubes approximating much nearer to each other than usual, the arch projecting inwards; the child's head too was of large size, evidently causing great pressure on the soft parts. As it had rested on the latter for some time, and I had not much reason, from the conformation of the pelvis, to expect success in the use of the forceps, I judged it prudent to employ the perforator, especially as the child had not been felt to move for the two previous days, and there was a strong foetus proceeding from it. The bones of the cranium were remarkably firm, and required some force in order to make an opening sufficiently large to evacuate its contents. It was gradually brought down by means of the craniotomy pinners (of Dr. R. Lee, I believe), which I have always found more safe and efficacious in these cases than any description of hook; but there was still very great difficulty in effecting the passage of the shoulders, owing to the size of the child. This I at length succeeded in, and the remainder of the body soon after followed. The shell which is generally used in our workhouse for infants was found to be too small, and a larger sized one than usual was sent for.

The placenta did not descend into the vagina as usual; and as at the expiration of two hours there was a disposition to hæmorrhage, I introduced my hand into the uterus, and extracted it from its adhesions to the fundus. The woman was remarkably patient and quiet during the whole time, hardly uttering a single exclamation. I ordered her to be kept as quiet as possible, and gave her ʒss. of vin. opii.

2d.—Going on tolerably well; pulse natural, but complains of pain in the lower part of the abdomen and in the vagina, her urine escaping on the least exertion. To have fomentations to the parts, and an aperient draught.

4th.—She was much better yesterday, and could pass her water voluntarily; but a severe cough, which she is now troubled with, forces it from her; and towards the evening she was again unable to retain it at all. Great pain in the vagina still continues. Symptoms

of *pleuritis* on the right side have appeared, attended by difficult respiration and wheezing. Both breasts are very troublesome and painful.

Vesicat. Scrobic. Cord. Hirudin. viii. and fomentations to the mammæ, poultices to the vulva, and the patient to take mild laxatives.

6th.—Sloughs now came away from the upper and back part of the vagina; she was in a high state of fever, and towards evening a copious hæmorrhage took place, which, however, was checked by the acidulated infus. rosæ. Haust. diaphor. nocte.

By the 9th she was better in every respect, though a fetid discharge still came away from the vagina. She now could pass her urine voluntarily, though not possessing perfect power over the action of the sphincter.

Ordered arrow-root and weak broth.

On the 17th she had recruited considerably. A more nourishing diet was allowed her, but was again obliged to be discontinued, owing to an attack of *puerperal phlebitis*, but by the immediate application of leeches, fomentations, &c., it was subdued after some days, and she at length recovered.

I heard nothing more of this patient till the 4th of the present month, Dec. 1834, fourteen months after her last confinement, when I was again called to her. Pains had commenced at 4 A.M., and the labour appeared to be going on well, the breech presenting, till, on its descent into the vagina, a substance in the latter presented a complete impediment to its passage, as I was informed by the midwife, who felt quite sure that it was not present during the last labour. I saw the patient at 11 A.M., and on making an examination, found a firm ligamentous band, about 1½ inches broad, extending across the posterior part of the vagina, against which the breech pressed with great force at every successive pain, it proving an effectual obstacle to any advance. As it was clear that it depended on a cicatrix, the result of the sloughing after the former labour, and as clearly evident that it must be removed, I introduced a curved bistoury, guarded up to within half an inch of its blunt point with linen, using the forefinger of my left hand as a director, and divided it completely, without the patient being aware of it, as it caused her no pain. I saw her again in

an hour, as I expected the head would, as before, prove a source of difficulty, and found that the body of the child had been expelled in a quarter of an hour after I had removed the impediment to its advance, and that the midwife had since that time been ineffectually endeavouring to extract the head, having turned the face from the pubes, towards which it had presented, her left forefinger being introduced into the mouth to assist, but in vain. My repeated efforts, though made with caution, succeeded no better, part of the head resting on the projection of the pubes, which prevented its exit. As there had been no pulsation in the funis from the first, I sent for the crotchet; and having opened the head sufficiently, and obtaining a firm hold with it above the ear, I succeeded immediately in relieving it. The operation was nearly similar to that represented in Smellie's 36th plate. The placenta was passed soon afterwards, and the patient has had no further bad symptoms. I have recommended her, should she again become pregnant, to apply at the seventh month, as the induction of premature labour at that period may save her from severe suffering, and probably enable her to bear a living child.

MENSTRUATION AT ADVANCED PERIODS OF LIFE.

To the Editor of the Medical Gazette.

SIR,

I HAVE always considered menstruation as a very important function in the female economy. I deem it proper for medical men to lay before their brethren all unusual cases that may occur in their practice. Having been engaged more than twenty-seven years in public practice, and not having met, till within these few years, with any cases like the following, I think it right to send them to you for insertion in your publication. I have read the *Medical Gazette* since its commencement, but I do not remember any similar cases recorded in that periodical.

Sarah Johnson, aged 87, was attended by me, in the year 1830, in the workhouse of the Liberty of St. Andrew's, and menstruated freely, but she in a few

days after died. She complained of considerable pain. The fluid did not coagulate.

1830.—Ann Lovell, aged 75, a patient of mine, in the Liberty of the Rol's workhouse, was attacked, the early part of this year, with violent menorrhagia. The common remedies, inf. rosa, acid, &c., removed the complaint. The fluid did not coagulate. This woman has continued at irregular intervals to menstruate till the date of this communication: she menstruated last week.

Mary Waller, aged 67, placed herself under my care, in the Infirmary for the parish of Islington, also in the year 1830. She was then labouring under a violent attack of menorrhagia. The fluid did not coagulate. She continued two or three years on my list, and died from exhaustion. The usual remedies relieved this woman. It struck me as curious, that in three public establishments, distant from each other, three similar cases should have occurred in my practice.

Mary Dick, aged 80, was attacked, at her own residence, with an abundant flow of the menstrual discharge. When I saw her, she was in great pain. She said she had not been unwell for thirty years before. Opiates relieved her, and she finally got well. This case occurred in the year 1829.

Mary Brown, a nurse in Islington Infirmary, is at the present time menstruating: she is nearly 80. She says her menses ceased when she was 40 years of age. She has had the discharge now regularly for two or three years, and at monthly periods. Dover's powder relieves her.

Ann Lovett, about 80 years of age, a bed-ridden patient, now under my care in the Infirmary of Islington, bleeds one month at the nose, and the other month menstruates regularly: the menstrual fluid does not coagulate. When the menses cease, leucorrhœa appears. She requires aperient medicines, and occasionally zinc lotions. This patient's case is similar to Lovell's, mentioned already in this paper.

A female consulted me, about two years ago, for an attack of erysipelas on the face and arms. She stated that she menstruated at 17, and continued to be regular till 30 years of age, when the catamenia finally disappeared. She was, at the time when under my care, 44.

In the year 1833, Mary Owen, aged 77, a pauper patient in the workhouse of the Liberty of the Rolls, was placed under my care, with an abundant menorrhagic discharge. She was in much pain. She had not been in such a state, she said, for these last thirty years. In a few days, however, she died.

1833, Aug. 31st.—Charlotte Kiernan, aged 71, a pauper patient in the last-mentioned institution, applied to me, with abundant coloured discharge from the uterine. She was in much pain. Purgatives and opiates relieved this female. She told me she "was in the same state that she was when at the age of 20." This woman is now quite well.

Mrs. Gray, a nurse at one of the public institutions under my charge, aged 55 years, told me, that seven years ago her menses ceased, but for five years she had a monthly discharge of blood from the nipples. Her health was unimpaired.

It is the general opinion, that when aged females are attacked with this peculiar discharge, they are sure speedily to die. My experience does not warrant me in forming this conclusion, for several of my aged patients subject to this infirmity are now as well as ever they were, and very likely to continue so; nor do I think they will die, except from extreme age.—I am, sir,

Your obedient servant,

ROBERT SEMPLE,

Member of the Royal College of Surgeons
in London, &c.

2, Rufford's-Row, Islington,
Dec. 23, 1831.

ON CLUB-FOOT.

BY PHILIP M. LYONS, M.B. A.M.

Physician-Accoucheur to the Brighton Lying-in
Institution, &c.; late one of the Physicians
to the Brighton General Dispensary.

THE appearance of the accompanying paper in its present form requiring some explanation, I trust the following remarks will not be deemed irrelevant. When I commenced an essay on "Crural Deformities," with the intention of offering to the profession the results of my own experience, I was comparatively very slightly acquainted with the opinions of others on this subject. As I

proceeded in my inquiry, finding that but little original information was to be obtained from the major part of those of our own country who had written on this subject, and as a great difference of opinion existed amongst the most approved foreign authors, both as to the pathology and practice, whilst the procuring of their works was attended with much difficulty, I was induced to think, that a paper containing a condensed history of the most interesting facts and opinions recorded by such authors as I had been able to consult, given as nearly as possible in their own words, and in which such facts and opinions would be compared not only with each other, but also with other parts of the works of their respective authors, might not be deemed uninteresting to such practitioners as had not leisure or opportunity to pursue a similar course of study. Cruveilhier, in the part of his work on Morbid Anatomy devoted to club-foot, has adopted an opinion, and supported it by his individual observations, which is so completely opposed to those of Duverney, Scarpa, Delpech, and many other modern writers both practical and pathological, and which, if established, would so materially affect the question of the practicability of cure after the very earliest periods, as to render it a matter of the utmost importance to those interested in this class of diseases, to be intimately acquainted not only with Cruveilhier's opinions, and the facts they are based on, but of those also who have taken a different view of the question. I shall therefore make no farther apology for embodying in this paper rather extensive extracts from such authors as I may deem it desirable to quote, and which, by being contrasted one with the other, shall, I trust, enable us to deduce conclusions that will justify us in discarding, at least to a considerable extent, the present mode of treatment, and in substituting one more rational, more nearly allied to surgery, and which claims as its original recommender the illustrious Hippocrates.

It is not my intention on the present occasion to enter into any investigation as to the remote causes of varus; I shall therefore at once proceed to consider the subject, as presented to us at birth. Distorted feet were classed by the ancients according to their principal characteristic marks, into two species: varus, or

proper club-foot, in which the plantar surface is turned obliquely upwards and inwards, and the dorsum inclined downwards and outwards; and valgus, or reel-foot, whose distinguishing marks are directly the reverse. Scarpa subsequently added another, termed, from an imaginary analogy, *pes equinus*, or pointed toe, the phalanges being in some cases bent downwards, and partly backwards under the tarsus; and still more recently, Maissonabe has described another, in which the metatarsus and phalanges occupy a position exactly the reverse of that in *pes equinus*. To the species already described I shall beg to be permitted to add another, which I do not recollect to have been described by any writer whom I have been fortunate enough to consult, and which, by an analogy similar to that adopted in *pes equinus*, I shall designate *torquipes*, or swing-foot. I purpose making a few remarks on this subject towards the close of the present paper, and by means of it, endeavouring to illustrate the views I entertain concerning that class of diseases of which it forms a species.

Writers have arranged distortions of the feet under two heads, congenital and accidental. Delpech, arguing upon a theory the nature of which will be explained as we advance, has subdivided them into primitive and consecutive. The older writers seem in general to have entertained the opinion that those deformities were to be attributed to a malformation, or at least irregularity, in the shape of some, if not all, of the bones that entered into the composition of the leg and tarsus; an opinion which Scarpa*, in his work on Distorted Feet, has completely refuted, at least in those

particular cases which he observed and dissected. These observations led him to consider, "that the essence of this congenital deformity consists in the twisting of the os naviculare, of the cuboid, and of the calcis, around their smaller axis, into which morbid direction are drawn the cuneiform bones, those of the metatarsus, and of the phalanges of the toes. For this malposition Scarpa does not attempt to account, though he denies the explanation given by Duverney in his "Traite des Maladies des Os," who says that "distortions depend solely on the unequal tension of muscles and ligaments, as those which are remarkably tense draw the limb towards them, whilst the others, by their relaxation, give way to them." This opinion was also entertained by Boyer, as evidenced in the following passage of Dr. Farrall's translation of his work "Des Maladies des Os." "Club-foot is caused by an inequality in the respective force of the adductors and abductors of the foot, which inequality may depend on the position in which the fœtus is placed in the womb, or on the manner in which it has been treated after birth."

It seems also to have been adopted, though but to a limited extent, by Dr. Colles, who, in his very excellent paper on this subject, thus expresses himself: "For I apprehend there are not only different degrees, but different kinds of this deformity, and am convinced that the bones themselves, by being long held or exercised in an unnatural position, will become distorted." Mangolin also, in his able article on "Orthopédie," "Dict. de Médecine de Paris, 1817," alluding to the opinions of Scarpa, Boyer, Delpech, &c. thus expresses himself— "We conceive, very differently from those celebrated practitioners, that in some subjects the deformity owes its origin to an irregular formation of the bones of the tarsus, or even of a single articular face; at other times it may be the result of a defect in the equilibrium of the forces of the different muscles which move the foot, or a deficiency in length in part of them; but in others it can arise from the preternatural mode of insertion of one or more of the principal tendons which are attached to that limb. Once that the first element of distortion has begun to produce its effect, the deformity must increase each

* At the time I commenced this paper, namely, the early part of the winter 1832-33, I was not so fortunate as to meet Scarpa's work, and was solely indebted for a knowledge of that illustrious author's opinions to the truly valuable paper of Dr. Colles; and though I searched all the libraries, both public and private, to which I had access, I could not meet with but one copy (in Italian, and devoid of plates), which I found in the library of the College of Surgeons, London; but recently, through the very urbane and gentlemanly conduct, and kind exertions, of his able translator, the late Mr. Weisheart, of Edinburgh, I have been fortunate in procuring a copy of his most valuable and interesting, and I regret to add, too scarce translation. This gentleman (I am bound to observe), in a letter which I had the pleasure of receiving from him at that time, informed me that several cases had been successfully treated in Edinburgh by means of Scarpa's instruments, of which an accurate delineation is given in the work alluded to.

day, because several of the other causes unite to deform the foot. After birth, when the infants begin to walk, the weight of the body tends powerfully to increase the deviation."

Delpech, in his treatise on "Orthomorphie," takes a view of the subject in many respects very different from the authors whom I have just quoted. Each of the two first species of club-foot he divides, as I before observed, into primitive and consecutive, the former comparatively extremely rare; I shall therefore follow his own arrangement, and commence with the latter; and that I may be the more intelligible, will avail myself of the author's own words:—"The three species of deformity, though founded upon a difference in form, are capable of being reduced to the same principle. It is unusual to see *varus* in new-born infants to the same extent that we find it in after life. At birth, or soon after, the foot is commonly inclined downwards; this inclination increases by little and little, until its axis completely enters the direction of that of the leg; the point of the foot is inclined of itself to one or other side, particularly when the little one walks, at first slowly, and more frequently inwards; the heel follows in the same direction; the whole of the foot becomes inverted; and by slow degrees we see it form an enroulement, or doubling, upon its plantar surface, and inner or outer edge, as the case may be."

Such, according to Delpech, is the course that all cases of consecutive *varus*, or *valgus*, run; commencing in trifling displacements, they gradually increase until they become decided specimens of the third species, or pointed toe. The foot then taking an inclination inwards or outwards, gives the distortion a new character, which the weight of the body, now coming for the first time upon the legs, renders confirmed club or reel foot. He considers the cause of the original displacement always to be found in a contracted state of the *tendo Achillis*, with a considerable degree of tension of the muscles of that tendon, in consequence of which the posterior portion of the *os calcis* is drawn upwards, and obliquely inwards or outwards, according to the character of the deformity. The correctness of this observation he thus endeavours to prove—"If, in young subjects, we di-

vide the *tendo Achillis*, we can easily restore the foot to its natural position, without leaving any alteration or trace of defect. In more advanced ones it is not sufficient to give this liberty in order to reduce the foot, as it leaves it to be restored but imperfectly; but even in these cases, if, after the division of the *tendo Achillis*, we offer violence to the aponeurotic and ligamentous structure of the sole of the foot, we shall find that the other muscles will afford us but very little resistance."

In explaining the appearances which the bones of the tarsus present on dissection, he particularly observes, "that the situation of the foot is such, that the inner edge of the pulley of the *astragalus* is alone lodged within the tibio-fibular cavity; that the internal malleolus embraces in part the inferior surface of the *astragalus*, whose connexion with the *calcis* is very much relaxed; the interosseous ligaments are also much distended, particularly posteriorly;" and here he adds a most interesting pathological observation, though directly opposed to the facts and opinions of Cruveilhier:—"However, the normal form of the articular surfaces of the various displaced bones is not at all altered, though the inclination of some of them places them in contact with the synovial membrane of the opposite surface, and beyond the limits of the arthro-dial cartilage." He subsequently thus explains his theory of the deformity:—"The shortness of the muscles of the calf is a general and primitive fact, and the *key-note* of the whole doctrine applicable to this part of the question; being comparatively too short, they resist the efforts of elongation made by the corresponding bones: hence the deviation of all the neighbouring articulations that can yield in their favour. Extension of the foot is the first consequence; subsequently, as an effect of this, follows the deviation *inwards*, because the *calcis* is naturally inclined a little to this side. In the rolled position of the foot, the muscles and aponeurosis being no longer solicited to elongation, in order to allow for the growth of the bones to which they are connected, these parts remain below of their natural dimensions."

To return to primitive *varus* and *valgus*. These exist completely formed at the time of birth, and are accompanied by tension of the different muscles,

which severally produce each of them; and which tension may be very much increased, even to the provocation of pain, by any effort made to restore the foot to its natural direction. The essential characters of club-foot, according to Cruveilhier, are—first, the elbow, or angle, which the first row of the tarsus forms with the second. The first is on a line with the leg, the second with the rest of the foot; hence a very obtuse angle projecting forward. This elbow is the effect of a rotation inwards, which I compute at a quarter of a circle, suffered by the foot on its vertical axis. In the phalanges, metatarsus, and cuneiform bones, we find a change in direction, but none in form; their conformation is so perfect, that the least possible trace of their belonging to a club-foot is not to be detected. It remains, therefore, to examine the scaphoid, cuboid, astragalus, and calcis. The scaphoid, according to Scarpa, suffers most; but a glance at the different plates of various ages is sufficient to convince us, that it, like the tarsal bones of the first range, is drawn into a consecutive common deformity, but does not form any essential part of that deformity: it often touches the internal malleolus, and is united to it by a ligament, and sometimes even articulated with it. The most remarkable change it suffers is a diminution in size, an atrophy caused both by the severe compression which it experiences, and by the displacement of the head of the astragalus, a portion of which, sometimes only the one-third, and even the one-fourth, corresponds to the fossa navicularis, whence the smallness of this fossa. What has been said of this last bone also applies to the cuboid, whose posterior articular face is reduced two-thirds, because it does not correspond to that extent to the portion of the calcis to which it is adapted.

“The astragalus is evidently the bone which has suffered most deformity: hence we have not only change of direction but of form; the deformity is exactly proportioned to the degree of club-foot. This bone draws into consecutive displacement the entire of the foot; it is in general diminished in volume; in all cases it is displaced, the pulley looking completely outwards, the external articular face downwards, and the internal upwards; which last is almost, if not completely, effaced, and in its place we do not find aught but fibrous tissue.

The articular cartilage of the pulley is sometimes in great part, in others completely destroyed. Compression in an improper direction is greatly the cause of this; but we must also blame the absolute immobility of the tibio-astragal articulation, in consequence of which compression is always made on the same points. The head of this bone, if large in its natural state, is reduced to two-thirds, and sometimes to one-third, or even one-fourth; or rather a large part of it, which has quite left the hollow of the scaphoid, places itself beneath the skin, and forms a tumor larger in proportion as the displacement is more complete. In some rare cases progression is made, in part, on the head of the astragalus, which, by a very extraordinary transposition, becomes a substitute for the heel; and in this case osseous growths, frequently very considerable, spring from it. The calcis follows the astragalus in its displacement; it does not rest on the ground, except on its outer edge; it is also curved on itself from without inwards; its posterior extremity is deformed, diminished in bulk, approaches the posterior edge of the internal malleolus, and looks inwards; its anterior face has abandoned, in part, the corresponding one of the cuboid, and forms a prominence under the skin, which, sometimes enormous, becomes a substitute for the posterior tuberosity. The skin is then rendered thick and callous, and sometimes inflames in consequence of too severe friction: hence spring interminable ulcerations, and often caries and necrosis of the subjacent bones. Under the skin corresponding to the outer side of the tuber calcis, as under that covering the patella, is formed a *bursa*. The same circumstance occurs with the astragalus, when it bears on the ground. A second bursa, which is nothing more than a synovial extension of the astragalo-scaphoidian articulation, exists between the astragalus and the fibrous layer, which forms the superior ligament of that articulation. New-formed cartilages encrust those new vegetations, which now become exposed to friction. Thus we see in bones continued pressure the cause of atrophy, intermitting of hypertrophy. The plantar aponeurosis, following the law of that structure in all parts of the leg and foot, is remarkably thin; it does not oppose the extension of the toes, nor does the division of it facilitate the mo-

tions of the tarsus, or the restoration of the devious foot. If persons say this is the primary, but alteration of the joints the secondary and essential cause, I answer, *the dissection of a new-born infant gives me the same results as that of an adult.*

"None of the ligaments of the tibio-tarsal articulation present any thing particular in their appearance. On their internal side there exists, first, a superficial, lateral, ligamentous layer, extending from the internal malleolus to the astragalus and calcis; this was the internal lateral ligament, which is by no means shortened. Secondly, from the circumference of the articular face of the truncated internal malleolus, and even from the face itself, arises a ligament, which is attached to the circumference of the corresponding face of the calcis. This newly-formed, or rather accidental ligament, is extremely resistent, and requires a great effort to break it asunder; and I am convinced that, if not the principal, it is the first obstacle to the restoration of the foot.

"The astragalo-scaploidean and calcaneo-boid ligaments do not arise from the circumference of their proper faces, but from their new tubera, which tubera are in general encrusted with recent cartilage; the muscles are atrophied; fatty transformation of all the muscles of the leg and foot, even to the accessorius, prove that they can have no power in causing the deviation, and that Maissonabe and others are in error, who place the effective cause of the deviation in the want of antagonism, or in the relative predominance, sometimes original, sometimes acquired, of one or other set of muscles over their opponents.

"The internal gemellus, soleus, and external gemellus, preserve the character peculiar to muscular fibre, because the limb exerts some slight motion inwards by means of them. *In new-born infants the muscles are perfectly natural.* Having, at the end of seven years, examined a child whom I had seen when a year old, I observed that the atrophy of the muscles was *consecutive*. The muscular nerves, the sciatic and internal popliteal, principally, were extremely slender, and appeared as if reduced in their neurilemma. The vessels suffer a corresponding diminution in their calibre.

"In many advanced cases we have an alteration in the character of the bones

of the leg, though they are generally straight in young subjects, and even in some adults. In some cases the internal and outer surfaces of both tibia and fibula are enlarged at the expense of the posterior surface, and form an angle forwards, as in rachitis. The inter-osseous space has almost completely disappeared in the lower part of its length; the tibia, inclined outwards, presented an oblique plane for the articular extremity of the femur; the cartilages of the outer condyle of the latter named bone, and corresponding face of the former, with the interposed semilunar cartilages, as also even the subjacent osseous layers, were all wasted away. The external malleolus is thrown outwards; the inner one is short, as if cut off horizontally at its base, but at the same time much larger than usual: its face, externally, presents a face which is connected sometimes with the scaphoid, sometimes with the calcis,—more frequently with the first,—by means of a loose symphysis, and occasionally of a perfectly formed articular face. The whole of this is consecutive. I reject, either as a primary or consecutive cause, the retraction, narrowing, or tension of the chief muscles; for in club-foot there is no luxation, predominance, retraction, or diminution of certain muscles or tendons. The great difference between an infant and adult is in the cartilaginous state of the astragalus, which, in the former, can more easily take a better direction than in the latter."

Such are the opinions and facts presented to us by Creuveilhier, and which I shall now proceed to compare with those of the other authors whom I have quoted, and by this means endeavour to arrive at some fixed data which may justify us in adopting such views of the pathology of the affection as will, I trust, lead to extensive improvements in the treatment, not only of this malady, but also of many other species of distortion, both congenital and accidental.

Scarpa states, that the essence of club-foot lies in the twisting of the os naviculare on its smaller axis; and that this twisting is the cause, and not the effect, of the contraction of certain muscles. But granting such to be the case in every species of varus, on what principles are we then to account for the distortions which we find to take place in the extreme and opposite kinds, as valgus, pes equinus, and that peculiar

reflected foot first described by Maissonabe, where the dorsum is turned obliquely upwards and outwards against the anterior and outer surface of the leg—a position of the limb which must have been produced by a different cause? In contradiction to this eminent professor, we have an assertion of Delpech, also based on pathological observation, that displacement of the astragalus is connected with the deformity; and that the essence of the disease is a contracted state of the tendo Achillis. But allowing this to be the case, and that pes equinus is the consequence, as Delpech asserts, what takes place next? The foot, he says, is inclined at first, and of itself, inwards;—an assertion subsequently qualified by his observing, that the tendo Achillis, having a natural direction inwards, gradually draws the heel into that direction, and thus turns the dorsum of the foot outwards and downwards. But supposing this to have occurred in the manner described, the result would be that varus must uniformly take place, and that valgus never could occur; even pes equinus could not exist for a moment after the tendency of the gastrocnemii to contract inwards had once commenced. But we know that both valgus and pes equinus, though not common affections, occur sufficiently often to establish the fact. The consequences arising from the division of the tendon do not appear to me to warrant the inferences Delpech would draw from them, since the weight of the heel, deprived of its support, would of course tend to drag into their proper direction those other muscles which were principally concerned in the deformity, and which, by the violence done to that tendon, had lost a powerful ally in their irregular action. With respect to the theory advanced by Delpech,—for an account of which I must refer my reader to the work above quoted,—we must acknowledge its ingenuity, while we utterly deny its correctness; for if a want of adequate and sufficient innervation were the cause, how could we account for a phenomenon interesting in itself, but doubly so as setting at rest this fanciful hypothesis—a phenomenon which has not escaped the observant mind of that sound pathologist and reasoner, Dr. Colles;—I allude to the extraordinary rapidity with which the muscles are developed in proportion as the limb resumes its natu-

ral position, and which I had occasion to notice in my own practice long before I had consulted either of those eminent writers. Cruveilhier has also completely refuted Delpech on this point, when he stated, that on examining a child at the end of six years, he found the wasting of the muscles consecutive. But he himself seems to have entertained almost as fanciful a notion, when adopting the opinion that deformities of this description were the result of pressure produced *by the fetus upon its own limbs*, without reflecting that the arguments which he adduced against its being the effect of external pressure were equally fatal to his own views, as the tendency of the waters of the amnios must necessarily be to prevent resistance either *internal* or *external*; and without resistance there can be no pressure. Besides, were the facts as he states them, in what cases would we be most likely to find infants with club-foot? Would they not be where there was comparatively no water; or in cases of twins, where one or both children are born breechlings? Are such those in which they are generally found? As far as my own experience may be adduced, it contradicts this conclusion. But to proceed to a more practical, and therefore perhaps a more valuable part of his essay, he tells us, that the astragalus is the bone which has evidently suffered most deformity; that it has not only changed its position, but also its form; that the deformity is exactly proportionate to the degree of club-foot; and that the great difference between an infant and an adult, in this respect, is in the cartilaginous state of this bone in the former, which, therefore, can more easily assume a better direction. That this may occasionally be the case, must be acknowledged; and were we inclined to be sceptical, his dissections, as individual cases, must be allowed to be convincing. But when we find Scarpa announcing, as the result of his investigations, also made on infants, that the astragalus is not deformed, and likewise Delpech, a pathologist, declaring that the bones of the tarsus undergo no alteration in form—an assertion which, let us take it with what limitation we may, is still deserving of some credit,—if we do not fully concur in opinion with Duverney, Boyer, Maissonabe, &c., we must at least join with Isidore St. Hilaire in thinking that “though con-

traction of certain muscles may generally be but an effect, there is, however, nothing to prevent its being sometimes a cause; and we must not lose sight of the fact, that though in cases where inequality of force between antagonist muscles does not become very evident until after distortion of the tarsus, we cannot always affirm that a slight inequality has not preceded the distortion in the order of time, and contributed to produce it." The testimony of Colles also appears capable of being adduced in favour of those who deem it the effect of irregularity in the formation or action of certain muscles or ligaments; for while his dissection of a child aged five years, and another subject still more grown, do not prove to him the existence of congenital malformation, his successful treatment of a child within the short period of eleven weeks,—and which, as he most ingenuously acknowledges, but for his too great haste, might have been accomplished in nine,—leads us to infer that malformation could not have been the cause of the deformity.

D'Ivernois also has succeeded in removing the deformity at the advanced ages of 35, 40, and even 50 years; though, as Marjolin, who mentions the circumstance on the authority of Briche-teau, acknowledges, the flexor muscles of the foot remained paralysed in those which we might almost term hopeless, and therefore require the constant use of the contusive apparatus.

I have myself, within an extremely limited period, succeeded in making an impression on limbs at the ages of eight, nine, and fourteen, as noticed in the cases detailed below—periods at which, if with Crenveillier we were to look on the disease as the consequence of congenital malformation of the osseous part of the system, we might feasibly conclude that the distortions were utterly incapable of relief.

To these opinions I might perhaps be allowed to add those of Hippocrates, who, whatever he may be thought of as a pathologist, must be acknowledged to be without a rival both as a surgeon and symptomatologist; who, in his chapter "De Articulis," thus expresses: "There is also a very great difference in the ligaments themselves; since in some they are too relaxed, in others too contracted." And again: "For some of those luxations which take place at birth, if they be not too much

dislocated, can be restored to their natural state; and particularly the articulations about the foot. Therefore the modes of deformity are not one, but manifold *."

As the result of a diligent comparison of all those observations, I think we may reasonably infer that though congenital malformation may be a cause of club-foot, we can also have the same affection as a consequence of some active or passive irregularity in the muscles and ligaments which are connected with the foot; an inference which, in my own mind, has become conviction, since I met with two cases of infants born with a distortion similar to that described by Delpech, where the foot is turned upwards and outwards against the fibula: one of those cases, slight in itself, was perfectly cured within the first week by the nurse, who, having gradually extended the feet, bandaged them in their natural position by means of a napkin. In the other I applied a small splint and bandage, and removed all appearance of deformity within the month.

[To be continued.]

OBSERVATIONS ON THE PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

IN the course of an investigation of the essential nature of the laryngismus stridulus, or crowing inspiration of infants, which has for some time engaged what of leisure I could command, I found reason to believe that this very peculiar symptom was generally, if not universally, owing to morbid enlargement of the thoracic or cervical absorbent glands, and that these acted by producing some injurious impression upon certain nerves which have an essential connexion with the respiratory

* Hippocrates, *enrante Vander-Linden*. Tom. II. Cap. De Articulis, Sect. 4, 51, 52.

I had almost forgotten to observe, that Baron Dupuytren, in his "*Leçons Orales*," seems to have entertained the same opinions as Delpech, and recommends a similar mode of treatment—namely, the section of the tendo Achillis; and still more recently, Dr. L. Stromegeer, who appears to have practised successfully his own improved operation with the same object.—*Dublin Journal*, May 1, 1834; *Archives General*, Jan. 1834.

function, and directly influence the movements of the glottis. In the progress of my inquiries concerning the nature of this influence upon the respiratory nerves in contiguity with these glands, I found myself materially obstructed in which the very interesting subject of the pathology of nerves had been treated, both in the systematic works and the detached communications of writers upon the subject, which fell within my reach. The language employed was often obscure; many of the general statements appeared to be merely conjectural, and unsupported by evidence; the same symptoms were often referred to different conditions of a nerve, and not unfrequently various and contradictory effects assigned to the same cause.

To clear up some of this obscurity—to remove the apparent anomalies, and to disentangle the intricacies which such different and even contradictory statements, not only of various writers, but even of the same author, sometimes in the same chapter of the same work, had produced—I was driven to the necessity of subjecting to a more exact and rigorous examination those recorded cases which are to us what “precedents” are to lawyers, and which alone, when duly examined, can justify the deduction of general principles, and the consequent enunciation of general propositions. I found, indeed, that the morbid appearances had been registered with great minuteness and fidelity, but no very definite or perspicuous attempt had been made to trace with accuracy the symptoms characteristic of each, although the association of the two in description must ever be the great end and object of pathological anatomy. Without this association, the record of appearances is little worth; it has about the same practical value as the mere *catalogue raisonné* of an anatomical museum.

All nosological arrangements are founded upon the resemblances and differences of the essential circumstances of diseases; upon similarity—the foundation of their being grouped together in classes and orders; upon dissimilarity—the foundation of their distinction into genera, species, and varieties. In examining these resemblances and differences in individual instances of “affections” of nerves, it appeared

that the phenomena, which I was to subject to examination, manifested themselves at their remote extremities, and that like causes, operating upon the trunks of given nerves, occasioned like effects upon all their branches beyond the point where the morbid impression is made. In further tracing these phenomena, it seemed to be established that nerves erred either by excess or defect—that each was characterised by its appropriate signs, and originated from causes exclusively productive of each.

These general facts constitute the foundation of that arrangement of the general principles connected with the pathology of nerves, which, in my former communications to the *GAZETTE*, upon the subject of the laryngismus stridulus, I thought myself justified in propounding, and the truth of which further and more extensive inquiries have tended to establish and illustrate.

But to some, these general principles may appear less satisfactory than to myself, and it has been represented to me that they require the confirmation which details alone can afford them. These details, therefore, will form the subject of the following communication, which, from its unavoidable extent, should you deem it worthy of insertion in your pages, will require to be given to your readers “in divided doses,” the apportioning of which I must leave to your own discretion and convenience. I do not indeed pretend, or expect, nor shall I attempt to exhaust this interesting and comprehensive subject, to which I am rather desirous to invite the attention of the profession, and to stimulate their curiosity and ardour in the prosecution of further inquiries. It is an extensive field of inquiry, which will amply repay the cultivation.

It may be objected to me, perhaps, that in entering upon this subject I am trespassing upon the manor of others, as these diseases are *local* in their character, produce commonly merely *local* symptoms, and require *local*, and in many instances surgical, means for their cure. But these maladies are upon the confines of medicine and of surgery, the boundaries of which it is not so easy, as seems to be assumed by colleges and corporations, accurately to define; and, at all events, I may well shield myself under the example of one of our most eminent and accurate patho-

logists (Dr. Abercrombie), who, himself a practical physician, has very briefly considered the subject of the pathology of nerves, at the conclusion of his valuable "Researches" upon the Diseases of the Brain and Spinal Marrow. But, in truth, these structural maladies are not sufficiently numerous to enable any single individual, to whatsoever artificial distinction in the profession he may be attached, or to whatsoever branch of the profession he may particularly devote himself, to do justice to a subject so ample, without availing himself of the experience and observations of others; and as the stores of medical literature are open to all, it is only requisite, that he who undertakes to investigate or newly arrange the morbid affections of the nerves of the human body, should be tolerably acquainted with their structure, course, distribution, and offices, and with the phenomena of disease in general; that he should have access to the ordinary sources of information, with industry to consult them; and that his habits and pursuits should have accustomed him to the selection, arrangement, and compression of the observations of others, and to the exercise of his reasoning faculty upon the materials which he may thus be enabled to collect. How far it may have been my lot to acquire these moral requisites, or to apply them to the subject under consideration, it is not for me to determine. My purpose has been to simplify the arrangement and facilitate the acquisition of knowledge, with regard to the diseases of these all-pervading instruments of sense and motion, rather than to add largely to the stock of information upon the subject; and if I shall have succeeded in the attainment of these objects of no inordinate pretensions, or of even promoting discussion upon the subject, I shall consider the time and labour which the inquiry has cost me amply repaid.

The general principles to which I here advert are the following:—1st, That if injury or disease affect the trunk of a given nerve, the principal effects will be observed at the remote extremity of its filaments; 2dly, that all the branches proceeding from such common trunk will have a similar disturbance of function from the same morbid impression; 3dly, that the morbid affections of nerves resolve themselves into those of

excitement, and those of defective energy, each presenting peculiar and definite symptoms; 4thly, that excitement may be the result of mechanical impulse, of vascular congestion and irritation, of inflammation, of structural disease, and perhaps sometimes of simple functional disorder; and 5thly, that diminished energy is generally the consequence of some extraneous pressure upon a healthy nerve, or of atrophy, either primitive or secondary, of the nerve itself.

These principles, almost elementary in character, are founded upon an extensive induction of facts; and abundant evidence of their truth might be adduced, if I were disposed to confine myself within such narrow limits, from a single collection of medical and surgical cases, the record of the transactions of a society which contains amongst its associates many of the most enlightened members of our profession. But it is unnecessary thus to restrict myself; and cautions only of the authority upon which I select my illustrations, I shall proceed to a detailed consideration of each of these general propositions.

1. *If injury or disease affect the trunk of a given nerve, the principal effects will be observed at the remote extremities of its filaments.*

This statement involves two propositions: the one of a negative character, rather implied than expressed; the other a positive allegation; and both requiring the evidence of facts in their support.

First, it conveys by implication that injurious impressions upon nerves do not produce their effects at the point where the injury is inflicted, nor at any point nearer to the sensorium commune; in the compressed language of a recent eloquent writer upon tic douloureux, "the seat of pain is not the seat of the disease*." This observation, however, applies only to the trunk of a nerve; but it is true in whatsoever part of its course the injury may be received, or the disease exist. If the impression be made at the remote extremity of the nerve, the effect is at first confined to the part injured, as where neuralgic suffering has resulted from pricking, pinching, lacerating, or cutting any part of the

* Sir Henry Hallford.

common integuments. This is well illustrated by Mr. Wardrop's case of injury to the sentient extremity of the fore-finger, which was pricked with a gooseberry thorn*. For above ten months after the infliction of the injury, the pain was confined to the two first phalanges of the wounded finger, after which, however, a new series of symptoms made their appearance. The observation also applies only to healthy nerves, for it is well known that disease of their texture will essentially modify the results.

Experiments upon animals, when instituted upon those fibrils of a nerve which minister only to sensation, give us little information upon this point, as "these creatures are unable to express what they feel, and their expressions of pain may be rather from cutting surrounding sentient parts than from the injury of the nerve; and at all events they will probably confound these sensations.†" But accidents and surgical operations, which are just experiments upon the human frame, the least obnoxious to objection, will enable us to verify the observation. Those who are guilty of the domestic offence of napping in a chair present abundant illustrations. During sleep under such circumstances, it is far from uncommon (and my experiments have been numerous upon the point), for certain nerves to be so compressed as temporarily to annihilate their function. If the occiput rests upon the sharp edge of the back of a chair, the sentient extremities of the sub-occipital branches suffer, and the occiput is benumbed; if the arm hang over the same edge the median or radial nerve is affected, and the finger and thumb which it supplies lose their sensibility: if the part of the arm immediately above the elbow rests upon the back or arm of the chair, or upon a table, the head being supported by the corresponding hand, the ulnar nerve will be influenced, and the half of the ring finger, with the little finger, will lose all power of sensation; whilst from long continued pressure in sitting in one position the sciatic is influenced and the foot paralysed. There is no peculiar sensation, in these cases, at the precise point where the nerve is pressed, nor are we conscious of the result until

some little time after waking, when the effects are observable at a distance. Hence it has with much truth been alleged that nerves in their natural and healthful state are in themselves little sensible, and are "probably media of transmission only,*" "*les agens de la transmission des impressions*†;" and if the part where the impression is made upon the nerve, is little sensible of that impression, *a fortiori*, it may be concluded that the parts supplied by the same nerve above that point, that is nearer to the nervous centre, cannot be cognizant of the injury, or suffer from its immediate effects; "*nihil patiuntur artus qui nervos habent supra sedem vinculi vulnerisque natos.*‡"

Secondly, it is made a matter of direct and positive statement, that the principal effects of injuries or diseases are observed at the remote extremity of the filaments of the nerves affected, and such is the force of habit and associations in this particular, that even if the parts, which they supply with nervous energy, no longer exist, as in some cases of amputation, uneasy feelings are constantly referred to the lost member. The husband of one of my patients, in a *sortie* for the recovery of a superior officer who had been taken prisoner by the enemy, lost his leg by nearly the last shot which was fired at the conclusion of the Peninsular war. From some mechanical irritation, or more probably from chronic inflammation, or other diseased condition, of the nerves of the stump, he is subject to such agonizing neuralgic affection, with spasm of his remnant of a thigh, as, notwithstanding his natural cheerfulness and courageous bearing, almost to make him faint. He constantly complains of his offending leg and toes which are buried in the South of France. Similar instances are mentioned by Portal, Swan, Descot, and others§, and they afford very une-

† Magendie.

‡ Haller, Elem. Phys. v. 4, p. 325. Galen has also well expressed the same principle founded upon similar facts: "*adeo certe magna quedam vis est in nervis, superne a magno principio affluens: non enim ex seipsis eam, neque connatam, habent. Cognoscere etiam potes hinc maxime, si incidideris quencunque istorum nervorum, aut spinalem ipsam medullam: quantum enim superius est: incisione, continuum cerebro, id quidem adhuc conservabit principii vires: omne autem quod inferius est neque sensum neque motum ulli præbere poterit. Nervi itaque rivorum in morem a cerebro, seu ex quodam fonte deducunt musculus vires.*"—*De Motu Musculorum*, lib 1.

§ Frequentissima et antiquissima est adnotatio, si quando digitus aut per, aut crus amputatum

* Med. Chir. Trans. vol. viii.

† Sir Charles Bell.

quivoceal, though indirect evidence, of the principle under notice—that when a strong impression is made upon a nerve in its course, the effects are commonly observed at its remote extremity: “if, however, a doubt should be entertained upon this subject, an attention to symptoms will soon dispel it; when a nerve is irritated at any part between its origin and termination, a sensation is felt as if some injury were done to the part which it supplies. If, therefore, the cutaneous nerves were injured, the integuments of the fore-arm would seem to suffer pain; but if the median nerve was wounded, the thumb and two next fingers would be affected with pain*.”

It may perhaps be somewhat difficult to reconcile this with a speculative opinion of Sir Charles Bell upon this subject, that “a pure and simple nerve has the influence propagated along it in one direction only, and not backwards and forwards: it has no reflected operation or power retrograde; it does not both act to and from the sensorium†.” There is no doubt that the ordinary course of sensation, from the impression on the part to the conception in the sensorium, is in a direction from the extremity of the nerve to the brain; but here an impression is made upon a nerve, and sensation is experienced at a point still more distant from the brain than the seat of impression. How are these apparently conflicting sentiments to be reconciled? Three modes of explanation suggest themselves to my mind: first, the observation which I have quoted may refer only to muscular parts, to which Sir Charles Bell has particularly, if not exclusively, applied his principle of the nervous circle; secondly, there may be actually no exertion of nervous energy beyond the part of the nerve upon which the injury is inflicted, although the limb and the nerve remain entire: the sensation of pain at the extremity may be a delusion, the result of those powerful principles in the physical and moral constitution

of man, habit and association, which we have seen in stumps, leading the patient to refer his sensations to the extremity which he has lost, even to the belief in the perception of flexion in the amputated member: thirdly, disease may alter the results; and in most of the cases of painful affections it must be borne in mind that there is some structural disease of the nerve in its course. But I am free to confess that these suppositions do not altogether remove the difficulty from my mind. Still, conceding all that may be deduced from this apparent anomaly, it remains substantially and perhaps universally true, that “if we select a filament of a nerve, and if its office be to convey sensation, that power shall belong to it in all its course wheresoever it can be traced, and wherever in the course of that filament, whether it be in the foot, leg, thigh, spine, or brain, it may be bruised, or pricked, or injured in any way, sensation and not motion will be the result; and the perception arising from the impression will be referred to that part of the skin where the remote extremity of the filament is distributed*.”

This general principle, then, as far as sensitive nerves are concerned, is abundantly established; but it is equally true of motor nerves. “*Irritato nervo convulso in musculo oritur qui ab eo nervo ramos habet†.*” “A rabbit was struck behind the ear, so as to deprive it of sensibility; and I then exposed the spinal marrow. On irritating the posterior roots of the nerve, I could perceive no motion consequent in any part of the muscular frame; but on irritating the anterior roots of the nerve, at each touch of the forceps there was a corresponding motion of the muscles to which the nerve was distributed. Every touch of the probe or needle on the threads of this root was attended with a muscular motion, as distinct as the motion produced by touching the keys of a harpsichord‡.” “The nerve of the fifth pair being irritated at its root in an ass, the moment it is killed, the muscles of the jaw act, and the jaw closes with a snap§.” The same nerve being irritated where it lies in the sphæno-palatine fissure, “the jaws came together with much force; indeed, so as to nip an assistant’s finger

pericit: in eo tamen amputato artu dolores vividos omnino percipi, ut sana, sibi que constans, anima fallatur, atque in eo artu dolorem se percipere suadentur: qui dudum detruncatus computruit neque nunc ulla pars est nostri. severely*." Again, "on dividing the roots of the nerve in a living animal, the jaw fell relaxed." These are happy illustrations of the function of the motor branch of the fifth pair of nerves, and afford conclusive evidence that the effects of injurious agents upon nerves are observable at the remote extremity of their fibres.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégier."—D'ALEMBERT.

Elements of Chemistry, including the Recent Discoveries and Doctrines of the Science. By EDWARD TURNER, M.D. F.R.S.L. & E. &c. Fifth Edition, enlarged and carefully revised.

THE high character which this work has hitherto maintained—being in fact, as a northern critic has entitled it, "the best elements of chemistry extant"—rendered us rather anxious, on the publication of this, the fifth edition, to ascertain how far it had really been made conformable with its title-page profession of including the recent discoveries and doctrines of the science. We have noted down a few of the results of our examination.

In the section on Heat, Dr. Turner assumes it as an established fact, that all gases undergo equal expansions by equal additions of heat; and that, knowing the law of expansion of any one gas, we may know all. He then quotes Gay Lussac for the quantity of the expansion of air, and seems quite satisfied with the calculations of that chemist. Now the doctrine here laid down, though generally admitted by chemists, would appear from certain recent researches not to be very tenable. The improbability of it, indeed, cannot but have often occurred to the chemical philosopher; he cannot but have been struck with the unlikelihood of cyanogen and hydrogen, for example, expanding in an equal ratio, when the former is so readily condensed into a liquid, the latter remaining refractory; might he not hence readily infer, that the particles of cyano-

gen are less influenced by heat than hydrogen; or that, at least, the two gases cannot be equally expandible by heat? But how happens it that Dr. Prout's recent experiments and doctrines on the subject have been left wholly unnoticed by Dr. Turner? In the important paper of which an abstract is given in the first volume of the Transactions of the British Association, Dr. Prout has shewn that

Grains.

100 cub. inch. Air 60° Fahr. weigh 31.0117
Ditto 32° Fahr. 32.7800

These results vary considerably from those of Gay Lussac. According to the law laid down by the French philosopher, if 100 cubic inches of air at 60° weigh 31.0117 grs., the weight of the same volume of air at 32° will be 32.8206 grs., which exceeds Dr. Prout's experimental result by .0306 grains—a material difference, when it is recollected that the weight at 32° forms the chief element in the calculation of all the other quantities of expansion. Hence the fraction $\frac{1}{135}$ cannot be safely assumed as the measure of the expansion for each degree of Fahrenheit; nor should the formulae and deductions in Dr. Turner's note (p. 35) be presented to the student, without inculcating some little caution. Yet we find not one hint to that effect. The theory of the construction of the thermometer, too, in the following page, involves at least a questionable principle. We can only infer from all this, that Dr. Prout's paper is unknown to the author of the *Elements*, which surely ought not to be the case when professing to give "the recent discoveries and doctrines of the science."

Another instance in which we fail to find due attention paid to "recent doctrines" occurs in the section on Light. The undulatory theory is summarily disposed of; Dr. T. mentions Herschell and Airy as its chief supporters in later times, and to *their* works he refers those who wish to study the subject. We cannot conceive with what good reason he does this. Have not Fresnel and Young done more for the theory than either Herschell or Airy, who have in fact, for the most part, only followed out the views of the former? And why refer the student to the elaborate mathematical (and to most medical students unintelligible) articles of Sir J. Herschell, in the *Encyclopædia Metropolitana*, or

* Ibid. p. 63; note by Mr. Shaw.

† Ibid. p. 35.

Professor Airy in his mathematical tracts, when there is so beautiful and simple a memoir on the subject by Fresnel, translated by Dr. Young, in the *Journal of Science* for 1827? and when so much more familiar sources of information are open in Peclet's *Traité de Physique*, and Pouillet's *Elémens*?

But Dr. T. is not quite correct in saying that *either* theory will serve the purpose of classifying facts and explaining most of the phenomena of light. Has he forgotten one very important instance to the contrary? Does the Newtonian theory explain how two rays of light, meeting under certain circumstances, produce darkness? The phenomena of diffraction, in fact, completely nonpluses the Newtonian doctrine; and Professor Airy himself has shown the bellowness of Newton's theory of the colours of thin plates. And the reason of our author for going into particular detail of the old theory, is surely not very solid. He admits that the strongest evidence is in favour of the undulatory theory—but he pursues the old track, *because* “the views of Newton are still generally used and understood!” Who would not have thought that this was the very reason why the undulatory theory should be adopted in preference, or at least in some measure explained? But Dr. Turner has not done either.

In the very short and inadequate notice bestowed on double refraction, there is not a little to be censured. When a ray of light passes through Iceland spar, we learn from Dr. T. that it is divided into two portions—one obeying the *ordinary* laws of refraction, whereas the other constitutes an *extraordinarily* refracted ray. Now any person unacquainted with the subject would fancy from this, that *in all cases* one of the rays is ordinarily refracted. Yet such is not the fact: for in all crystals having two axes of double refraction, neither ray is ordinarily refracted.

The examples of polarization given by Dr. T. are miserably scanty, being confined merely to reflection from the surface of glass or water. And the subject is dispatched *in toto* by the following brief announcement. “The phenomena of double refraction and polarized light constitute a department of optics of great and increasing interest; but it is *too remote* from the pursuits of a chemical student to be treated of at length in this work. Those interested in such

studies will find an excellent guide in Sir D. Brewster's *Treatise on Optics* in the *Cabinet Cyclopædia*.”

With respect to the advantage arising to the student from the consideration of this subject, we do not agree at all with Dr. T. It is by no means remote from his pursuits. He cannot understand the structure of crystalline and other bodies, nor the changes that take place in certain crystals by the action of heat, without being familiar with the phenomena of double refraction and polarization; at all events they deserve, we should think, at least *as much* notice in this work as the “generally used and understood” principles of reflection and refraction, which occupy from page 86 to 99.

In pointing out what he considers as the chief points connected with the decomposition of light by the prism, we perceive that the author wholly omits to notice Fraunhofer's lines in the spectrum. And in shewing the chemical agency of light, we observe that the author is equally negligent, in never once alluding to the beautiful experiments of Fresnel (*Jour. of Science*, Jan. 1829.) Rumford's photometer, we also observe, is mentioned with some commendation: this ought not to be, for it is an instrument liable to great fallacy, as Herschell has proved.

On the whole, the article *Light* by Dr. T., is, whether considered chemically or physically, a meagre one; and the author, we think, would have better consulted the interests of students, had he given them, on the subject of the chemical relations of light, an abstract from *Gmelin's* excellent *Handbuch*.

In stating the rationale of the production of oxygen gas from chlorate of potassa, the author omits to notice the fact that part of the chlorate is in the first instance converted into perchlorate—a discovery of Serullas, of which there is an account in the *Journal de Chimie Medicale*.

Under the head of chloric acid, we find no mention made of Wheeler's method of procuring that substance.

In noticing hydrosulphocyanic acid, Dr. T. says, that “with a *salt* of copper it yields a white precipitate—the sulphocyanuret.” This should be qualified: the result here mentioned only takes place when a *proto* salt of copper is used. With a *persalt*, indeed, the same result may be obtained, if a deoxygenizing agent be present.

We regret to find no notice taken by our author of Bousdort's opinions on the subject of salts, which attracted so much attention at the meeting of the British Association in 1832, and an account of which is given in the Report of that year.

But perhaps the most remarkable omission in a work like this, professing to be *au courant* in chemical science, is that there is no account given in it of RASPAIL'S views in the department of organic chemistry. This we consider a capital omission. One should have thought that no book of elements could appear, touching however slightly on the subject, without more or less embodying the striking and valuable results of Raspail's researches. Not even when treating of albumen does Dr. T. once allude to Raspail's account of soluble and insoluble albumen in white of egg; nor of the opinion given by the same distinguished analyst of the relations which subsist between fibrine and albumen.

Such are a few of the points which struck us in the course of our examination of Dr. Turner's new edition. The book, as a whole, we admire much, and we recommend it as the best that the student can purchase; but thinking, as we do, that some of the omissions we have pointed out are not unimportant, we cannot but suggest that it is in the author's power to render the *sixth* edition still more valuable than the present one.

MINUTE ANATOMY OF THE LIVER;

Being a Concise and Popular View of MR. KIERNAN'S Researches.

We have already laid before our readers Mr. Kiernan's elaborate and valuable paper, but we have received from so many correspondents applications for explanations of particular points, that we are quite satisfied some difficulty is found in fully understanding the author's views. We have endeavoured to give the chief points in a detached form, in such manner as we hope will render the importance of Mr. Kiernan's investigations more generally appreciated, still, however, referring to the paper itself, as contained at pages 324, &c. of the present volume, for more complete and satisfactory details. We may add, that

370.—xy.

the present abstract has been seen by Mr. Kiernan, who has permitted us to express his approval of its accuracy.

SURFACES OF THE LIVER.—The liver has three surfaces—viz. 1st, the *external*, commonly so called; 2dly, the canals or perforations which contain the larger branches of the portal vein, hepatic artery, and hepatic duct, and called the *portal surface*; 3dly, the canals which contain the hepatic veins—the *hepatic-venous surface*.

SUBSTANCE OF THE LIVER.—This is made up of lobules, vessels, nerve, and cellular tissue prolonged from the capsule of Glisson.

LOBULES OF THE LIVER.—These are small bodies, based on certain branches of the hepatic vein, and bounded by a fine cellular expansion and plexus of vessels. The subdivisions of the hepatic vein are likened to the branches of a tree, and the lobules to leaves without foot stalks resting upon them, as in Fig. 1, which represents a magnified longitudinal section of a small

FIG. 1.

hepatic vein (*a a*) with lobules also divided longitudinally, and having a foliated appearance (*b b*).

The lobules are packed close together, but being of various shapes, and gene-

rally more or less rounded, they leave interstices between them, which are called the interlobular spaces (Fig. 3, *b*), while the part where the flat surfaces

FIG. 3.

appear to touch, are called the interlobular fissures (Fig. 3, *c*.) The lobules constitute the secreting portion of the viscus; each has its own system of vessels, and may be regarded as an independent gland.

VESSELS OF THE LIVER.—These are the hepatic vein, the hepatic artery, and vena portæ; to which may be added the hepatic duct.

Hepatic Vein.—The larger branches of this within the liver are called *hepatic-venous trunks*; the smaller branches on which the bases of the lobules rest are called *sublobular veins*; each lobule, where it rests on the sublobular vein, is perforated by a minute ramule; and this little vessel, which occupies the centre of the lobule, is called the *intra-lobular vein* (See Fig. 1, *e c*.) When the lobule is cut across, this vein is seen to ramify from the centre towards the circumference (See Fig. 2, *b, c*.) The

FIG. 2.

intra-lobular vein of one lobule has no communication with that of another, but returns its blood exclusively into the sublobular vein.

Hepatic Artery.—This artery, which follows the ramifications of the portal vein and hepatic duct, is distributed ex-

clusively on the vessels and other textures of the liver, for their nourishment. Its blood is then collected by minute veins, and carried into ramifications of the portal veins, where, being now venous blood, its farther course becomes the same as that of the vena portæ.

Portal Vein.—The ultimate destination of this is the spaces and fissures between the lobules, whence it is distributed to each particular lobule ramifying from the circumference towards the centre. The branches of the vena portæ running between the lobules are called the *interlobular veins* (Fig. 7, *b b b*.) The minuter ramifications within the lobule are called *lobular venous plexuses* (Fig. 7, *c c c*), and these last inosculate towards the centre with the *intra-lobular*

FIG. 7.

ramules of the hepatic vein (Fig. 7, *d d*.) The *interlobular veins* of one lobule communicate freely with those of the adjoining lobules (Fig. 7, *a a*: three lobules are here represented.) The larger branches of the portal vein are not in contact with the interlobular spaces on the surface of the portal canals, but are surrounded by a capsular investment, in common with the hepatic artery and duct. In such situations the three vessels just named send forth branches, which form plexuses in the sheath surrounding them; and these are called the *vaginal branches* and plexuses. They in turn give origin to *interlobular branches*. The smaller portal branches, called *sublobular veins*, are in contact with the interlobular spaces, except where the duct and artery (which always accompany them), interpose.

From that part of the circumference of each vein which is in direct contact with the interlobular spaces, interlobular veins

FIG. 4.

are given off *directly*, but at the other part vaginal branches first arise.—See Fig. 4, which represents a transverse section of such a portal canal, containing the vein (*a*), the duct (*d*), and the artery (*c*). On one side the interlobular branches are seen arising from the vein directly (*b*), while on the other side vaginal branches are seen to arise (*c*), and afterwards to subdivide.

Hepatic Duct.—The lobular plexuses of the portal vein (see Fig. 7) are accompanied by ducts, to carry away the bile as it is secreted. These are seen with a microscope as minute yellow points when a lobule is cut across, and constitute the acini of Malpighi.

FIG. 6.

—Fig. 6, *bb*, interlobular ducts; *d*, lobular biliary plexuses; *e*, intralobular or hepatic vein.

CAPSULE OF GLISSON.—This is a celulo-vascular membrane, in which the vaginal, interlobular, and lobular branches of the portal vein, hepatic duct, and hepatic artery, divide and sub-

divide: it lines the portal canals, enters the interlobular fissures, and forms the capsules of the lobules; nay, it enters the lobules with the blood-vessels: and these several parts of the capsule are called *vaginal*, *interlobular*, and *lobular* portions respectively.

The portal canals, then, are occupied by the portal vein, hepatic artery, biliary duct, absorbents, nerves, and the capsule of Glisson. A general idea of the arrangement may be gathered from the adjoining cut, which represents a longi-

FIG. 5.

tudinal section of a small portal vein:—*b*, the vein, which occupies by much the largest space; *g*, the duct; *h*, the artery—all of which are seen giving off vaginal branches; the fine tissue of the capsule investing the whole.

Sometimes one set of the vessels above described is in a state of congestion; sometimes another. When the *intra-lobular* veins are congested, the centre of each lobule appears of a more or less dark red, while the circumference is of a yellow colour: when the *interlobular* veins are congested, the circumference is dark and the centre lighter. The former is called *hepatic venous* congestion, the latter *portal venous* congestion. Both may exist together, and then the liver shows an uniformly dark colour. In *hepatic venous* congestion, which is by much the most common, the dark portions are detached; but in *portal*

congestion they may be continuous. Considerable modifications take place in the aspect of the mottled appearance, according as one or other of these forms of congestion preponderates, and according as it is general or partial; but no such thing exists as the medullary, cortical, red, yellow, or other analogous substances, described by previous anatomists (by all of them, indeed, except Professor Müller, of Berlin), and on the supposed existence of which Andral has based his morbid anatomy of the liver.

MEDICAL GAZETTE.

Saturday, January 3, 1835.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

FACTS AND INFERENCES FROM THE POPULATION RETURNS.

IN the number of the *Annales d'Hygiène* recently published, there is an article which we have perused with much pleasure: we allude to an analytical essay by M. Villermé*, on the population of this country, as reported in the parliamentary returns of the late census. We have noticed those returns ourselves some time back, and on various occasions have had to refer to them as documents of much importance in enabling us to draw certain inferences relative to matters connected with medical statistics. But this did not render us the less anxious to have the opinions of so very distinguished a statistical writer as M. Villermé, on the voluminous materials presented to him in our population papers. It is only they who have looked through the documents in question who can appreciate the intrepidity of a foreigner wading through three ample folio volumes of English parliamentary manufacture; and only they

who are familiar with statistical research who can properly estimate the critical sagacity and expertness with which M. Villermé contrives to separate the wheat from the chaff, and to serve up to his countrymen all the best things that are to be selected from the erude mass which he had to deal with. We shall point out a few of the facts and deductions which the author puts most prominently forward, following as nearly as possible the arrangement of the subject which he has himself adopted.

The general results of the census are first stated, comprising the number of families and inhabited houses in Great Britain, the several portions of the population engaged in agricultural, manufacturing, and professional pursuits, and the relative numerical force of the sexes (38 females to 37 males); but M. Villermé regrets that the distribution of the population according to the respective *ages*, has not been given in the late returns.

The author then proceeds to notice the facts connected with the *movement* of the population, gathering from Mr. Rickman's preface the chief points relative to our registers of marriages, births, and deaths. With regard to the first, he says that probably the *marriage* registers are more regularly kept than any other in the kingdom; for, with the exception of Quakers and Jews, who follow their own peculiar rites, and certain other parties who enter into the matrimonial state in the neighbourhood of, or beyond the Scottish border, all the rest seem to be duly enrolled. Mr. Rickman thinks there are not more than about 320 marriages contracted annually throughout the country, not entered in the church books. The proportion of marriages for the last decennial period was about 1 in every 128 of the population. In Middlesex it was highest, 1 in 103; in Hertfordshire lowest, 1 in 175.

* Sur la Population de la Grande-Bretagne, considérée principalement et comparativement dans les districts agricoles, dans les districts manufacturiers, et dans les grandes villes. Par L. R. Villermé.

But it is in registering the births, or rather the baptisms, which take place yearly, that our archives are most defective. Mr. Rickman computes the deficiency to be not less than 17,124 annually for England and Wales—a computation founded on very uncertain data, and probably not much to be depended on. The causes of this great lacuna in the registers are well-known; we need not repeat them after M. Villermé; but the fact that, of our unregistered infants, a larger proportion are males than females (in the ratio of about 24 to 23), is too remarkable not to obtain at least a passing notice.

For the first time, a return was made, in the last census, of the number of *illegitimate births* occurring in Great Britain. There were 20,939 of them in the year 1830, in the proportion of about 41 males to 40 females; and as compared with *legitimate births*, they are reckoned at 1 in 18 for the whole of England and Wales. A curious circumstance, with regard to this subject, must not be overlooked—namely, that the ratio of illegitimate births is at its minimum in Middlesex, being 1 in 38, while in Wales it is at its maximum—1 in 12. “This fact,” says M. Villermé, “is the more singular, inasmuch as in other parts of Europe it is in the large and densely peopled manufacturing and commercial towns that the greatest number of bastard births are found. Something probably may be owing to the deficiency of Foundling Hospitals in Great Britain—establishments which rather tend to encourage bastardy: but it should be observed, with reference to the Middlesex return, that it includes London, which, owing to the general opulence and density of its population, affords peculiar facility for concealing the births of children. It is certain that the lists of bastard births are very negligently kept in the metropolis; a circum-

stance not surprising, when such serious irregularity prevails in the registration of the legitimate offspring also.”

Regarding the *mortality* returns, it is computed by Mr. Rickman that the omissions in the burial registers amount annually, on an average of ten years, to 9387. M. Villermé enters into a close scrutiny of the statements put forth on this head by the *rédacteurs* of our national returns; but as there is nothing new in the arguments on either side, and sufficient perhaps has been already said on the subject in this journal, on former occasions, we may proceed to notice some of the author's remarks on the mortality of Great Britain, with regard to sex and age.

The table drawn up with this view, in the present returns, is decidedly the most comprehensive ever formed. It is founded on 3,938,496 actual deaths (1,996,195 of males, 1,942,301 of females) registered during eighteen successive years, from 1813 to 1830; and our author renders the results doubly interesting by comparing them with those supplied by M. Quetelet, in a valuable document lately presented to the Parisian Academy of Sciences, but as yet, we believe, unpublished. The following is the abstract given by M. Villermé, in which we see at a glance the number of deaths, in the 1000, at the ages mentioned in the first column.

Age.	Male.	Female.	Both Sexes	In Belgium
1	219	176	195	225
2	289	241	265	295
5	369	321	345	376
10	412	362	388	417
15	439	389	414	440
20	470	426	448	465
30	543	509	526	532
40	645	582	591	591
50	670	649	660	652
60	741	717	730	728
70	833	810	821	830
80	931	918	926	941
90	992	988	990	993
100	999.7	999.4	999.5	1000

One curious fact immediately suggests itself on inspecting this table—namely, the superior *vivacity* of females, as compared with males. At every epoch of life it would seem that of an equal number of either sex, born at the same time, there are fewer deaths of females to be reckoned than of males.

And comparing the law of mortality, as expressed in this table, with that calculated by M. Duvillard for France, the following are the inferences deduced by the author:—

“At the end of the first year, the mortality in England is scarcely a fifth; in France it is nearly a fourth. At five years, a third is dead in England, two-fifths in France. At twenty, the respective proportions are 9-20ths and $\frac{1}{2}$. At sixty, nearly three-fourths have died in England, four-fifths very nearly in France. And, lastly, at the age of 90, there should be ten survivors out of the 1000 in England, while but four in France.”

M. Villermé further observes, with reference to the copious English tables which he had before him, that it appears from them, that as the age of the individual advances from birth, the chances of death in the course of the year diminish constantly up to 15, while after that age they go on increasing up to a late period of life. The same results are deducible from the Belgian tables, while those of France, according to Duvillard's calculation, give 11, or rather perhaps 4, as the epoch of the greatest tenacity of life.

The classification of mortality, according to the respective ages, helps us to yet another important inference—namely, that in this country the mean *probable life*, at the moment of birth, is 26 years (not 25, as Mr. Rickman states it.) In other words, an even wager might be laid, that a child just born, not taking the sex into account, would reach its 26th year; for at that age the number born at the same

time is exactly reduced to one-half. If the infant be a male, the probable life is less—only 23 years; if a female, it is more—28.

We shall stop here for the present, reserving for another opportunity the observations of M. Villermé on the respective mortality of our agricultural and manufacturing districts.

COLLEGE OF PHYSICIANS.

WE need scarcely say, that the statement put forth last week by one of our contemporaries, regarding certain proceedings in the College of Physicians, is fictitious. The fact is simply, that the government has it in contemplation to relieve Dissenters from their civil disabilities, more particularly as regards law and physic: with respect to the latter, it is proposed that the College of Physicians should confer the requisite degree without the parties having to leave England for the purpose of graduating. But the obtaining of this privilege would require to be accompanied by some considerable changes in the constitution of the College. A committee has been appointed, for the purpose of considering what these ought to be: no easy task, if we may judge either from the difficulties which present themselves to our own minds, or from the result of former deliberations in the College upon this subject. We shall probably recur to the subject; meantime we would venture to say to the Committee (and certainly in no factious or unfriendly spirit), “either do nothing, or leave nothing for others to do.”

THE LANCET'S FIRST LIE FOR 1835.

AN article in the LANCET of *this day* (January 3d, 1835), done we presume to order, as a puff of the London University Hospital, contains the following passage:—“At the *Middlesex, St. George's*, and other metropolitan institutions, the pupils have long been denied the opportunity of visiting patients unless in the presence of one of the medical officers.” We beg to state, for the benefit of those whom it may concern, that the above assertion is a gross FALSEHOOD. In this respect it is in keeping with most of the statements regarding the London hospitals which emanate from the same respectable quarter, and we only give it as the *first* offering of the year from our contemporary to the gullibility of his readers.

CHEMICAL EVIDENCE

IN A CASE OF ALLEGED POISONING AND
CHILD-MURDER.

LETTER FROM DR. TURNER.

To the Editor of the Medical Gazette.

SIR,

My attention has been directed to an article on a case of supposed child-murder, in the last number of the *Medical Gazette*, where my evidence is given in the form of a quotation, I presume, from some newspaper. The quotation represents me as saying something very like nonsense, which nonsense your commentator charitably supposes to be a correct representation of my meaning, and then honours with a criticism. I beg to state, as a correction of the absurdity imputed to me, that the quotation is correct neither as to my words nor my meaning. What I intended to express was, that no satisfactory evidence had been obtained of the presence of any poison; but that the fact of such not being discovered was not a conclusive proof that death had not been produced by poison. The remark was applied to opium and prussic acid; and my reasons for making it were of a chemical nature. The tests for the common mineral poisons are so precise and delicate, that such poisons rarely cause death without some trace of them being, in some form or other, discoverable in the stomach; and therefore their absence, when properly searched for, is so far a presumption that death was not caused by them. But the case is different with substances of difficult detection, or of a perishable nature, especially when, as in the present instance, a considerable interval has elapsed between the periods of death and the chemical examination. The quantity of opium capable of destroying an infant, supposing the opium to have remained unabsorbed in the stomach, might well elude detection when mixed with a coloured putrid mass, seeing that the separation of morphia from mixed fluids, when in minute quantity, is a point of much difficulty. Prussic acid was also referred to, because its volatility and ready decomposition rendered its detection so long after death hopeless, even though it had been administered in a large dose.

Your commentator seems to make it matter of complaint against me, that I did not make the examination myself, and that I gave written instead of oral testimony. In regard to the latter charge, I would have attended the coroner and given oral testimony at length, if the coroner had asked me to do so. As to the former, I did more than I had undertaken. When asked to make the examination, I replied that my occupations did not permit me to conduct the inquiry personally, and that the most I could undertake was to have the experiments made under my direction by a careful assistant. But on finding that no evidence could be obtained of the presence of mineral poisons, I made a careful examination for those of the vegetable kingdom, especially for opium.

Your commentator appears also to throw blame on Mr. Shaw, for not himself testing for poison. Mr. Shaw, however, did no more than what is habitually done by the leading men in the profession—namely, endeavour to transfer to some friend specially engaged in chemical pursuits any chemical investigation which devolves upon them; nor is it surprising that they should do so. Your commentator, if a practical chemist, will know that testing for poison is one of the most delicate operations in chemistry; and if he is not a chemist, then would he have acted on the same principle as Mr. Shaw, or, by trusting to himself, have run a great risk of conducting the inquiry in an unsatisfactory manner.—I am, sir,

Your obedient servant,

EDWARD TURNER.

University of London,
Dec. 22, 1834.

[Dr. Turner “presumes” that we quoted him “from some newspaper.” We said we did, in the article to which he alludes, and therefore there was no great occasion to “presume” about it. That the quotation was “very like nonsense,” we could not help: we took it verbatim from the *Times*, where to this hour, we believe, it remains uncorrected. The *Herald*, and other papers besides, repeated the passage either literally or substantially; so that writing at the time we did, several days after the report of the inquest was before the public, we could have no reason for sup-

posing it inaccurate. Dr. Turner says he did "more than he had undertaken." In our opinion, he had done better had he undertaken *nothing*, when he did not intend to do *all* that was wanted. To Mr. Shaw we attach no "blame," except for having bandied about, apparently on his own sole responsibility, the *pièce de conviction*, the stomach and its contents, which the coroner alone should have permitted the chemists of the London University to meddle with.—*Ed. GAZ.*]

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.
Surgeon to the Middlesex Hospital.

IX.—Of the Brain and Spinal Cord.

THE textures, of which the morbid alterations are now to be considered, are—1, the cerebral tissue, including both the medullary and cineritious substances of the encephalon and spinal marrow; 2, the pia mater; 3, the arachnoid; 4, the dura mater. In speaking of the pia mater separately from the brain and spinal marrow, the external layer only of that membrane is referred to. The innumerable productions from it, which, entering the cerebral substance, form sheaths to all the nervous fasciculi, cannot be considered apart from the cerebral substance itself; nor would it even be proper to treat as a separate subject the external layer of the pia mater, but that this portion of the membrane is at particular parts gathered into detached folds, or reduplicatures, which contain in them no cerebral substance, and that elsewhere the free surface of the pia mater constitutes the organ of a special secretion.

I.—Of the cerebral tissue.

a. The cerebral tissue from its softness is easily injured; it possesses considerable powers of reparation.

The brain and spinal marrow may be bruised, without fracture of the bony chamber in which they are lodged: concussion alone will produce this effect. The cerebral tissue, if examined after a recent bruise, appears blood-shot, with spots of extravasation, resulting from rupture of the small vessels. Under favourable circumstances, the bruised cerebral substance may recover itself, the blood effused being absorbed. A more severe concussion causes either rupture of the larger ves-

sels, with considerable extravasation of blood, or complete disorganization of the bruised part, which appears, when examined, like a mixture of blood and brain. The last cases are necessarily fatal: but it will be seen that when blood has been effused from the giving way of a vessel (in the cerebri and cerebellum, at least), without external violence, the part has a power of self-restoration.

A different instance of cerebral restoration occurs after hernia cerebri: when the extruded part has separated, and healthy action supervenes, the exposed surface becomes covered with granulations, resembling those which form on other tissues, and which coalesce with the granulations of the dura mater and integuments, to form a cicatrix.

b. When a considerable vessel gives way within or upon the cerebral substance, blood is freely poured out. It may escape upon the external surface, or into the ventricles, or into the cerebral substance. The two former cases are necessarily fatal; the third is not so. Blood effused into the substance of the brain is generally collected into an irregularly round mass, varying from the size of a pea to that of a hen's egg, or orange*. It is either of dark red, or almost black; coagulated, wholly or in part. The cerebral substance in contact with the cord is always more or less ragged, and portions of it are sometimes broken down and mixed with this fluid. The lacerated cerebral substance forming the walls of the excavation, which contains the blood, presents a number of dark points, or dots, of coagulated blood, many of which indicate the orifices of ruptured vessels.

The blood which has been effused gradually changes in colour: the red deepens till it amounts to black; the colour then successively passes to brown, dull green, orange, pale yellow, or yellowish white. When the latter changes of colour have taken place, and the fibrin, separated from the other constituents of the blood, has assumed a fibrous laminated appearance, blood-vessels are observed to form in it. The subsequent changes are of two kinds: the structure may either retain for a long time its primitive arrangement, that of fibrin, and afterwards become converted into a firm fibrous tissue, which, gradually diminishing in bulk, is at last reduced to a small circumscribed thin portion, which constitutes the cicatrix of the original lesion of the brain; or the organized fibrinous substance may be converted into a

* In this account of cerebral hæmorrhage, and afterwards in that of softening, I borrow freely from Dr. Casswell's important work on Pathological Anatomy.

loose cellular tissue, filled with a serous fluid, and is generally traversed by a considerable number of blood-vessels. As the quantity of the serous fluid increases, that of the cellular tissue diminishes, as well as the number and size of the blood-vessels with which it was before provided. In this manner a cavity of considerable extent is formed, filled with serum of a citron colour, and bounded by the remaining cellular tissue in contact with the substance of the brain. It is this portion of the cellular tissue, which appears to be transformed into the yellowish serous membrane, which afterwards lines the entire surface of the cavity, and which converts it into the apoplectic serous cyst. The obliteration of this cyst is the next circumstance which takes place in the progress of cure. This is accomplished by the gradual removal of the serum contained in the cyst, and the consequent approximation of its walls, which become united and form a cicatrix. Lastly, the cicatrix itself, whether formed in this manner or in the manner previously described, disappears; such, at least, seems to have happened in cases of paralysis which have undergone a complete cure.

c. In this tissue every variation of condition becomes of moment. The quantity of blood contained in its vessels deserves and admits of being accurately noted. In hyperæmia, it may be observed whether the increased quantity be in the capillaries or in the veins, or both; in anæmia, whether their emptiness result from compression of the vessels, or from other causes.

d. *Hypertrophy*.—The cerebral substance is susceptible of hypertrophy. The following instance, which I quote from Andral, describes the appearance of the brain when in this state. The age of the patient at his death was 29. On opening the head, the membranes did not present any unusual appearance; but the character of the upper surface of the brain was strikingly peculiar: the intervals between the convolutions had disappeared; there was no fluid between the arachnoid and pia mater, nor in the ventricles. Upon a section, the brain appeared bloodless; it was singularly firm, having the consistence and elasticity of white of egg; the cineritious substance of the convolutions, and of the striated bodies and thalami, had lost its natural colour, so as to be distinguishable with difficulty from the medullary substance. The convolutions at the base of the brain, the cerebellum, and the annular protuberance, presented a healthy appearance.

e. *Atrophy*.—The cerebral substance is liable to atrophy. The instances which Andral gives, as exemplifying this state, appear to me, however, cases either of im-

perfect development, or of recovery from hæmorrhages or other diseases. Nevertheless, there properly exist two forms of atrophy of the brain and spinal marrow, both produced by pressure. In the one case the cerebral substance is diminished in volume at the part compressed, with no change of structure; in the other the diminution is attended with hardening. The first I have seen both in the brain and spinal marrow. Of both the first and second, Andral gives instances under other heads.

f. *Inflammation of the cerebral substance*.—The general effect of acute inflammation is to diminish the consistence of parts. This effect is primarily produced by effusion of serum from the capillaries; afterwards the deficient nutrition of the inflamed part contributes to deprive it of its natural cohesion.

The effects of inflammation upon this tissue are the following:—The degree of *softening* of the cerebral substance from this cause may vary from a slight diminution of the natural consistence of the part affected, to that of cream or milk. The first stage of the softening is often so slight as to be hardly perceptible to the touch, so that even when considerable, if not accompanied by some peculiarity of colour, it may be easily overlooked. A gentle stream of water allowed to fall upon suspected surfaces of the cerebral substance, is the best means of ascertaining whether a portion of it has undergone a diminution of its natural consistence. As yet the cerebral substance is not broken down; it has only lost a certain degree of its cohesion: it is still continuous with the firm substance by which it is surrounded. In the second stage, the diminution of consistence is so great as to be recognized at first sight. Upon a section being made through it, the softened substance sinks by its own weight beneath the least of the rest of the cut surface; while parts that are naturally prominent, such as the thalami, corpora striata, and convolutions, being involved in the softening, are sensibly flattened. In the third stage, a solution of continuity has been effected by the separation and partial removal of the softened cerebral substance. The dissolved texture, now of the consistence of cream or milk, is contained in an excavation of variable extent, situated in the substance of the brain, or confined between the membranes and convolutions of this organ. The colour of the softened part is liable to be modified by an admixture either of blood or pus; and its consistence, at the same stage of the disease, by the greater or less proportion of membrane which remains undissolved in the softened cerebral substance.

The nervous matter adjoining the softened part presents traces of increased vascularity, often in a very high degree; it is occasionally found hardened at different points for a small extent, as another result of inflammatory action.

Abscess.—Abscess in the cerebral substance is another consequence of inflammation. In general the matter is contained in a membranous cyst; and the process of its formation differs from softening in this alone, that a complete instead of a partial absorption of the inflamed substance is effected, from the cavity of the abscess. Sometimes depôts of matter are found in the cerebral substance, not contained in a cyst, but directly in contact with the nervous matter.

Of softening less evidently dependant on inflammation.—This is of two kinds: one of them, which, indeed, is attributed by Dr. Carswell to inflammation, is thus described by him:—Pale softening in the white and brown substance of the brain is a frequent occurrence in hydrocephalus; and it is also this variety of softening which is sometimes met with in those fevers in which the brain is primarily or secondarily affected. In such cases the substance of the brain, in general, is pale; its vascular system contains but a small quantity of blood. The other results from disease of the arteries of the brain, with obstruction or obliteration of their cavities. It is distinguished, however, from inflammatory softening by the presence of these diseased vessels alone; and as senile gangrene from the same cause is preceded by inflammation, it is far from clear that this softening has not likewise its precursory inflammation.

g. Of hardening.—It has been already mentioned, that in the neighbourhood of a softening of the brain, the inflamed texture is sometimes, at one or more points, prematurely hard. In an instance of *hernia cerebri* which was under my care, the cineritious matter of a portion of brain, which protruded and was removed, had acquired an almost cartilaginous hardness; it was of a bluish-grey colour. The medullary matter, though hardened, was less so than the cineritious. Atrophy, or diminution of a part of the encephalon from pressure, is liable to be attended with hardening.

h. Strumous and scirrhus tubercles, melanoma, medullary sarcoma, form in the cerebral substance.

II. Of the pia mater.—The external surface of the pia mater naturally secretes a certain quantity of transparent liquid, the use of which is to keep up an equal pressure upon all the irregular surfaces of the brain and spinal marrow. Its abnormal

increase is very frequent; sometimes it may arise from obstruction of the cerebral veins—sometimes, as it is possible to imagine, from feebleness of the cerebral circulation,—but in general it is the consequence of a low degree of inflammation.

In a higher stage of inflammation, the pia mater secretes semi-opaque or lactescent serum, containing albuminous flakes—purulent serum—pus. These deposits are more frequent upon the surface of the brain than in the ventricles.

Cysts containing serum are found in the pia mater, both of the choroid plexuses, and on the surface of the brain.

Flakes of semitransparent elastic substance, resembling cartilage, varying in size and number, are found between the pia mater and arachnoid. It is conjectured that they are formed in the cellular tissue, which unites the two membranes.

Deposits of tuberculous matter, and of white matter of the same consistence, are met with, singly, or in groups—as milary tubercles of the pia mater. The glandulæ Pacchioni are probably substances of this description.

III. Of the arachnoid membrane.—Alterations of the arachnoid are less frequent than those of the pia mater. The arachnoid, however, is liable to be inflamed—to become slightly thickened and opaque—to secrete a viscid serosity—to secrete pus,—to secrete lymph, which forms layers of false membrane, that for a time remain nearly unattached, but subsequently become organized, and cohere strongly with the arachnoid. The opposed surfaces of the two layers of the arachnoid are liable to contract partial adhesions of the consistence of pleuritic bands.

IV. Of the dura mater.—The dura mater has two important relations—one to the cranial bones, of which it constitutes the principal periosteum: through this relation, it becomes the seat of all those alterations of structure which originate on the superficies of the bones. These changes have been already adverted to. To follow its second relation,—upon its inner surface the dura mater adheres to the reflected arachnoid, and rests against the soft substance of the brain, between the divisions of which it sends falces and tentoria. The habitudes under disease of its cerebral surface and productions are now to be considered.

The dura mater is susceptible of inflammation. Blood is sometimes found effused between the dura mater and the arachnoid lining it, which that effusion has detached. Small collections of pus have likewise been found in the same situation.

Fibrous tumors, of the size of a nut, and larger, and of a tissue resembling that of the dura mater, sometimes grow from its

inner surface; they commonly adhere to it by a narrow pedicle.

Tumors of a similar appearance are occasionally met with, which contain deposits of phosphate of lime, constituting osteo-fibrous tumors.

Phosphate of lime is frequently deposited, in flattened masses, between the layers of the processes of the dura mater, especially in the falx cerebri.

In the vertebral canal, the external surface of the dura mater has not a periosteal character. In this situation it is liable to give origin to deposits of the consistence of tuberculous matter, either white or yellow, with which melanoma may be mixed.

Having thus gone over the various morbid changes which have been observed in the tissues contained in the cranial cavity and vertebral canal, I am disposed, before enumerating the diseases which they produce, to consider a question, the solution of which must be sought in the natural anatomy of these parts.

When palsy is produced by disease of one hemisphere of the cerebrum or cerebellum, it commonly affects the *opposite side* of the frame. Through what channel does this take place?

The analogy of the nerves leads us to conclude, that the transit of impressions in the brain follows the course of the fasciculi of the cerebral substance. This analogy is strengthened by the single case of transit of function in the encephalon, from one side to the other, the course of which has been ascertained: the case to which I allude is this. A connexion exists between one optic thalamus and the opposite eye: that connexion is certainly maintained by nervous fasciculi, which pass from one thalamus to the opposite eye-ball. Following this analogy, we expect to find, in some part of the structure of the brain, a crossing of fasciculi from one side to the other—some interchange—some decussation—by means of which, in the case before us, the transit of the palsy-stroke to the *opposite side* may be explained.

Several circumstances concur in pointing out the decussation of the anterior pyramids (at the part where the medulla oblongata joins the spinal marrow), as the probable channel through which the paralyzing impression is made. In the first place, this decussation, or transfer of fasciculi from one side to the other, is the *only one* that has been detected in the central masses of the encephalon. In the second place, there is important evidence to prove that the point, at which the transit of the palsy-stroke takes place, must be somewhere about this part. The evidence to which I refer, is contained in a very interesting paper, by Dr. Yelloly, in the first

volume of the Medico-Chirurgical Transactions. It seems to me satisfactorily to determine that there are certain limits between which the place of transit must lie. It consists of an experiment made by Sir Astley Cooper, and of a case that was witnessed by Dr. Yelloly himself.

The experiment was this. The spinal marrow of a dog was exposed between the atlas and the occiput, and one half (*the right half*) divided. The animal became palsied on the *right side*;—showing, as it appears to me, that the transposition of fasciculi sought for must be above the part cut through in this experiment.

The case given by Dr. Yelloly is the following. A patient died, having been afflicted with palsy of the right side. On examining the head, no diseased appearance was found on the right side; but on the left, a tumor was discovered in the annular protuberance: it was about the size of a hazel nut, and was lying on, or sunk into, the protuberance, at its inferior part on the left side. It extended to the corpus pyramidale of the same side. This case appears to me almost to prove that the place of the transit of the palsy-stroke is *below the annular protuberance*.

The next point in the inquiry is, whether, admitting that the anterior pyramids are in the situation where the transit of the paralyzing influence is made, the connexions of these fasciculi is such as reasonably to account for the phenomena of partial palsy, which have been observed.

The principal of these phenomena, or those in accounting for which any difficulty exists, are referable to three heads.

1. Hemiplegia of part or the whole of one side of the body, from disease or injury of the opposite hemisphere of the cerebrum.

2. Hemiplegia of part or the whole of one side of the body, and of the *same side of the face*, from disease or injury of the opposite hemisphere of the cerebrum.

3. Hemiplegia of part or the whole of one side of the body, from affection of the opposite hemisphere of the cerebellum.

It appears, at first sight, that the decussation of the anterior pyramids, which is the only decussation to be found in the medulla oblongata, [that recently described by Sir Charles Bell, in the Philosophical Transactions, certainly not existing] will serve well enough to explain the first of these cases specified, inasmuch as it takes place above the origin of all the spinal nerves. Yet it is not, in truth, so sure a conclusion as it at first appears, that this decussation will account for *all* the phenomena. In palsy of one side of the body, *sensation is often impaired as well as motion*. Is there, in the terminal distribution of the fibres of the anterior pyramid, that which will equally

account for *both* these phenomena? I answer that there is. But, to establish this point, it may be desirable that I should minutely describe (and the adjoined figures will assist the description) what the points of structure are, to which I refer.

The decussation is effected by filaments of the two anterior pyramids passing over in four fasciculi (the uppermost the largest) that descend obliquely, crossing their opposites, to plunge into the centre of the opposite half of the spinal marrow. In the first figure adjoined, I have delineated the course of the uppermost of the fasciculi of the anterior pyramid of one side.

The anatomical reader will see that the figure represents a portion of the tuber annulare, with the medulla oblongata, and a part of the spinal marrow, seen obliquely in half profile from the front. The letter *a* is attached to the anterior and lateral portion of the spinal marrow and medulla oblongata, on the side turned to the observer, and shews the point at which the right half of the cord has been (in the preparation) partially transversely divided. The letter *d* marks the lower extremity of a line, at which the anterior and lateral fasciculi (divided at *a*) of the spinal cord and medulla oblongata were separated from the lateral and posterior fasciculi.

The preparation displays the manner in which the uppermost decussating fasciculus of one anterior pyramid (*b*) throws its fibres obliquely downwards into the centre of the opposite half of the spinal marrow. A point of additional interest shewn in this preparation, and presently to be referred to, is the mode in which the filaments, which are ascending from the right side of the spinal marrow to the same side of the medulla oblongata, are implicated with the descending fibres derived from the opposite pyramid (*b*).

But for the present, let us follow the former point alone, namely, the connexion of the decussating fibres with all parts of the opposite segment of the spinal cord. To make this matter clearer, I have given another, but very imperfect,

figure, which represents, on a scale about three times magnified, the uppermost decussating fasciculus, *d*, of one of the anterior pyramids, followed into the upper part of the opposite half of the spinal marrow; the latter has been separated from the medulla oblongata by a transverse section, the surface of which is presented to view. The letter *e*, in the diagram, points to the anterior surface of the segment of the cord. The figure is intended to represent the mode in which the fasciculus, *d*, plunges into the centre of *both* of the cineritious capsules, which occupy, the one the anterior or motor region, the other the posterior or sentient region, of the spinal marrow,—besides extending into the lateral part.

It thus appears sufficiently established, that on the supposition that a paralyzing influence can be conveyed along the anterior pyramid, it may be thrown by the terminal fasciculi of the latter upon both elements of the spinal cord, and may affect through this channel sensation and motion equally.

2. But if it should be admitted that the structure which has been thus displayed explains well enough the phenomena of the first case, how will it apply to the second? How is to be explained, through it, the very common occurrence of disease of one hemisphere of the cerebrum producing *palsy, not only of the opposite side of*

the body, but likewise of the opposite side of the face? How can the decussation which has been described influence the portio dura of the opposite side, which rises from the medulla oblongata an inch above it? and how does it miss striking with palsy the portio dura of its own side?

The latter question is easily answered. The anterior pyramid is in no ways implicated, in its descent, with the portio dura (or with the fifth nerve) of its own side; it therefore could not be expected to affect either of those nerves. But how can it influence the same nerves of the opposite side? I am afraid the only conjecture which I have to offer will be hardly thought satisfactory, but it is this: when the terminal fibres of the anterior pyramid expand into the centre of the opposite half of the spinal cord, they are, as I have represented in figure 1, closely implicated with fasciculi of the cord, which are ascending directly to the spot at which the portio dura of that side rises. Is it impossible that these fasciculi, the production of which downwards we may readily admit to carry the palsy stroke in that direction, should carry *upwards likewise*, to the seventh and fifth, the same influence?

3. But a question of greater apparent difficulty still remains. How can disease of one hemisphere of the cerebellum influence the opposite side of the spinal marrow through the anterior pyramids? This question again, however, admits of an hypothetical answer. If the preceding explanation be admitted, it is easy to find a parallel explanation of this instance. The transverse fibres of the annular protuberance are formed of fasciculi, which emerge from the hemispheres of the cerebellum. When one side of the cerebellum is diseased, it is natural to suppose that some effect is produced by the disease upon the fibres of the same side of the annular protuberance. But across and between those fibres, the fasciculi of the anterior pyramid descend, with a wonderful closeness of interlacing. Is it impossible that, in this contact and close pressure (for no continuity is traceable), the paralyzing force proceeding from the diseased hemisphere of the cerebellum along the transverse fibres of the annular protuberance, should impart its influence to the fibres of the pyramid that are intermingled with the former?

It may be asked by some, why disease of the cerebellum should not communicate the palsy shock to the spinal cord, through the fasciculi of the corpora restiformia? The obvious and only answer consists in referring to the fact, that it does not. The corpora restiformia descend from the hemispheres of the cerebellum, each along the lateral and posterior part of the cord; if palsy were transmitted by them, disease of one hemisphere of the cerebellum would

produce suppression of sensation on the same side. Instead of this, it produces muscular palsy, with or without anæsthesia of the opposite.

One consideration appears to me to give a shadow of value to the hypothetical explanations which I have advanced. The palsy of the opposite side of the body is often strongly developed and decided, without palsy of the face attending it. But if the route of the palsy stroke for the facial nerves lay *downward*, how should these nerves ever escape? On the other hand, supposing the palsy stroke to be reflected upwards, (agreeably with my hypothesis) would not its natural course be to attack first the portio dura, which lies directly in its way; perhaps the eighth, ninth, and fifth, or either of them capriciously, as their origins are not far apart? it could hardly extend its influence as high as to the third;—but this is exactly what happens in different cases of hemiplegia.

Finally, an expression has occurred repeatedly in these remarks which requires a full explanation. The decussating fasciculi of the anterior pyramids have been described as the channel of the *palsy stroke* in hemiplegia. Let me explain what I mean by this term *palsy stroke*, or *paralyzing influence or force*.

I do not think that the idea which commonly prevails as to the mode of the production of palsy, from disease of the encephalon, is correct. The idea commonly entertained is, that palsy results from the *interruption*, or suppression, of the communication of some part of the brain with that part of the spinal cord or medulla oblongata in which the palsied nerves arise. I believe that such an *interruption* is not the cause. I rest this belief upon the history of acephalous infants, which have lived some period after birth, and on the results of equivalent mutilation made on animals. If the cerebrum, optic tubercles, and cerebellum, are cut away in a rabbit or guinea-pig, with a sharp instrument, and with the least possible violence to the adjacent parts, the mutilated animal is not palsied. It sits collected on its limbs, squeals when a hair of its whisker is pulled, moves its limbs co-ordinately, when one of them is injured; exhibiting sensibility, and the capacity of voluntary motion, as the acephalous infant does. Upon this evidence I believe that the *interruption of continuity* between the brain and medulla oblongata is not adequate to produce palsy, and is not the cause of hemiplegia. [The case is a widely different one from the division of a nerve, to which it is commonly assimilated.]

But I believe that the fasciculi which pass from the brain to the spinal cord are capable of transmitting a *palsying shock*. In a guinea-pig the cerebrum and cerebellum may be

cut away without materially disturbing the heart's action. But if, instead of separating them, (that instructive experiment, the force of which, in another relation, Dr. Wilson Philip has well pointed out, be made,)—if a part of the undetached cerebral masses be *crushed*, the heart's action is suddenly paralyzed; and in addition (which may be considered by some as more directly conclusive) through the animal's entire frame sensation and voluntary motion are at the same time instantaneously suspended. By the term palsy stroke, or paralyzing influence, I therefore mean to express, not a deficiency of excitement, not the effect of an interruption of continuity, but the transmission of an impression suddenly or slowly conveyed from the brain to the medulla oblongata and spinal marrow, with the effect of palsyng more or less completely the voluntary nerves, or the sentient nerves, or both, which arise from those parts.

There are some important features in hemiplegia which agree curiously with the view which I have thus advanced. The arm is more frequently palsied than the whole side;—in palsy of the entire side the disease first attacks the arm, then the leg;—in recovery from hemiplegia, the leg recovers before the arm. It is evident that these phenomena are highly consistent with the hypothesis of a palsy stroke. The spinal cord and medulla oblongata, with the nerves proceeding from them, are sufficient, it is proved, for sensation and volition. Now the supposed palsyng influence, propagated thither from the brain, would strike directly and first upon the upper part of the spinal marrow, and that should be first and principally paralyzed: if the palsyng force were feeble, it might paralyze the upper part alone, or that which supplies the arm with nerves, leaving the lower part in the possession of its functions: if the force were considerable, it should reach (but perhaps after an interval) the lower extremity. In recovery, again, the part which would have been most feebly struck (the leg, by my hypothesis) would naturally be the first to mend. It is equally evident that these phenomena are irreconcilable with the idea of a deficiency of excitement from interruption of continuity being the cause of hemiplegia.

I would even venture to adduce the experiment made by Magendie of dividing one of the anterior pyramids in a living animal, without any sensible result, as a confirmation of the preceding views. To some, however, that experiment may appear to militate against them, and to shew that the anterior pyramids have no control over the voluntary or sentient nerves. In my mind the experiment has not the latter force. Upon the grounds already gone into I can suppose that a

part can transmit a paralyzing influence in disease, the division of which part in a healthy animal would produce no distinct result. To make Magendie's experiment complete, and fit for use in this argument, it should be coupled with such an injury of the corresponding cerebral hemisphere as is calculated to produce hemiplegia. I think such an experiment might be made. But I have no intention of making it; for although I trust I am not less disposed than formerly to interrogate nature, I certainly begin to shrink from putting her to the question.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

IN our last number, we gave a catalogue raisonné of the papers lately read at the Royal Medico-Chirurgical Society, but were obliged to postpone our fuller report, which is now given in the usual form.

Dr. Wilson Philip on the Sympathies of the more perfect Animals.

The author commenced by observing, that although many of the most celebrated writers in our profession have treated of the nature and laws of sympathy, the meaning of the term has remained vague, and its phenomena ill defined; a probable inference from which is, that all the facts relating to it have not been before us; that something has been overlooked which is essential to the clear understanding of the principles on which it depends.

It was necessary, in the first place, to define what is meant by the term Sympathy. According to Dr. Philip it includes those phenomena "in which distant parts influence each other, between which the mere structure of our bodies, compared with the phenomena, do not point out the exact channels of communication."

After stating the facts, from which it has been generally admitted that the phenomena of sympathy are produced through the medium of the nervous system, and those which have satisfied the best informed writers of our times, that they depend on changes which take place in the central parts of that system, and not, as was once supposed, in the nerves themselves, which appear, from a variety of facts, to be mere channels of communication, incapable of originating the changes observed in those phenomena, Dr. P. comes to the inferences to which he has been led, relating to the subject of his paper, by the physiological investigations in which he has been so long engaged.

"Is there a common centre of sympathy, or are there more than one such centre?" The author refers to an extensive set of experiments, undertaken for the purpose of determining the line of distinction between the sensorial and nervous functions, properly so called, and the relations these

functions bear to each other, and to the other functions of the living animal; from which it appears that as the muscular is independent of the nervous power, but in its various functions more or less subjected to it, the nervous, in like manner, is independent of the sensorial power, but in all its functions more or less under the influence of that power; and that in the more perfect animals there are two systems—the sensitive and the vital system—so distinct that all the functions of the latter remain after those of the former are finally lost.

It therefore follows, that if the functions of both are dependent on organs belonging to the brain and spinal marrow, as is evidently the case, it cannot be on the same organs; which is farther proved by the parts of the brain and spinal marrow, with which the organs of the sensitive and those of the vital system are associated, having different localities, and the functions of the one being often greatly impaired by disease, while those of the other remain wholly unaffected. Thus it is evident that, if both the vital and sensitive organs throughout the various parts of our frame sympathize, it cannot be through the same parts of the brain and spinal marrow. Their centres of sympathy, therefore, are different.

On the other hand, it appears from the facts stated in the paper before us, that the phenomena of sympathy themselves lead to the same conclusion, namely, that there is a centre of sympathy independent of the sensitive system, and therefore of our feelings—a fact on which depends one of the greatest difficulties which beset the practice of medicine, and which has led, and does still lead, to errors of the most fatal nature. While the sympathies of the sensitive system cannot fail to make themselves felt in the organs they influence, those of the vital system are often obscure, and generally too indistinct to enable us to regulate our plans of treatment by them, until a comparison of the symptoms with the appearances on dissection after death, has gradually unfolded the nature of such cases. For example, bilious headaches were at once referred to their source, but ages elapsed before the hydrocephalus internus was traced to the vital sympathies of the liver, and till thus traced it was almost uniformly fatal; because the cause which, at least in nineteen cases out of twenty, had produced, and was supporting it, was overlooked.

The obscurity of such cases is farther increased by the sensitive and vital sympathies not prevailing most in the same organs, so that disease often takes a fatal course with little or no affection of those organs, in which the sensitive, which are always the most prominent sympathies,

are the most powerful. Of all our organs, the sensitive sympathies are most powerful in the stomach; but the most powerful vital sympathies belong to the liver. It is rare for the sympathies of the stomach essentially to influence the vital functions of distant parts, except through the intervention of the liver. Hence it is that the sympathies of the former are generally more distressing than dangerous, while in those of the latter—an organ of little sensibility—the suffering often bears no proportion to the risk. Without betraying themselves by any symptoms of a formidable appearance, or greatly affecting those organs, the sympathies of which, from their sensibility, are the most prominent, they may be undermining all the powers of life.

It is here, the author observes, that the practice of medicine is at present most defective. Dissection after death is constantly pointing out cases, the progress of which might have been checked, had we been aware of their nature before the secondary, generally the more formidable, affection shewed itself; or even after its appearance, had we been aware of the cause which had produced and was supporting it.

Our limits do not permit us to follow the author in his illustrations of the principles we have been considering, nor in what he says of the general laws of sympathy, the operation of which may be traced in the affections of all parts of the system. As he regards the vital sympathies as the means by which diseases of continuance become complicated, he considers the little attention which these sympathies have obtained, as the principal cause of the obscurity which attends almost all such cases.

Nor can we follow him in what he says of the other causes, which tend to give to the liver the influence possessed by it in the animal economy, and for a fuller account of which he refers to what is said in his *Treatise on the influence of Minute Doses of Mercury*, in restoring the functions of health. The most powerful of these causes is the peculiar influence of the liver on the brain, through which it appears, from the experiments above referred to, that not only the heart, but the vessels also in every part of the body, and that to their minutest ramifications, may be directly influenced in every way of which they are capable. A ready channel is thus opened, through which the state of the liver may influence any part of the frame, however distant.

The author ascribes to the circumstance of the vital sympathies of the liver being so powerful and extensive, the fact that in sultry climates, where the sympathies are most active, all diseases of continuance,

whether acute or chronic, terminate in derangement of this organ; and that even in such climates as our own we meet with few formidable diseases in which its affections do not form a more or less prominent part; and in which it is not necessary that the treatment should be more or less modified by the state of this organ.

His conclusion from all that is said in the paper is, that our object in all, and particularly diseases of continuance, should be to watch the vital sympathies, which little obtrude themselves on our attention, but powerfully influence the progress of disease; and which, although modified by causes which he points out in individual constitutions, are in their great outlines the same in all.

Cases of Mental Derangement successfully treated by the Acetate of Morphia. By EDWARD J. SEYMOUR, M.D.

AFTER some remarks on blood-letting in mania, Dr. Seymour proceeded to observe, that it is seldom attended with good effect, and that of late years, the soothing system has very generally been adopted by medical men; which system, founded, as it is, on true principles of physiology, is more likely to lead to success than any other. To diminish the increased and morbidly acute conceptions—to soften the sensibility of the organ, and reduce the exaggeration of its natural functions—seems to be the great object; and so far from such a condition being the result of too great a flow of blood to the head, morbidly stimulating the organ, it often occurs in those who have rather less blood than usual for the maintenance of life in the brain, occasioned by excessive evacuations, watching, anxiety, and by intemperate living.

About three years ago, Dr. Seymour published some lectures on this subject, in which he described the great advantage which had been derived, at the large Lunatic Establishment on Bethnal Green, by the preparations of morphia, under the care of Messrs. Beverley and Phillips; and in the present paper he detailed several cases which had occurred to him in private, and which illustrated the same principle.

A lady, aged about 48, was attacked in the month of August, 1833, after exposure to violent distress. Her mind was filled with gloomy ideas, from the imaginary neglect of great and solemn duties.

Her bodily health was unusually robust, and she had scarcely ever suffered from bodily ailments. In the first instance the patient was bled, and took repeated doses of purgative medicine, but without any beneficial effect.

It was now resolved to try the morphia, and a grain of the acetate was ordered to be taken every night, and the bowels to be kept

open by small doses of castor-oil. I see was kept to the head, in a bladder, day and night, for several days. The morphia never failed to procure a good night, and thus gradually, without any other remedy, the mind cleared up; but the morphia continued to be administered every night for three months, although all trace of insanity had disappeared six weeks from the commencement of the employment of the remedies. No relapse whatever has occurred in this patient.

Two other analogous cases are detailed, and several of a more chronic nature referred to, as having occurred in the author's practice, in which the success of the treatment was equally conspicuous. The remedy appears, according to Dr. Seymour's experience, to have been more remarkably useful in melancholia, "when the mind is tortured by imaginary want, ruin, or crime," than where the patient is possessed by the conceit of superiority (as of superhuman wisdom, &c.), or when it is exclusively engrossed by one all-absorbing idea.

INQUEST AT BRISTOL.

Medico-Legal Disinterment.

AN exceedingly interesting case of poisoning has been investigated at Bristol during the last week. The body of the deceased was exhumed after fourteen months, and full proof of death by arsenic obtained from a medico-legal inspection of the stomach. A verdict of "Wilful murder" has been brought in against the accused. We shall give a full account of the medical evidence next week.

WEEKLY ACCOUNT OF BURIALS,

From BILLS OF MORTALITY, Dec. 30, 1834.

LECTURE XV.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

ADVENTITIOUS DEPOSITS.

I now call your attention to that class of diseases of the lungs which are consequent upon adventitious deposits in their structure.

Definition.—By adventitious deposits, we mean matters placed in the substance of an organ, foreign to its normal structure, depending upon an aberration of secretion or nutrition, and having for their consequences the atrophy or destruction of the organ, to a degree proportionate to their quantity and nature.

Inorganic and Organic.—There are two classes of adventitious deposits. The first we shall call inorganic, because no vessel has ever been seen to exist within them. They appear to grow by external accretion. The most important of these is *Tubercle*, the immediate cause of phthisis pulmonalis. The second are organic; so called because they are more or less vascular. They grow from within, and occasionally attain a considerable volume. The organic adventitious deposits have been considered by Craveilhier as parasitical growths, connected with the living animal by a system of vessels plunging into their mass, and increasing it by

the deposit of similar matter: these are of rare occurrence in the lungs: I shall dwell therefore but little upon them, but devote almost the whole of our attention to the important subject of tubercular disease.

TUBERCULAR DEPOSIT.

Tubercular matter has for its result the accumulation and succession of symptoms known under the appellation of *phthisis pulmonalis*; and observe, gentlemen, that I restrict that term to tubercular disease alone.

Tubercular matter may be defined to be an inorganic substance, varying in form; so that it may be isolated, or infiltrated in irregular masses in the substance of the lungs. It is usually at first gray, and semi-transparent, becoming afterwards yellow and opaque, being then called *crude*. It finally softens, and is expectorated, leaving an *excavation* in the lungs, which excavation may be lined with a false membrane. The cavity is then denominated a tubercular *fistula*. The parietes of the fistula may approach, unite, and form a *tubercular cicatrix*.

The following is a tabular view of the various forms which tubercular matter presents at its commencement:—

Isolated Tubercular Matter.

1. Miliary.
2. Granulations.
3. Encysted.

Infiltrated Tubercular Matter.

- Gray.
Gelatiniform.

In whatever form the tubercular matter appears at the period of its primitive deposit, it subsequently becomes yellow and opaque, or, as it is called, *crude*; after which, the mode of destruction of all the forms is the same, and the effect upon the

lungs identical—that is to say, in its softening, formation of excavation, fistula, and cicatrix.

I shall first describe the various forms of tubercular matter in the lungs to the period of *crudity*, and then the common effects upon the pulmonary structure.

Miliary Tubercles.—*Period 1st.*—The first form to be considered is the miliary tubercle: its size is generally small, something like that of a milletseed: it appears to be round, at least to the unassisted eye; but on examining it with a powerful glass, it is found to be somewhat angular: its colour is gray, and it is transparent; its firmness is nearly equal to that of cartilage; it adheres with considerable force to the pulmonary structure, so much so, that on tearing away a tubercle you detach also a portion of the pulmonary substance. The position of these tubercles is most commonly in the cellular texture, separating the cells from each other; but they may also exist in any other part of the tissue of the lungs, as in the cells themselves. As to quantity, there may be very few—four, five, or six—or there may be thousands, for they are sometimes perfectly incalculable; I have seen the whole lungs completely gorged with them.

Period 2.—In the second period, the tubercle becomes enlarged by accretion to its external surface: it cannot grow from within, since it is inorganic, at least no injection can be made to penetrate it: another proof is, that however large that may become, the original form is still preserved. When there are few, the isolated tubercle may acquire a very considerable size, even to that of an almond. The colour now changes, and a small yellow spot is seen towards the centre, and this tint gradually pervades the whole of the tubercle to its circumference. In this stage it is called the *crude yellow tubercle*. These tubercles, in consequence of their increased growth, approximate to each other. Fresh ones form also in the intermediate pulmonary tissue, so that a large yellow amorphous, or irregular mass, of cartilaginous density, is the result. If you examine closely into a section of this mass, you will find that the tubercles are not so impacted as to prevent their original rounded form being here and there observable.

Tubercular Granulations.—They are very small, and generally perfectly uniform in their volume; their form is round or ovoid, their colour gray and transparent, and they exist in innumerable quantities in the otherwise healthy lungs: these tubercles generally continue isolated, and rarely form in groups; when they do, a section of the nucleus or mass shews them still separated from each other, by a tissue

perfectly or slightly infiltrated with serum.

The centre of the granular, like the miliary tubercle, becomes yellow and opaque, which appearances gradually spread to its circumference, and then it is called *Crude*.

A dark spot is to be seen in the centre of either the miliary or granular tubercle, which disappears as the adventitious deposit enlarges. This coloration probably depends upon the presence of a particle of black pulmonary matter. They may also become coloured by the accidental presence of another disease; thus icterus will give them a yellow tinge, particularly on their surface, and in gangrene of the lungs they become black.

It sometimes occurs that, in consequence of the immense accumulation of tubercles, death may result before the process of softening takes place: these cases are very rare; I have seen but two or three.

Encysted Tubercles.—The next species, the encysted tubercles, is so rare that I have never seen a single instance of it, and Laennec, in the space of twenty-four years, only met with three or four: he describes the cyst to be of the consistence of cartilage, that internally it is rugous, although the rugæ are smooth, and polished. Its external surface is attached firmly to the pulmonary texture, and the tubercular matter is so loosely adherent to the interior as to be very easily separated from it.

Gray Tubercular Infiltration.—This infiltration is frequently formed around tubercular excavations: it exists, though very rarely, independently of isolated tubercles: it forms large masses of a somewhat transparent grayish appearance. Under these circumstances, the pulmonary tissue is of a cartilaginous density, humid, and perfectly impermeable to air: if, then, sections of it be made, their surfaces are smooth and polished, of a homogeneous texture, and the pulmonary cells are no longer distinguishable: small yellow and opaque spots appear disseminated in the mass; they gradually enlarge and unite, until the whole is converted into a body of *crude tubercular infiltration*.

Gelatiniform Tubercular Infiltration.—Between miliary tubercles, there is often found a matter of the consistence of jelly, colourless or slightly sanguineous; the natural appearance of pulmonary structure is there utterly lost, no air-cells can then be seen: gradually this matter becomes more consistent, and is transformed into the species just described; yellow spots are frequently seen in the most liquid and transparent part of the deposit, shewing the commencement of its conversion into *crude tubercular infiltration*. This

formation is probably only a modification or germ of the preceding species.

The transformation of these two forms of tubercular infiltration into the crude state, is sometimes so rapid as to present no traces of their primitive appearances: they then are seen in irregular masses of a palish yellow colour, of an angular, but never of the rounded form of ordinary tubercles. The tubercular matter is here evidently infiltrated into the pulmonary tissue, totally destroying it, so that no remains of its texture are visible, whilst the miliary tubercle is plunged into the substance of the lungs, compressing but not uniting with it molecule by molecule. These masses often occupy a considerable portion of the organ, but never project beyond its surface.

Softening of the Tubercular Matter.—In whatever form the tubercular matter be first deposited, when it has arrived at the crude state, it softens and liquifies; this softening commences at the centre of each tubercle or tubercular mass, or if the mass be considerable, simultaneously at many points. Some authors assert that this process begins at the external surface: that it may occasionally do so, I do not deny; but, gentlemen, examine for yourselves, and you will find, on making a section of crude isolated tubercles, that the greater number of them are perfectly soft within, whilst their external parts are still in a state of considerable firmness. The softening proceeds until at last it affects the whole tubercle or mass of tubercles.

The softened matter may appear in two forms; sometimes it is like a thick pus, inodorous, and of a yellower colour than the crude tubercle; sometimes it is of the consistence of soft and friable cheese: this latter state occurs principally in serophulous individuals, in whom also the matter is occasionally like fragments of curdy substance floating in whey.

According to Thenard's analysis, tubercular matter consists of

Animal matter, principally fibrine and gelatine.....	} 98.15.
Muriate of soda, phosphate of lime, carbonate of lime	
Oxide of iron, a few traces.	} 1.85.

Tubercular Excavation.—When the tubercular matter is completely softened, it bursts into the nearest bronchial tubes, and is gradually expectorated, leaving an excavation in the lung: the orifice of communication being narrower than the excavation into which it opens, becomes, as well as the cavity itself, fistulous.

It is rare to find one excavation only; it is generally surrounded by miliary tubercles, or masses of tubercular infiltration,

which gradually soften in their turn, and burst into the primitive cavity, often forming irregular sinuses, communicating more or less freely with each other, and occasionally extending to the very extremity of the lung.

It is in this way that bodies, presenting somewhat the appearance of the carne columnæ of the ventricles of the heart, are seen to traverse these excavations: they are usually thinner at their centres than at their parietal extremities, and were thought by Boyle to be blood vessels: they are, however, merely portions of lung in a state of crude infiltration. Often, too, masses of lung of amorphous forms are attached to the parietes of the cavity, hanging loosely within it: there are also pieces of lung in a similar state. It has happened, though rarely, that a small portion of these masses has broken off, and remained in the excavation as a foreign body.

The columns or masses I have described, form, in their interstices, by their confused arrangement, a series of irregular sinuses rather than cavities; or you may consider the whole a general excavation, intersected by a number of incomplete partitions: it then may be called a *multilocular tubercular excavation*. As these infiltrated masses successively break down, the cavity becomes more open; and when their obstruction is complete, it is called a *unilocular tubercular excavation*.

The tubercular matter appears to throw aside the large blood-vessels, for they are often seen spreading along the parietes of the excavations: these vessels are frequently flattened, though but rarely obliterated, except in their ramifications directed towards the cavity, for no coloured matter can be made to penetrate the excavation. This fact was also observed by Storck and Baillie: Storck found these vascular extremities obliterated by coagulated blood. The vessels passing into the columns become impervious a little after they have entered into them.

The bronchial tubes, instead of being thrown aside, are evidently enveloped in the tubercular mass, and become involved in the general destruction of the portion of the lung in which they are placed, so that these vessels are not opened at their sides to transmit the softened matter, but appear clearly cut at the level of the parietes of the cavity.

One or many bronchial tubes always open into a tubercular excavation.

Tubercular Fistula.—As the excavation becomes emptied of its softened contents, its parietes are covered by an opaque, thin, soft, and friable membrane, which may easily be detached. It usually lines the

whole cavity: sometimes, however, a partial pseudo-membranous exudation is found, thicker, of greater transparency, less friable, and more adherent: its thickness, however, is generally unequal.

Often, the last-described membrane is super-imposed upon the previous one; it is then but loosely attached, and is even lacerated at many points, so that the second membrane appears to be only the primitive stage of the first.

The two membranes I have already described are succeeded by a third, which completely lines the parietes of the excavations; it presents a greenish tint, is unequal in its thickness in different parts of the cavity, and is of semi-cartilaginous density. The tubercular fistula may now be said to be completely formed.

Tubercular Cicatrix.—Tubercular fistula is evidently the result of nature's efforts to cure the disease by establishing an internal cicatrix; but the healing process is sometimes carried on still farther, by the parietes of the tubercular excavation closing and uniting with each other, and completely obliterating it: I have seen many instances of this process, and there are before you preparations demonstrating it. In one case there had been a considerable cavity in the upper lobe of the right lung, and the parietes of its superior part being thin, and not adherent to the costal pleura, collapsed, and fell upon the floor of the excavation, and firmly united with it, so as to form a complete cicatrix. You perceive, gentlemen, that the lung offers a puckered appearance, arising from the manner in which the parietes of the cavity had drawn with it that portion of the lung situated above it which had not been destroyed. On pressing the cicatrix it gives the resistance of cartilage. The cicatrix is here in a horizontal direction.

I present you with a preparation in which the cicatrization of the cavity had proceeded in a direction perpendicular to the lung. The cavity had evidently been of considerable size, its sides had collapsed, united, and formed a large cicatrix. You perceive, by closely examining the section of it, that it consists of two layers of cartilage, almost completely united at all points; leaving, however, here and there, light separations, shewing that the union had not been perfectly effected. In the same preparation there is a section of another cicatrix which takes an oblique direction.

It sometimes occurs, as I have already stated, that, when there is a vast accumulation of tubercles in the lungs, death takes place, whilst they are yet in the gray state, or at least not advanced beyond the period of crudity. It occasionally hap-

pens that when there are but few, they are all found softened, or that excavations are completely formed; far more commonly, however, the tubercular matter is discovered in every state, from the gray and transparent to the final cicatrization of the excavations formed by them. Thus this deposit is almost invariably first placed in the superior lobes of the lungs; there, consequently, the process of destruction originates, the excavation is primitively formed, and the rest of the organ may be healthy, and perfectly free from tubercles; but it is more usual to find them crude or softened, and excavated, in the upper lobes, and gray, transparent, and frequently in innumerable quantities, in the middle or lower. From these appearances it is inferred, that all the tubercular matter found in the lungs could not be deposited at once, but that it is formed in successive crops. It is indeed difficult to conceive that so large a quantity as is sometimes seen could have been deposited at one effort, or being so, what could have retarded their destruction in some parts of the lung, and accelerated it in others. It is much more reasonable to suppose that these deposits occur at successive periods.

I have now, gentlemen, demonstrated to you the various forms and the mode of destruction of the tubercular adventitious deposit in the lungs: you have seen that it may exist in that organ in the isolated state, or infiltrated into its substance; that the matter is primitively of a gray colour and transparent, afterwards becoming yellow and opaque; that then nature endeavours to reject it to the exterior by softening it, and thus putting it into a form in which it can be readily expectorated; that the result of the softening is the partial destruction of the lung by the formation of a cavity within it; that nature endeavours to repair the loss by converting the cavity into a fistula; and that occasionally the reparation is rendered still more complete by the union of the parietes of the fistula, and the consequent formation of a cicatrix.

We have thus, gentlemen, studied the tubercular deposit as it occurs in the lungs; let us now examine certain conditions of the body, caused by or concomitant to this adventitious formation.

Tubercular matter is rarely found in the lungs alone, it co-exists in various other organs. Laennec did not neglect this part of the subject, but has given us a list of the different parts in which they may be found, placing the organs in the inverse order of the frequency of deposit; thus they are seen, in the following table, existing most commonly in the lungs, then in the bronchial glands, then the mediastinal, &c.

Lungs.	Epididymis.
Bronchic glands.	Testes.
Mediastinal glands.	Spleen.
Glandulæ conca-	Heart.
natae.	Uterus.
Mesenteric glands.	Cerebrum.
All the other con-	Cerebellum.
gate glands.	Base of cranium.

Prostate gland.	Intervertebral sub-
Peritoneum.	stance.
Pleura.	The bones.
In the false mem-	In cancers.
branes formed in	Voluntary muscles.
the peritoneum	
and pleura.	

Louis has examined this subject still more minutely, and has formed the following table, after the examination of 350 subjects who had died of phthisis.

In the above number, tubercles were found in the following proportions:—In the

Small intestines	$\frac{1}{3}$
Large intestines	$\frac{1}{9}$
Mesenteric glands	$\frac{1}{4}$
Cervical glands	$\frac{1}{15}$
Lumbar glands.....	$\frac{1}{12}$
Prostate	$\frac{1}{13}$
Spleen	$\frac{1}{11}$
Ovaries	$\frac{1}{20}$
Kidneys	$\frac{1}{30}$
Uterus.....	} In one subject only.
Brain	
Cerebellum..	
Spinal cord..	
Ureters	

It has been observed, that tubercular matter has been deposited in the right lung more frequently than the left, and that it exists more commonly in men than women.

Lombard de Genève, on examining a

vast number of children who had died of various diseases, found that the mortality arising from phthisis, compared with other affections, varied according to their ages. Thus—

It was rare in the *foetus*, and in the first months of life.

From 1 to 2 years, it was found in	$\frac{1}{4}$
— 2 to 3	$\frac{2}{7}$
— 3 to 4	$\frac{4}{7}$
— 4 to 5	$\frac{3}{4}$

and from five years to the age of puberty, less frequently than from 4 to 5, but more than before 4 years.

You perceive, by the above table, that tubercular disease occurred the least frequently before 2 years, and the most between 4 and 5.

Bayle had previously examined the proportion of deaths arising from phthisis, compared with other diseases, and he found it to be nearly one-third, or as 244 is to 696. He found also that the periods at which death occurred from this disease after the age of puberty, in 100 cases, were as follows :

From 15 to 20 years of age, there died 10	
— 20 to 30	23
— 30 to 40	23
— 40 to 50	21
— 50 to 60	15
— 60 to 70	8

Bayle examined 200 patients, with reference to the duration of the disease from its commencement to its fatal termination. I think his table cannot entirely be depended upon, although it is no doubt as correct as the subject admits; for it is extremely difficult to obtain a precise history of a disease, especially from the lower classes of the people, who commonly date their complaints only from the period they became incapacitated from attending to their occupations.

Table of the Duration of Phthisis before Death was produced, in 200 Cases.

Quarters of the Year.	Half Years.	Years.
1st quarter16	} 1st half year60	} 1st year121

		7th.....3
		8th.....1
		9th.....3
		10th.....3
		From the 9th to the 10th6

In reference to the seasons of the year in which the mortality occurred, he found it as follows in 240 cases:—

There died in the spring	54
————— summer	68
————— autumn	64
————— winter	54

210

We find that various lesions of different organs of the body are consequent upon the existence of tubercles in the lungs. Louis has investigated this subject with great patience; and the following observations are principally derived from his work.

The absorption of the fat in the cellular tissue is often extraordinary: this secretion diminishes greatly in the orbits, so that the eyes sink; between the buccinators and masseters it disappears, and the rotundity of the cheek is lost; in extreme cases, the outer surfaces of the teeth are seen elevating the skin upon them, giving, as Aretius expresses it, the appearance of a ghastly grim or smile. From the loss of the soft parts, the malar bones appear projecting. The fat of the whole body becomes at last totally absorbed.

The intestines, brain, nerves, spleen, pancreas, and other glands, do not diminish.

The liver becomes larger, and is also fatty in about two-thirds of the cases. This appearance occurs more frequently in women than men.

The specific gravity of the bones diminishes; and where there is great marasmus, their circumference lessens.

The chest contracts at the sides from previous pleurisies, and often also at its anterior superior parts, in consequence of the presence of large and old excavations.

The muscles and the heart are smaller and redder than natural. The calibre of the aorta is generally diminished, and its internal surface is reddened in one-fourth of the cases.

The mucous surfaces are peculiarly subject to alterations. Louis found, in examining 102 subjects who had died of phthisis,

Ulceration of the larynx ..	in 23
————— epiglottis in	18
————— trachea ..	in 31

In most cases the ulcers occupied the posterior surface of the air tube, and the laryngeal face of the epiglottis.

The stomach was affected in the following proportion in 96 cases of phthisis; and a comparison was also made by Louis of the same lesion of this organ in 96 cases of death from other chronic diseases.

Stomach enlarged to double or triple its volume.....	9 times.
Same lesion in 96 cases of other chronic diseases	2 do.
Softening, with thinning of mucous membrane of the stomach	19 do.
Same lesion in 96 cases of other chronic diseases	6 do.

The mucous membrane of the different parts of the intestinal tube was diseased in the following proportions:—

Duodenum—ulcerated, rarely.	
The glandulæ agmenatæ of the jejunum and ileum ulcerated in five-sixths of the cases.	
The mucous membrane of the small intestines were rarely thickened or softened.	
The large intestines not so frequently ulcerated, but their mucous membrane softened in three-fourths of the cases.	
Ileo-colic valve.—It is rare, indeed, not to find ulcerations there.	
Fistula in ano often co-exists with tubercles in the lungs.	

The whole of this lecture was elucidated by a series of preparations, shewing the various forms of the tubercular deposit in the different organs, and especially its changes in the lungs. The secondary lesions of the mucous surfaces were exemplified in the same way.

ON THE ORIGIN AND NATURE OF HYSTERIA.

By JOHN ROBERTON, Esq.

Surgeon to the Manchester Lying-in Hospital.

[Concluded from p. 463.]

THE distinguishing, I may say the essential, feature of the constitution liable to hysteria, is a *peculiar irritability of the nervous system, existing throughout the duration of life, and often manifesting itself in a degree greater than the power to resist particular hurtful impressions*. To this latter circumstance it is owing that various causes, mental as well as physical, produce certain effects (already characterized and partially enumerated) of the nature of disease—effects which, in the aggregate, have received the name of hysteria. The inordinate and peculiar irritability * I have spoken of, probably

* It is common to pretend great amusement at the vagueness of many of the terms used in medicine, but not always with sufficient reason. A word (*irritability*, for example) may be vague, merely because the *idea* for which it stands is vague.

in all cases originates in congenital defect in the nervous structure, although it may doubtless often afterwards be aggravated by a great variety of circumstances, the chief of which are derangement of the menstrual function—an idle, sedentary, luxurious manner of living—and the cultivation of the emotions and passions, to the neglect of the understanding*. I have said that there is probably always congenital defect of the nervous system; and the same observation may perhaps with some reason be extended to other systems of organs and parts, more especially to the digestive and assimilative organs; for although, in many instances, the hysteric patient is robust and vigorous, much more generally she is of slender, delicate make, capricious appetite, feeble digestion, and exceedingly variable bowels.

This opinion of the nature of hysteria I am desirous to state with as much clearness as possible, not simply because I think it the most tenable, but rather because of its leading (as I hope) to a just and comprehensive view of the nature of hysteria as a disease. That the multifarious symptoms included under this vague name, which yet may be traced to a common parentage, are often (daily, I might say), mistaken for inflammatory and other organic diseases, and treated as such, to the immediate aggravation of the symptoms, and the lasting injury of the patient, is well known. It will therefore be useful to have pointed out, however imperfectly, the more uniform and abiding features of the hysteric constitution, that being caught by the eye of the attentive practitioner, he may thereby steer his course with some degree of assurance, where not a few have unhappily floundered.

A question naturally arises, how are we to distinguish hysteria from hypochondriasis? This often controverted point I have not space to discuss. The two may exist together in the same person, although I think that they are unquestionably different diseases. Hypo-

chondriasis would seem to be an affection of the digestive organs modified by temperament; the prominent symptoms referable to the nervous system being timidity, continual dread of impending evils, with excessive attention to every bodily sensation, as though it indicated some latent but fatal disease. The complaint comes on gradually, increases progressively, and sometimes ends in structural disease of the abdominal viscera, of the brain, or other internal organs. Hysteria, on the contrary, comes on suddenly, with spasmodic affection of some part of the *prima vie*, and may as suddenly cease. True there is often timidity, and always a crowd of distressing sensations, but not necessarily, nor even ordinarily, despondency and valetudinarianism; nor, unless the exciting causes are very long and constantly applied, is there any tendency in hysteria to become gradually worse; and the ultimate effects are rarely, if ever, known to be structural disease. Upon this topic Cullen has the following admirable remarks:—"Purple is a compound of red and blue, and there are some purples in which it is difficult to say whether the red or the blue prevails; but in many other cases we distinguish them; and whether we can distinguish in all cases or not, this never embarrasses us in distinguishing between blue and red when these colours are totally separated. So these diseases may also be mixed in certain degrees; but that does not prevent them from being truly, and very often totally, distinct and distinguishable diseases; and after considering both the one and the other, I believe the difficulty of distinguishing them will seldom occur."

The exciting causes of hysteria admit of division into three classes. 1st. Such as immediately affect the mind; as surprise, terror, anger, grief. 2d. Such as plainly affect the body; long-continued pain, hurtful ingesta, great fatigue, sudden atmospheric change from dry to humid, the outstriking of eruptive complaints, disordered menstruation, &c. 3d. Obscure changes in the bodily health, that are rather inferred than actually observed.

There can be no question that hysteria readily occurs in the predisposed, whenever the menstrual function is deranged, suppressed, or performed with pain. This generally-acknowledged fact I fully admit, and regard it as the prin-

When I witness a slight surprise, or a trivial disappointment, occasion in any one a burst of hysteric passion, I am led to express the impression made on my own mind by the term I think best fitted to excite a like idea in the mind of another; but the idea I have received being itself complex and vague, is surely not likely to be rendered more clear and definite by the use of any term that can be selected.

* "Si votre fille lit des romans à dix ans, elle aura des vapeurs à vingt."

cipal reason why hysteria is chiefly confined to the female sex. The following cases, however, illustrate the effects of certain exciting causes, where the menstrual function was in no respect faulty.

Mrs. S—, a widow, aged 56, lusty, usually in tolerable health, and who had ceased menstruating about seven years. I was hastily summoned to visit her, on account of what was thought an alarming seizure, when I found her in bed, cold, pallid, torpid; complaining of pain at the pit of the stomach, and about the umbilicus. This attack had been ushered in, a couple of hours before, by a violent paroxysm of hysteric crying and raving. The illness she ascribed to what she had eaten at dinner; but an attendant hinted to me that it was owing, not to what she had eaten, but to a piece of very distressing intelligence she had received, affecting the moral character of an old and valued house-keeper.

Miss M., aged 25, well formed, and healthy. I found her with a dull look, cold surface, feeble pulse; complaining of an intense head-ache, and manifestly affected with *globus*. There had been a succession of convulsive attacks. On careful inquiry, the menses, I found, were regular, and in every respect natural. I found also that the exciting cause was a severe and prolonged tooth ache, which had deprived her of rest for several nights.

Mrs. H., aged 35, stout, plethoric, but very vigorous; the mother of a number of children. When I saw her she was sitting up in bed, the angles of her mouth strangely relaxed, the aspect dull and stupified, and having almost entire loss of the power of articulation. A little before my visit she had had a violent fit of laughter, and, on making inquiry, I learnt that this was not the first attack of the kind. As to the menses, they were in every respect regular. A general herpetic eruption, which was just becoming visible, that soon spread over large portions of the surface of the body, producing great irritation, was evidently the exciting cause.

Miss D., aged 28, robust in figure, but of feeble stomach and variable health. When I saw her, she was lying on the floor of a Sunday-school, whither she had gone after dinner, in what her friends around called a *shake*—i. e. she was screaming, and frightfully convulsed in the trunk and extremities, but not

the face; these fits alternating with periods of calm. She had for years been a frequent sufferer from hysteric attacks: on the present occasion the exciting cause, in the opinion of her sister, who was in attendance, was a heavy dinner of roasted pork, which she had taken about half an hour before the commencement of the paroxysm.

Mrs. S., aged 24, twelve months married, without family. On entering the room, I saw a slim elegantly formed lady, lying on a sofa, in moderate convulsions. The contractions were chiefly in the lower and upper extremities; her thin but fine features being very slightly agitated. After a little, she was still, and faintly answered my queries; but the convulsions soon returned. The pulse was hurried and languid, and the surface cold. On particular inquiry, I was assured that the catamenia were, in every respect, natural and regular. She had been subject to such attacks for a number of years, had an affectionate husband, all the comforts of life, and knew of no cause whatever for the fits. Occasionally she would be quite well for months, and then have fits, she knew not why.

An attendant of the hysteric-diathesis, which I mention by the way, as being too important to be altogether overlooked, is a remarkable liability to abortion. A considerable proportion of such as miscarry in the early months of pregnancy are of this constitution; and few child-bearing women, highly predisposed to hysteria, escape repeated abortions. I have said abortion in the early months, because in the later months miscarriage may occur from various local causes, as the death of the fœtus, or a slip in walking, irrespective of the constitution of the mother.

It is not my intention, as, indeed, it would be out of place, to enter on a fuller consideration of the ordinary forms of hysteria, familiar to most practitioners; but there is one form less known, and far from being well illustrated in any treatise I am acquainted with—I mean the voluntary hysteria. Dr. Cullen, it is true, expresses his belief that the hysteric affection can be, and often is, renewed at pleasure; and he has attempted, with much ingenuity, to explain how this happens, remarking that the occurrence is doubted, rather because it is difficult to explain how involuntary motions should thus be raised,

than from any weakness in the evidence for the fact. "Merely by recalling to my imagination," says he, "any piece of indiscretion which I thought I had committed, I have, in my chamber and alone, often blushed as warmly as when the indiscretion was committed. Many laugh by themselves in the same way; and still more can, by the imagination of mournful scenes, induce a flow of tears. None of these, however, are voluntary motions; but they serve to shew, that by teaching, as it were, the imagination the ideas that can excite such and such emotions and involuntary actions, we can in a manner render such emotions and actions subservient to the will." He then proceeds to relate a case to exemplify this reasoning:—"I knew a lady who was subject to violent hysterics, for which, for a long time, I could assign no reason, till at length, on mentioning by chance the name of a man from whom she had received the grossest injuries, she fell into a severe paroxysm; and then it appeared that they always came on when she thought of that person."

To me neither the reasoning nor the illustration appears conclusive. The instance of a person blushing in secret, on happening to recollect a particular train of thought, is an example of emotion, which never becomes subservient to the will, as Dr. Cullen would have discovered had he retired into his chamber *on purpose* to make the experiment. The predetermined recollection of that indiscretion, the accidental recurrence of which, in the mind, had always hitherto called up a blush, would now, we may safely predict, have been followed by no such effect,—emotions of whatever kind, and however often renewed, being in their very nature, I apprehend, absolutely involuntary. The hysterical fits, too, of the lady, were as plainly involuntary. Had she, at the request of her physician, set herself to think of the obnoxious person, the very idea of whom excited fits, is it likely that by such a pre-arranged effort of the imagination she would have fallen into a paroxysm? I think not. The violent emotion hitherto excited by this idea, when obtruded on the mind *unbidden*, would now have given place to some mental state of a totally different kind—probably to curiosity. Another of Cullen's illustrations—the power of shedding tears at will—is very much more to his

purpose; not, however, when it takes place as the effect of recalling to the memory some mournful scene, as he has stated, for then it is in its nature involuntary; but when it occurs as the effect of voluntary effort, which there is reason to believe many persons possess, almost at any time, the ability to make—a power in its nature similar to what is obtained over several of the other physical signs of emotion, by those dramatic actors who possess the true genius of their difficult art. The distinction I have here drawn ought not to be lost sight of. The power of assuming a doleful look, accompanied by a flow of tears, is one phenomenon; and the flow of tears, as the sign of a sorrowful emotion, is another and different phenomenon.

It is not easy to say what the power I allude to really is—the power of acting at will "the rueful look and gushing tear," nor do I think that every one is capable of acquiring it. The act itself, I imagine, is always preceded by a momentary general sensation or *thrill*, the faculty of causing which at pleasure, is the nearest approach that I can conceive to the power of falling at will into a true hysterical paroxysm. Perhaps the latter may not require a greater or very different kind of mental effort for its production than is required in the production of the former, for it is easy to believe that when once the earliest feeling which denotes the accession of the hysterical paroxysm, and is its antecedent, has taken place, the remaining train of symptoms will follow, not voluntarily but *necessarily*, according to the ordinary law of sequence, or, as it is commonly called, of morbid association. The remarkable case I shall now relate may help to exemplify this observation.

During my residence in Warrington, late one evening, August 22nd, 1821, I was taken to visit a person in the workhouse, who had been discovered in a field adjoining the town, apparently dying, in consequence of violation, and other injury inflicted on her, as she alleged, by two ruffians. I found a slender young woman, having a gipsy cast of countenance, lying on a bed, in what appeared a well-marked paroxysm of spasmodic hysteria. On coming out of the fit, she complained, in a feeble voice, of great pain in the limbs, in the throat, and on the left side of the abdomen. Applying her hand to the latter part,

she screamed and relapsed into a fit. Her look was quite ghastly, and expressive of great exhaustion. The surface of the body (notwithstanding the state of the weather, which was extremely sultry) was cold as a corpse; and the pulse was under sixty, and extremely feeble. An attempt to swallow a little spirit and water excited apparently a near approach to suffocation, during which the fluid was forcibly ejected from the mouth. She complained of pain in the pudenda; hinted that she was flooding, and that all her sufferings were owing to personal violence; but, on the plea (and it seemed very reasonable), of great exhaustion, she declined for the night a more specific examination. The same description of fits continued for three days and nights. On the evening of the 25th, that is, three days after her admission, she fell into a most violent paroxysm; and was thought by myself and others to be actually dying. Two men in the course of the day had been apprehended on suspicion of perpetrating the dreadful outrage she was supposed to have suffered; and on being confronted with her, she instantly identified one of them as her violator, who, in consequence, was sent to jail. Her tale, however, it now began to appear, did not hang well together. It was true, marks of violence were found on her person—on the arms, and particularly on the left side of the abdomen. On the inner surface of the labia pudendi, also, were two slight wounds, such as might have been inflicted by the finger or thumb nail: but not to spin my narrative too long, by the most convincing circumstantial evidence, and ultimately by her own confession, her story was discovered to be fiction, invented for the purpose of exciting charity, and that all her injuries were self-inflicted. She had fallen down in a fit in a field adjoining the public road, near the hall of a widow lady, noted for benevolence, where she was found, and, probably, contrary to her expectation, thence conveyed to the workhouse. In due time, Miss Mary Ann Sherratt, for that was the heroine's name, had to shift her quarters from the workhouse to Bride-well, where from the indulgent hands of her medical friends, she passed into those of the lawyers, and found herself a match even for the latter, for whenever they began to press her hard with unpleasant questions, she treated them with an hysterical paroxysm; not a sham fit, but one

having every feature of actual hysteria. During these fits, I have repeatedly found the pupil immobile on the near approach of a lighted candle; and the effects on the surface of the body, the pulse and the countenance, were exactly such as warranted me in pronouncing the paroxysms *real*.

From Warrington Miss Sherratt was removed to Kirkdale, tried for imposture, convicted and imprisoned. On the expiration of her term—on the very day of her release, I believe, (I speak without possessing exact information) she wandered into Cheshire, and there fell not into a fit, but into labour. This time she chose her opportunity better, for great commiseration was excited, and she had presents of various kinds showered on her. An accoucheur was likewise summoned, whose obstetric examination she contrived to parry throughout the ensuing night; but in the morning, before she could escape, it was discovered that she was not in labour, nor to all appearance, even pregnant. Again was she conveyed to jail at Knutsford, tried and punished. A number of years elapsed before I heard further tidings of this singular person. However, in glancing over the columns of a London paper, I chanced to light on a notice to this effect:—That a young woman of the name of Sherratt, who some years ago played a variety of strange tricks at Warrington, had absconded from the Penitentiary, carrying with her property to the value, if I rightly remember, of 40*l*. It appears that before finding shelter in the Penitentiary, she had contrived to fall into a fit in the street so opportunely as to attract the notice of Mr. Alderman Wood, who took compassion on her, and had the influence to obtain her admission where I have stated. There Miss Sherratt soon became a great favourite with the ladies who superintended the institution; and having a wonderful turn for repeating from memory portions of scripture, (a turn I well recollect her possessing when under my care), she was looked on, up to the moment of her elopement, as a most exemplary and hopeful penitent. More of her story I do not know. I have never, however, seen reason to change the opinion I originally formed, that the fits were truly hysterical; and that she could fall into a paroxysm by a mere act of the will.

If not intermediate between involun-

tary and voluntary hysteria, yet differing a shade from the ordinary character of the former, is hysteria from imitation—a variety characterized by the fit supervening on the patient witnessing an hysterical paroxysm in another. We should, *a priori*, imagine that the predisposition must be strongly marked indeed, in those who fall into hysterics from this cause. But it is doubtful if such is the case; since sometimes on one in a ward falling into a fit, the whole or greater part of the inmates immediately follow the example. A case of dysphagia in a female in Guy's Hospital, Dr. Bright informs us, required the employment of the probang; but no sooner was the instrument introduced than the patient fell into hysterics, "which was followed immediately by hysteria in several females in the ward." Instances of this description are often met with, and curiously illustrate the wonderful physical influence which one human being, under particular circumstances, exercises on another. Nevertheless, it would seem to have been reserved for the modern advocates of animal magnetism to perfect us in this kind of lore, of which kings, with their curative touch, were the first great professors; while the credulity of the former has taught us that the world may increase faster in knowledge than in wisdom.

The power of throwing off an hysterical seizure, by a voluntary effort, is a remarkable circumstance, and by no means rare. Hysterical patients, in hospitals, are said to recover more speedily under the care of certain nurses than under others; owing solely to greater personal control. The following case is instructive. Happening to be in attendance on a lady, distressingly affected with hysterical sighing, I had occasion to converse with another lady, a particular friend of the patient, respecting the somewhat singular nature of the complaint; when she addressed me in these or similar words. "Miss A. might, if she would, do much by her own effort for the cure of this sighing. When I was very young I exposed myself to a silly disappointment, and was taken with the same kind of sobbing; the moment my mother, who possessed both sense and firmness, perceived the slightest signs of an attack, she made me get my bonnet, and drove me, forthwith, out of the house, into the street. This acted

more effectually than Miss A.'s large doses of ether; for the fear of being noticed sighing in the street, effectually, for the time, overcame the tendency. After a while my mother's perseverance and my own efforts wrought a complete cure." In such instances as this, the paroxysm probably originates in no act or even consent of the will, and yet steals on with a force so gentle as admits of its being effectually reisted, if the patient is determined, or compelled, to make the attempt.

The medical treatment of hysteria, having nothing new to offer, it is not my intention even so much as to touch upon; and I hasten to conclude by a brief enumeration of those points which it has been my wish to bring especially under notice:—

1st. Hysteria manifests itself in various forms, and several of these again split into many varieties; illustrating the remark of Sydenham, that in diversity of feature this disease may be compared to the shapes of Proteus, and the colours of the chameleon. Hence it does not easily admit of definition; or rather, to every definition there must be exceptions so numerous as to render it altogether worthless for practical purposes.

2nd. It is an error to regard hysteria as exclusively a symptom of uterine derangement, or of spinal irritation; or an affection of the brain; or as being solely a disease of females.

3rd. The peculiar nature of the causes, as well as the symptoms of hysteria, in all its forms and varieties, points to the nervous system as the primary seat of the disease; and it would appear, further, that not always the whole of that system is affected, but rather, sometimes, a particular part thereof—an inference illustrated and strengthened by sound analogy.

4th. We have reason to believe that there is *as absolutely* an hysterical constitution, or congenital predisposition to hysteria, as that there is a scrofulous constitution, or congenital predisposition to scrofula; and consequently that none are liable to hysteria but only such as possess this constitution.

5th. The hysterical constitution is characterized by irritability *sui generis* of the nervous system as a whole, or sometimes more particularly as connected with certain organs; and that although this condition cannot be *origi-*

nated by modes of living, and other external circumstances, it may be greatly aggravated by them.

6th. There is nothing whatever more mysterious in hysteria than in any other complaint—scrofula, for example. The difference consists in hysteria being more complex and obscure, that is to say, more difficult of observation, than the other; and this is, doubtless, an important difference. But, when observation and reason have done their utmost, all we can ever hope to know of hysteria, or of any other disease, are its *causes*, its *seat*, and its *phenomena*. If we imagine that we are capable of attaining to knowledge more recondite than this, we deceive ourselves, and overlook the first principles of medical inquiry.

7th. The mind exercises a remarkable power over the phenomena of hysteria; in rare instances causing paroxysms of the spasmodic form of the disease by a mere act of volition, and, in other cases, sufficing to effect, or powerfully to aid in effecting, a cure;—facts which seem to prove that hysteria is as purely and unequivocally an affection of the nervous substance, as perhaps any disease which could be named.

OBSERVATIONS
ON THE
PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and
the General Lying-in Hospitals.

[Continued from page 479.]

2.—*All the branches proceeding from a common trunk, will have a similar disturbance of their function from the same injurious impression.*

This is unquestionably true, as a general proposition; but as there are some exceptions to the rule, it must be taken *cum grano salis*. By the terms “similar disturbance” is here meant a resemblance in kind, rather than sameness in degree. If, for instance, a nerve of sensation be excited, as some of those branches of the fifth which proceed from its ganglionic root, there will be morbid sensibility—neuralgia—in all the parts of the surface supplied by those branches, of which innumerable instances are upon record. If it be a nerve which ministers

exclusively to motion, that is excited, spasm, convulsive movement, will be the result; if a compound nerve, there will be commonly the combination of suffering from neuralgia, with convulsive movement; and the excited state will be sometimes conveyed from the nerve originally affected to others in its vicinity, or with which they may be associated by nervous communication or interchange of filaments. So, decayed teeth have, by irritating and inflaming the nerves of the gums, occasioned painful affections and muscular spasms, not only of the face, from the extension of diseased action to the sensitive branches of the fifth, and the portio dura of the seventh, but also in those muscles of the neck, and even upper part of the back, which are supplied by the respiratory system of nerves. Of this the extremely interesting case recorded by Mr. Mitchell* affords a striking example.

A similar extension of diseased action was observed in a case of medullary tumor of the ham, related by Mr. Travers*. In this case, the pain was at first confined to those parts upon which the long cutaneous branch of the peroneal nerve is distributed, as “the toes and outer side of the foot,” but afterwards the loin upon that side, together with the sciatic and crural nerves, partook of the neuralgic affection, probably from the extension of inflammation upwards. It is generally the same where similar nerves are paralysed: all the parts which derive their energy from the same trunks will lose at once their sensibility and muscular power; but this seldom extends upwards above the part affected. The ischiatic nerve, compressed by sitting, or by an aneurismal tumor, is attended by a diminution or total loss of sensibility, and the power of muscular action, in all the parts which it supplies. There is not increased sensibility in one part of its course, with diminished sensibility in another; neither is there convulsive movement in one part of its course, with defective muscular power in another. Be the state that of muscular spasm upon the one hand, or paralysis upon the other, acute pain upon the one hand, or defective sensibility on the other, the affection is the same throughout the whole course of the

* Med.-Chir. Trans. iv.
† Ibid. xvii.

nerve, and generally through all the ramifications which proceed from the same trunk. Haller has stated this with his usual clearness and precision*; and subsequent observations have confirmed the accuracy of his opinions.

But although, in a compound nerve, sensation and motion are commonly affected in the same way,—although they generally err together, either by excess or defect,—yet it is not always so. Motion may be impaired and the sensibility retained, or the converse of the proposition may be true. A case, which some years since I communicated to Sir Charles Bell, and which he has done me the honour to insert in the appendix to his work upon the nervous system, was an interesting example of both these conditions. Upon one side this patient had defective power of motion, without any diminution of sensibility; but, on the contrary, a sense of heat; upon the other she had impaired sensibility, without any diminution of muscular power. With the arm of this side she could readily hold her child; but it required the constant direction of the eye, as well as a distinct effort of the mind, to keep the arm from gradually loosening its hold, and allowing the child to fall. Indeed, these two conditions of nerves in the same limb may even be in an inverted proportion to each other, as in an instance communicated by Sir Charles Bell to Dr. Cooke, who has given an outline of it in his work upon palsy. “Pain, of a most agonizing kind, periodical, and alternating, had confined the patient for two years, and had quite subdued a powerful frame, while the muscles supplied with nervous energy from the same source were become paralytic and shrunk.” These facts are inexplicable, according to the ancient notion that the different offices of sensation and of muscular activity, to which a given nervous cord ministered, were the result merely of varied degrees of energy or action in some filaments, but are intelligible upon the principle so amply established and aptly illustrated by modern physiologists, that what Mr. Abernethy called “a packet of nerves,” though united in

a single cord, is a compound of fibrils of different function, some contributing to sensation, others to muscular activity, but maintaining throughout their whole course a distinctness of texture, as of office, and each, probably, circumscribed, and separated from the other by its own tunic.

This principle, of which it was left for the physiologists of our own time, especially Sir Charles Bell and Magendie, to prosecute the development, as well as to supply us with copious proofs and illustrations, did not altogether escape some medical writers of an early date. Even Galen was aware that a nerve, although to appearance a single cord, still consisted of many nerves contained in a single sheath‡; that some of these were distributed to the muscles, and were for the purpose of motion, whilst others went onwards to the skin, for the purpose of sensation†; and that some of these nerves might have their function impaired, to the exclusion of others: but he retained the doctrine prevalent at his time, that, after all, muscular motion required a stronger exertion of nervous energy, while a slighter would suffice for sensation‡; an opinion which was entertained also by Haller§. Willis, too, had more than a glimpse of the modern views with regard to the diverse functions of the several filaments of which a nervous cord consists, and applies them particularly to the recurrent, with respect to which, he has this remarkable passage:—“The returning nerve, although it seems a branch sent forth from the trunk of the wandering pair, yet, for better conduct’s sake, it is contained under the same coat with the rest of the wandering pair||.” And again: “it is very likely that of the fibres which are complicated together in the trunk of the wandering pair, one is distributed to the returning nerve, ano-

ther to the præcordia, a third to the lungs, and, lastly, another to the ventricle; all which, although they have communications among themselves, and, for the sake of a better conduct, are gathered together into one, yet they are distinct from their very original, and constitute divers passages for the animal spirits*." Van Swieten also considered it as a point well known amongst physiologists, that some nerves minister to sensation, others to muscular motion; and that, although they are perfectly distinct at their origin within the cranium, yet that, collected into one common trunk, they proceed together to their several destinations: the nerves of motion, therefore, might have their function impaired, whilst the nerves of sensation might either altogether escape or be only slightly affected; or the converse might be true †.

It appears, then, and it is explained by this view of the intimate structure of a nerve, that the filaments of sensation may be affected, whilst those of muscular movement are unimpaired; or the latter may have their function disturbed, whilst the former are uninfluenced; or their morbid conditions may be incommensurate with each other; or the sentient and motor filaments may even be in opposite states in the same nerve. The late Mr. Shaw, in considering "why sensation should remain entire in a limb when all voluntary power over the action of its muscles is lost, or why muscular power should remain when feeling is gone," thinks "it is not too much to suppose that one origin of a nerve may be affected whilst the other remains entire;" and arrives at this practical conclusion: "if only one set of functions of a spinal nerve be deficient, we should apply our remedies to that part of the system from which the nerve arises; but if both functions are impaired, we must then direct our inquiries to the state of the nerve in the whole course, from its origin to its distribution, as the loss of power is probably owing to some affection of a part of the nerve after the two sets of fila-

ments by which it arises are united together*." The case to which I have before adverted, in which these two opposite conditions existed on different sides of the body, would seem to give countenance both to the principle and practice of my late lamented friend; but they are far from universally applicable. In the case, before alluded to, in Dr. Cooke's work, although the sentient filaments were in a state of excitement, the motor filaments paralysed, there was no suspicion of any affection of the roots of the nerves. The trunks were found tender, and acutely sensible to the slightest pressure, and the case was cured principally "by repeated purging, and the application of leeches along the course of the nerves." In the case also related by Mr. Denmark †, to which I shall have occasion hereafter more particularly to advert, there were violent pains, without, however, muscular spasms, although the symptoms arose from a wound followed by inflammation of the radial nerve in its course; and in many cases of ischias, where it depends upon some inflammatory condition of the nerve, as in the examples related by Cotugno, Martinet, and others, the pain is often considerable, and shews itself in different parts of the limb, but the muscles often altogether escape. These are glaring exceptions to the pathological principle and to the "rule of practice" to which I have already alluded, and point decidedly to the conclusion that even "after the two sets of filaments by which it arises are united together," one function of a nerve may be affected, to the exclusion of the other, by an impression made upon its trunk; but there is nothing in all this which is calculated in the smallest degree to discomtenance the statement, that the condition of a nerve will be identical throughout its whole course, whatsoever character the morbid affection may assume; whether it be that of excitement, an exaltation of function upon the one hand, or defective energy upon the other.

3. *The morbid affections of nerves resolve themselves into those of excitement and those of defective energy.*

This general principle is so well established and so familiarly known, that it will perhaps be readily conceded

* Ibid. p. 151.

† Notum est physiologicis, nervos quosdam sensul, alios motui servire, qui distinctissimi licet sint in sua origine intra encephalum, tamen in truncos majores nervorum collecti ad partes corporis una deferuntur. Potest ergo impediri functio nervorum moventium, dum nervi sentientes adhuc illibati sunt vel minus læsi; et vicissim.—Comm. in Aph. Boerhav. §. 1087.

* Med. Chir. Tr. vol. xii. p. 149.

† Med. Chir. Tr. vol. v.

without proof or illustration. The only modification of the statement, requiring even the slightest notice, is this—that in the nerves which supply the organs of the external senses, their function may not only be excessive or defective, but also vitiated or depraved. The eye may be unable to distinguish colours, though this may arise also from some imperfection in the perceptive faculty; the tongue may fail to recognize the true flavour of sapid particles; the ear may be assailed with particular sounds, without the corresponding external impressions; and the touch may be variously perverted. The causes of these disturbed states of function in nerves which minister to the external senses, have hitherto been little investigated, and have eluded the discovery of pathologists. They have been recorded as insulated facts, without further arrangement than that founded upon the organ affected, and without any connecting link in the form of a general law or principle by which they may be associated. But even if I possessed materials for the prosecution of the very interesting, though difficult, inquiry into the pathological history of these perversions of the external senses, it would be unnecessary for me to enter upon a subject which is not even remotely connected with the objects of my present investigation.

Excitement of a nerve, where it exists, will be recognized by the occurrence of pain, or muscular spasms, or the combination of the two, according as the nerve is one devoted to the purposes of sensation, or of motion, or of both. The branches derived from the ganglionic root of the fifth pair, which are distributed upon the surface of the face, are nerves exclusively of sensation, and morbid excitement in these branches occasions the agonizing sufferings called neuralgic, and familiarly known as “*tic douloureux*,” or “*the tic*.” The portio dura of the seventh pair is a nerve exclusively of motion, and, when in a state of excitement, produces excessive and anormal movements of the muscles which it supplies. Excitement of a voluntary, compound, or symmetrical nerve, as in those gangliform enlargements which not unfrequently form on the extremities of the nerves in an amputated limb, will occasion at once violent neuralgic paroxysms, referred to the former remote distribution of the

nerve affected, and violent “convulsive jumping” of the limb.

The pain of a morbidly excited nerve, commonly called neuralgic, or neuralgia, is of a peculiar kind. It is sometimes periodical, much more frequently merely paroxysmal. It recurs at irregular periods, and from very slight causes, or occasionally from none that we can trace. It is also fearfully severe, and is commonly attended with local determination of blood to the part, with a distressing sense of heat; if situated in or near a secreting surface, with an increase of secretion from the part, and a proneness to inflame from slight causes.

Of its intermitting character, Mr. Swan has offered an explanation which is, perhaps, as near an approximation to the truth as any that has hitherto been adduced. “It may be,” he says, “that a nerve cannot at first bear a diseased action without rest, any more than it can a healthy one; and therefore the diseased action, after a certain period, ceases to make any impression; but after this rest, the nerve acquires fresh powers, and is again fitted for action*.” There is in this explanation some confusion, arising from a want of discrimination between the action and the producing cause. “The diseased action” is the painful paroxysm, not “the impression” which causes it. The author’s meaning is probably this—that nerves, like other organs and faculties, in a diseased state, are fatigued and exhausted by their vehement exertion; that they cease to act; that after resting for a while they again recover their power, when, in consequence of their morbid state, their renewed exertion is irregular and violent. But this, to me, is not altogether satisfactory. It appears to be rather a statement of fact than of explanation; and amounts, after all, to little more than that the attacks of neuralgia are intermitting. The opinion of Bichat upon this point appears to have been somewhat similar; though this distinguished anatomist presents it rather in the garb of a matter of fact than an explanation, and applies it as a general law or attribute of the nervous system, in a state of health rather than disease†. Were it not for this peculiar

* On Diseases and Injuries of Nerves, p. 13.

† Dans les expériences, la sensibilité animale du nerf semble s’épuiser peu à peu, et cesser enfin. Si on cesse d’exciter le nerf pendant une heure ou deux, la sensibilité se renouvelle avec beaucoup

attribute of neuralgia, life would more frequently fall a sacrifice to the disease; as it is, these pains may "quite subdue a powerful frame*," and, in some instances, "may wear out the patient's health, and destroy him at last†."

It might be expected that, where disease exists in those parts of the animal body upon which sensibility and sensation depend, the pain would be inordinately severe; and no stronger proofs that such is the case are required, than the physical and articulate expressions of agony which the most patient sufferers from this malady present to us. Nothing can exceed the distress depicted upon the countenance during a paroxysm, and the language is by no means extravagant, or hyperbolic, when patients designate their sufferings as acute and severe beyond endurance—as excruciating, agonizing, fearful, horrible; expressions, all of which I have again and again heard from individuals labouring under the *tic douloureux*.

Neuralgic affections are also frequently attended with local determinations of blood to the part, with, probably, increase of arterial action. That nerves do in reality influence the capillary circulation, as the minute extremities of the arterial tubes are often denominated, is a point which has been elaborately, but somewhat diffusely, argued by Mr. Swan, who decides in the affirmative; and there is, in fact, no dearth of evidence of the effect of nervous influence, even in the most healthy condition of the nervous system, in increasing the activity of the arterial circulation. A hint, or an indelicate allusion, which affects the sensitive mind of a delicate female, calls a blush upon the cheek, and is followed by a sense of heat. She is conscious of the change, and literally feels that she blushes. The consciousness of this adds to her embarrassment; the action of the vessels of the face and neck is still further increased,—“she blushes up to the eyes,” and her whole neck is suffused with redness; her cheek and neck also burn with heat; and at length, upon some occasions, the vessels unfold themselves by pouring out a partial, though often a copious, perspiration. In these cases the moral impression must be upon the

nerves; and what is here observed in a state of health, is also manifest in a diseased condition. The existence of such local determination of blood to parts which are the subjects of painful affections of the nerves, has been established by the concurrent testimony of most writers upon these diseases; but by none has it been so explicitly stated as by Mr. Earle, in his valuable and instructive paper, “On the Influence of the Nervous System in regulating Animal Heat.” He exemplifies it in an instance of a painful condition of the nerves of the forehead and face, in which “there was a well-defined red line in the whole course of the supra-orbitary nerve, accompanied with so much heat as readily to evaporate any cold water which was applied.” And he further thus sums up the result of his extensive experience:—“In no case, perhaps, is the effect of a local determination of blood more marked than in the *tic douloureux*. In every instance of this distressing malady which has fallen under my observation, during each paroxysm of pain there was an evident increased flow of blood to the part, accompanied with an increase of heat, more or less perceptible*.”

The result of this local determination of blood to a part is a corresponding increase of temperature. This is incidentally noticed by Mr. Swan, but minutely considered by Mr. Earle, who ascribes it to some direct influence of the nervous system unconnected with the arterial circulation. He states this explicitly with respect to the coldness from defective nervous energy, in which “the circulation of the blood has been apparently *unaltered* either in degree or quantity;” and thus countenances by the argument *e converso*, that increased nervous energy causes an increase of temperature also by some direct influence upon the evolution of animal heat, unconnected with the arterial circulation; or if the two have any relation to each other, this eminent surgeon is disposed to think that “the principle of vital heat is the result of the action of the arterious blood on the nerves,” rather than of the action of the nerves upon the capillary circulation. With the utmost deference, however, to one who deserves so well of his profession, I may be permitted to doubt the accuracy

d'énergie, lorsqu'on vient à le tirailler de nouveau.—Anatomie Générale, tom. i., p. 163.

* Bell, in Cooke on Palsy, p. 98.

† Bell's Operative Surgery, vol. ii. p. 330.

of this opinion; and this without casting the slightest degree of discredit upon the interesting experiments of Sir B. Brodie and Dr. Davy, whose accuracy and fidelity are unquestionable. All chemists agree that the capacity for heat of arterial blood is greater than that of venous blood; and the inference is obvious, that in the transition from arterial blood to its venous state, which takes place in the capillary circulation, the capacity for caloric is diminished, and latent heat therefore evolved. In the experiments of Mr. Brodie, no disengagement of heat took place during artificial respiration, because the functions of secretion, and more especially of assimilation, were deranged or suspended in consequence of the annihilation of that nervous energy which is required for these operations of the economy. It is in evidence, then, that in cases of morbid excitement of nerves, there is "a local increased action of the blood-vessels*," "an increased flow of blood to the part†," proved by the well-defined red line in the whole course of the nerves affected; there is "*fièvre au moins locale*‡." It is further known, that it is in consequence of the change of capacity for caloric, which takes place at the moment of the transition from venous to arterial blood in the capillary circulation, that animal heat is extricated; and it is quite intelligible, therefore, how an increase of the arterial circulation should evolve an additional quantity of animal heat. But it is neither proved nor attempted to be explained how an increase of nervous influence, unconnected with the circulation, should produce that effect.

Another consequence of the increased flow of blood to the part is some degree of swelling, with frequently increase of secretion. When the ophthalmic branch of the fifth pair is the seat of neuralgia, during the paroxysm, tears will flow in abundance from the eye upon that side, the lachrymal gland deriving its nervous energy from that source. Mr. Swan has advanced, in proof of the existence of a local increased action of the blood-vessels, "the appearance of the parts to which the affected nerve is distributed, and frequently the increased secretion of

saliva when the nerves distributed to these glands are implicated*;" and in the case of "severe nervous affection after a punctured wound of the finger," related by Mr. Wardrop†, the skin of the finger became "so acutely sensible, that she could not bear it to be touched; even the dread of any thing coming in contact with it would make not only the finger but the whole hand flow with perspiration."

[To be continued.]

DECUSSION OF THE POSTERIOR CEREBRAL COLUMNS.

[Communicated by SIR CHARLES BELL.]

Brook-Street, Jan. 3, 1835.

DEAR SIR,

SOME time ago I had the base of the brain from Mr. Owen, for the purpose of investigation. I return you the same, having made a dissection to shew the posterior roots of the spinal nerves in their relation to the posterior column of the cerebrum.

In this preparation you will see the union, decussation, and divergence, of the two posterior columns, and the continuance of their filaments into the spinal nerves.

I hope you, or Mr. Owen, will be so good as to let the members of the College who visit you see it; and pray point out to them, that the descending processes of the cerebellum have nothing to do with this decussation. It is only by entertaining this mistake, that any one can be led to say that there is no union of the columns.

I wish to let my anatomical friends at home see these dissections, so that they may not, as on former occasions, withhold their assent until the observations are confirmed by foreign authorities.—I am, dear sir,

Yours truly,

CHARLES BELL.

To Mr. Cliff,
Senior Conservator of the Museum of the
College of Surgeons.

PUFFING OF THE UNIVERSITY HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

I SHALL be much obliged by your inserting the following observations in your valuable pages, as they are the result of experience, and written with the intent of contradicting and exposing a stupid calumny in the last number of the *Lancet*.

The fabrication to which I allude is contained in a *notice* of the London University Hospital, which the writer recommends in no measured terms; while, doubtless from a love of justice, he then abuses all the other London hospitals.

The following passage I shall select, as it forms the pith of the falsehood, and I do not think it necessary to give any specimen of the abuse:—"At the Middlesex, St. George's, and other metropolitan institutions, the pupils have long been denied the opportunity of visiting patients, unless in the presence of one of the medical officers."

Now, did I not actually know that the plausible impudence of this artful deceiver had succeeded in some instances in misleading young students just arrived from the country, I should not have wasted either my time or my ink on the subject. Experience is ever our best guide; and medical students ought to be convinced only by their own eyes. I am myself a pupil of St. George's Hospital, and although I have regularly attended both its medical and surgical practice for a considerable period, yet I *never* met with the least obstruction in gaining admission to the wards whenever I wished; and when I visit the hospital, I constantly see the more diligent pupils questioning patients, although neither physician nor surgeon be present. This is a matter of fact, incontrovertible, and therefore requiring only to be stated.

I will now give you another case. A friend of mine, who is a pupil of the *London University Hospital*, wished to investigate a case; but on entering the ward for that purpose, he was civilly informed by the nurse that she had *express orders not to allow any one to examine cases, unless in the presence of*

the physician or surgeon. Here, then, we have a very pretty editorial blunder. Mr. Wakley has actually accused others, in order to puff the London University Hospital, even when the said hospital is itself guilty of what he has *falsely imputed* to others.

I will venture to give Mr. Wakley a little advice. Let him refrain at present from writing any further puffs for the London University; and on his next visit to the establishment which he honours with his patronage, let him examine the branches as well as the root of that institution, that he may so frame his account of it as to have at least the semblance of writing to afford information, and not merely to serve a party purpose.

But I have yet another circumstance to mention, which I think will fully expose the absurdity of Wakley's puffing as regards the London University Hospital. I find on inquiry, that no pupil can ever hold the office of dresser, unless he has entered *PERPETUAL* to that hospital! This is liberality with a vengeance! Only think how the future mass of surgeons emanating from this not-to-be-equalled establishment will shine when endeavouring to put on a bandage!

A friend of mine asked my advice as to what hospital he should attend; he thought of the London University Hospital: but I told him, after duly considering the advantages *offered* to the medical student there, and comparing them with those which were *certain* in the other London hospitals, it seemed to me that the latter possessed very great advantages *ever* the former—namely, a far greater variety of cases; more accidents of every kind; more operations; and though last, by no means least, both physicians and surgeons of far greater experience in their hospital duties.

I fear it may but too fairly be argued, from the uniformly boasting addresses delivered by the learned professors of the London University at the commencement of the medical session, that they themselves are favourers of the degrading system of puffing adopted towards them in the *Lancet*.

Now, sir, if the professors of the London University really deliver the most valuable lectures in the world, and their hospital, small as it is,

be the very best in the universe, they surely need not have recourse to this eternal puffing, but be content, as in other establishments, to rest upon their merits.

Hoping the contents of this budget may prove beneficial, I am, sir,

Your obedient servant,

A PUPIL OF ST. GEORGE'S
HOSPITAL.

January 6, 1835.

[The writer of the above has sent his name, as a guarantee for his accuracy: he also mentions, in explanation of his quoting the same portion of the *fabrication* which we gave last week, that he had not received the *GAZETTE* when he penned his letter.—*ED. GAZ.*]

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégér.”—D'ALEMBERT.

Aufsätze und Abhandlungen aus dem gebiete der Medicin, Chirurgie, und Staatsarzneikunde. Von Dr. J. N. RUST, &c. &c. Erster Band. Berlin, 1834. Schloss.

(*Memoirs and Essays on subjects connected with Medicine, Surgery, and State Medicine.*)

THIS is a selection from the numerous papers published by the author in various journals for the last twenty years. He has an aversion, he says, to posthumous works, and prefers gathering together his scattered property, and presenting it to the public in an authentic form, rather than to leave this to be done, perhaps injudiciously, by others hereafter. Much tact is displayed by Dr. Rust in the arrangement he has adopted; for he has contrived, by the skillful disposition of his materials, to construct quite a systematic work; and he is practical throughout. “Here,” as he says himself, “the reader finds me wholly devoid of hesitation or reserve, just as I think and act at the bed-side of the patient.”

The volume, we have no doubt, will be very acceptable to our surgical brethren, as the subjects treated in it chiefly belong to their department; but general medical readers will also be much interested with certain parts, such

as the able paper on Animal Magnetism, the essay on the Influence of Diet, and the author's views on Clinical Instruction: in the latter we observe there is a full account of the organization of the hospitals of Berlin.

Wanderings in New South Wales, Bataria, Pedir Coast, Singapore, and China: being the Journal of a Naturalist in those Countries, during 1832, 1833, and 1834. By GEORGE BENNETT, Esq. F.L.S. Fellow of the Royal College of Surgeons, &c.—2 vols.

MR. BENNETT is known to the readers of this journal as the author of various highly-interesting papers on natural history. The volumes before us do credit to his previous reputation, and evince a great degree of zealous perseverance in the pursuit of his favourite objects, as well as a clear and lively style in detailing the results. The volumes contain much general information on the state of New South Wales, and the other countries visited by the author; but it would be foreign to our legitimate calling to enter upon these, and we must content ourselves with recommending them to general perusal.

Some curious medical matters are scattered through the narrative, and these we shall cull from time to time as we can afford space.

MEDICAL GAZETTE.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

POISONING, AND ITS PROOFS AFTER A LENGTHENED IN- TERMENT.

WE commit to our pages, in the present number, the whole of the medical evidence given at the late inquest at Bristol. The details, in our judgment, are unusually interesting and valuable. Nothing can be more satisfactory than the mode in which the proofs, pathological and chemical, were adduced;

and the facts of the case seem to have been as clearly established as they could be were the deceased only interred a few short weeks ago. *Fourteen months*, however, have elapsed since the poisoning was effected.

The first step of the investigation,—and that not the least important one—was conducted with the requisite caution and ability: the identity of the party disinterred was fully ascertained. The coffin, it was proved, had not been meddled with, from the time the undertaker screwed down the lid, until the same man unscrewed it again at the inquest; nor had the grave been disturbed. The body, though externally much decomposed, was yet to be recognized, by the stature, hair, teeth, and the *initials* worked on the stockings. Whether it be customary to bury in pauper coffins with stockings on the corpse, we know not; but it was surely a singular accident—shall we call it oversight?—in the present instance; as if nothing was to be left wanting to render the circumstances leading to detection complete. In short, the body disinterred was identified as that of a female aged about sixty, who had lodged with the person now accused of her murder. In the body, as we shall presently see, were found abundant proofs of poison. The general evidence tends to shew that the prisoner, against whom a verdict of wilful poisoning has been brought in, had shortly before the death of the old lady administered to her a basin of gruel; that certain symptoms, since recognized as those of poisoning, were observed; that the whole affair was more than suspicious; that there were motives to tempt to the crime, in the wealth that the deceased was possessed of; that wealth did seem suddenly and unaccountably to accrue to the prisoner after the death of her lodger;—all this, with much more of the same kind, was testified

in the circumstantial and moral evidence. We merely mention these facts generally, as, in the few remarks we have to offer, we wish to confine ourselves wholly, if possible, to the points ascertained through the professional witnesses: we only look to the proofs adduced of violent death—of death effected by the ingestion of a particular poison. With the question, by what hand that poison was administered, we have nothing to do; being anxious simply, in the brief notice which we can give of the case, to set forth the services tendered in it by medical science, as the assistant of justice, in the exposure of crime.

The external examination of the body was, perhaps, as complete as was absolutely necessary. We suspect, however, that our French brethren would not have been content without taking a *sketch* of the *appearances* after a fourteen months' disinterment. Whether our friends in Bristol were equally on the alert, we cannot pretend to say; but we would suggest that, in the event of their not having been so, they should secure some graphic memorial of what they saw, while yet the impression is fresh upon their minds. In this country, unfortunately, little or nothing is known, from actual observation, of the changes effected on the human body after death. That adipocire is formed under certain circumstances, as in the present case, we are all aware; and our attention was first drawn to the fact by the French, many years ago: but how little else do we know of the effects of putrefaction, and how poor a figure would most of us make, were we to attempt, without foreign assistance, to determine, from an examination of the parts, how long any given body had lain in the earth! Being able to solve that problem, however, we should be possessed of another and most valuable element in proving the identity.

The methods of testing for arsenic have been so much simplified of late years, that there are few things in toxicology now more easy: the merest tyro in practical chemistry may readily become competent to detect the presence of the deleterious substance. Yet this must in no measure detract from the merit of Mr. Herapath, who was engaged in the Bristol inquest: he performed his task in a very superior and masterly manner, and so as, we doubt not, to carry conviction to all who witnessed his manipulations. On the supposition that the yellow matter found in the stomach contained sulphuret of arsenic, he tried the reduction process, in the first instance, upon a small portion of it, and speedily procured a metallic crust. To prove that this crust was the metal arsenic, he oxidized it, dissolved the oxide, and dividing the solution into two parts, obtained from one, by the ammoniacal sulphate of copper, the characteristic mineral—green precipitate; and from the other the bright yellow precipitate, by the addition of the ammoniacal nitrate of silver: finally, he precipitated sulphuret of arsenic by a stream of sulphuretted hydrogen gas. Thus, from one and the same portion of the contents of the stomach, the presence of arsenic was proved by no less than five conclusive indications. The *quantity* of the poison in the organic mixture no doubt favoured the facility with which the analysis was effected: but on the whole, the proceedings were, as we have said, masterly, and well calculated to show the remarkable advance made in toxicology in recent times. Had such a case as this occurred half a century ago, it is probable that the examination of the body would not have been even attempted; or if it were, the methods of analysis were so defective as to lead to no satisfactory result. In a learned treatise on Poisoning, published at Stras-burg in 1781, we find the author

gravely advising, that when a body has been interred for some time, and there is a well-founded suspicion that there is arsenic in it—in which case only should the imminent danger of infection be risked—either the whole body or a part of it should be burned, for the purpose of ascertaining the presence of the drug by its alliacious odour: a piece of advice, by the way, involving what are now well known to be two silly errors—the danger of infection in such cases, and the possibility of perceiving the garlic smell from *oxide* of arsenic burnt along with animal matter.

There is, however, one point connected with poisoning by arsenic, which this Bristol case will serve more particularly to illustrate;—we mean the alleged antiseptic property of the mineral. The state of the stomach and bowels of the deceased was, it appears, as perfect as if the parts had been but recently deposited in the grave; and it is said that the formation of adipocire in other parts of the body was owing to the same cause—the presence of the poison. But this latter assertion may safely be doubted: at least there is no sufficient reason for having recourse to an extraordinary explanation of the phenomena, when an ordinary one is so adequate and so obvious. Those parts converted into adipocire were *under water*, and thus exposed for a length of time to the influence usually efficacious in producing such a change.

But the fact of the preservation of the parts containing the poison, and perhaps of some of those adjacent, through the agency of the arsenic, is placed beyond a doubt by the observations made in this case; and it supports, we would add by the way, in a very remarkable manner, an inference made by Dr. Christison, in his Treatise on Poisons. “If, in a case of poisoning,” says Dr. C., “the arsenic be *not discharged by vomiting*, and the patient

die soon, it will act as an antiseptic on the stomach at least, perhaps on the intestines also, while the rest of the body may decay in the usual manner." We have now, indeed, as it would seem, a superabundance of evidence on the subject; for the instances already on record, and noticed by the author just quoted with his usual perspicuity, had already assured us of the certainty of the fact. Our readers may be glad to see one or two of those instances, the first of which we extract the more willingly, as it offers a very striking parallel, in some of its leading particulars, with the case which forms the subject of the present remarks. About the year 1811, "a lady near Bayreuth died of five days' illness, under symptoms of violent general irritation of the alimentary canal. Some months afterwards, a variety of circumstances having raised a suspicion that she had been poisoned by her maid, a judicial investigation was set on foot, the consequence of which was, that the same woman came under suspicion of having also previously poisoned another lady and a gentleman, with whom she had been successively in service. The bodies of the three people were accordingly disinterred, one of them five months, another six months, and the third *fourteen months* after death. In all of them the external parts were not, properly speaking, putrid, but hard, cheesy, or adipocirous; in the two last, the stomach and intestines were so entire, as to allow of their being tied, taken out, cut up, and handled; and in one a sloughy spot was found in the region of the pylorus. Arsenic was detected in two of the bodies."

Another curious example of the same kind is afforded us in an experiment performed by Dr. Borges. A rabbit was killed with ten grains of arsenic, and its body buried for thirteen months in a very moist place. "At the end of this period it was found that the skin, mus-

cles, cellular tissue, ligaments, and all the viscera, *except the alimentary canal*, had disappeared, without leaving a trace; but the alimentary canal, from the throat to the anus, along with the hair and the bare bones, was quite entire*."

Even in the unique seven years' case that occurred not long ago at Lyons†, there seems to have been no small indication of this same antiseptic property being at work; as if, we would almost say, by a providential arrangement to lead to the murderer's conviction. A woman had long been suspected of having poisoned her father, but for seven years nothing sufficiently tangible could be alleged against her, to warrant the interference of justice. At length it was thought expedient to disinter and examine the body; and the parts were found, whether from the nature of the soil, or the peculiar cause of death, in remarkably good preservation. The head, trunk, and muscles, it appears, maintained their natural position; but the thorax and abdomen had given way. Close by the spine, however, corresponding to the position of the stomach, was found a brownish soft mass, from which, by the appropriate application of tests, the medico-legal examiners, MM. Ozanam and Ide, procured ample evidence of the presence of arsenic.

We intended to have added a few words on the morbid appearances in the case at Bristol; but, in truth, Dr. Riley's evidence is so copious, and the observations elicited from him by the Coroner and Counsel so much to the point, that we should only repeat, and perhaps less interestingly, what the reader will find fully set forth in a subsequent page. The whole investigation, indeed, has been highly creditable to our Bristol brethren; the case will, we

* Christison, p. 316, from *Bernt's Beiträge*, iv. 219.

† See this journal, vol. v. page 411.

doubt not, be cited ere long in every part of the globe where medical science is cultivated, and be frequently referred to both at home and abroad, as at once an example of the great importance of medico-legal research, and an illustration of several curious facts connected with the animal economy.

SUPPLY OF SUBJECTS.

THE supplies afforded to the anatomical schools have of late considerably increased, so that both teachers and pupils are now well provided. An investigation into the causes of the late deficiency has been conducted by some members of the Council of the College of Surgeons, with the concurrence of the government. The impression at first was similar to that expressed in the articles lately published in this journal; but we understand that the conclusion to which they have come, and which is likely to be acted upon, is, that while the Bill remains as it is, no change in the manner of working it can be made with any prospect of advantage. It is quite clear that the mortality both in London and Paris was unusually small during the last three months of 1834—a circumstance which in great measure explains the dearth of *subjects*.

WAKLEY AN M.P.!!

To the surprise even of those who were aware that St. Giles's and Saffron Hill are in the borough of Finsbury, but most of all, we believe, to the astonishment of that worthy himself, Mr. Wakley has been returned to Parliament! This singular and rather amusing event has obviously resulted from the palpable want of consistency displayed by the other candidates; a fault which we suppose no one can lay to the charge of the new member;—at least *we* have always found him the same. The utter nothingness of such men in the House of Commons has been proved by the fate of Hunt, Cobbett, and many others; yet indirectly some advantage may possibly accrue, for we presume even the ultra-conservatives will admit that there is a necessity for some reform in a profession which they see represented by Messrs. Hume, Whalley, and Wakley!

INQUEST AT BRISTOL,

ON THE BODY OF MRS. CLARA ANNE SMITH.

Charge of Murder by Poisoning—Report of the Professional and other Evidence.

THE proceedings of this important inquest commenced on Wednesday, the 24th ult., and were continued, with the intermission of Christmas Day and Sunday, until Tuesday evening, the 30th, when the jury delivered in their verdict of Wilful murder against Mrs. Burdock, *alias* Wade.

On Friday the coroner transferred the scene of the inquest to the theatre of the Bristol Medical School, and the first witness examined on Saturday morning gave

Evidence regarding the Morbid Appearances.

DR. HENRY RILEY stated that he went with Mr. Kelson and others to open the body of a female interred in St. Augustine's church-yard. On the coffin-plate, which was partially destroyed by rust, was written "Mrs. Smith," aged 60 odd years; the grave was much deeper than usual for so common a coffin, and there was no water at the bottom; the coffin was made of common elm, such as is used for burials of paupers, and was screwed down in the usual way. On the lid being removed by the undertaker, they saw the remains of a human being; there was some loose earth on the breast and abdomen, which had got in through a slit in the lid, and a considerable quantity of water, which covered part of the breast, the abdomen, legs, and arms; the upper surface of the face and neck were above the level of the water; the body had on a shroud, an under garment, a pair of stockings, marked with red thread C. S., and the remains of a cap could be traced on the head. The body clothes were slit down the centre, so as to throw the dirt which had fallen through the opening of the lid on either side; by these means the body was exposed to view; it was that of a thin person; the chest had not fallen in, and there was no appearance of its having been opened. Mr. Kelson and witness then opened the chest and abdomen, by cutting through the cartilages of the chest and ribs on either side of the sternum, continuing the incisions downwards; thus the chest and abdomen became fully exposed. They found that all the parts which were below the level of the water were turned into adipocere; the external surface of the stomach and intestines appeared of a pale bluish colour; there did not appear any traces of disease or inflammation of the peritoneal surface of the abdomen; he did not think that there was any water in the latter cavity until it flowed into the thorax,

and thence into the abdomen, at the time of opening; they next took out the whole of the intestinal canal from the œsophagus downwards, and placed the different parts in separate vessels; in separating the small intestines from the duodenum, they noticed a considerable quantity of a yellow substance covering the mucous membrane of the latter, and were surprised to find that the whole of this canal presented such an extraordinary degree of firmness, and was so slightly decomposed; it was as firm as that of persons who died in an ordinary way, and who have been dead but a few days; the liver had shrunk to a fourth or fifth of its natural size; it was not thicker than his hand; the pancreas presented nothing peculiar in its appearance; the lungs had collapsed, and were reduced to a fourth of their volume; they were of a dark colour, approaching blue or grey; he did not see any thing like tubercles in them, nor any thing peculiar with regard to the pleura, nor did he observe any adhesions; the heart was collapsed and shrunk, but there was no appearance of disease in it; the diaphragm was little changed, and perfect. Witness cut off the head, for the purpose of identity by the teeth. The stomach and alimentary canal were removed to the Medical School for examination; there were yellow spots in several parts of the peritoneum; they were of a bright yellow colour, identical with that alluded to as being seen on the mucous membrane of the duodenum; they were in the largest quantity on the stomach, and also visible on the upper part of the intestines, and were besides visible in one or two places on the mesentery; where the spots were seen outside, they were also traced internally, as extending through the whole substance of the intestines; the mucous membrane of the stomach was firm to an extraordinary degree, and there were no ulcerations upon it; the dark red colour it presented might either proceed from intense inflammation or from decomposition; he inclined, however, to the opinion that it was the former, otherwise the membrane could not have been so firm; the greater portion of the spots were near the pyloric extremity of the stomach; the yellow matter was spread over the whole mucous membrane of the stomach as well as the duodenum; it could be scraped off in large quantities, and especially from the stomach; the matter most resembled in colour sulphuret of arsenic, commonly called orpiment; he did not think that it arose from an infiltration of bile; the mucous membrane of the jejunum presented the same dark colour; it was equally firm with the other parts; traces of the yellow matter were also seen in this portion of the intestine; in the great intestine the

mucous membrane was of a very dark red, it was extremely firm, and spotted of a dark slate colour, particularly so in the neighbourhood of its upper part of the near ilio cœcal valve; it had no yellow spots or ulcerations; the appearances of this intestine were such as are commonly found in cases of chronic diarrhœa of long standing; the slight change it had undergone was as striking as that of the stomach; in the latter and duodenum he saw little else but this yellow substance; in the smaller intestines there was a small quantity of brownish fluid, something like cocoa. He attributed the firmness of the intestinal canal to some antiseptic substance, and sulphuret of arsenic was said to be so in a very great degree; he did not mean to say that there were no tubercles in the lungs, but merely that he did not see them; the dark slate colour of the mucous membrane of the intestinal canal is said by the French pathologists to indicate chronic inflammation.

Cross-examined by Mr. PAYNE (counsel for the defence).—A chronic inflammation would certainly occasion death, and it might have occasioned a gripping pain in the side. Witness had not seen much of the effects of arsenic on the human body, that is, to the extent of death; the sulphuret has the same general effects as the white oxide of arsenic; the old opinion was that they did corrode, and the modern one that they do not; he was convinced that the yellow spots on the stomach penetrated from the inside to the outside; witness has never seen a person killed by taking arsenic; it was used in cases of cancer, and some others, as cutaneous diseases, fevers, &c.; it was never administered in this country as orpiment, but when combined with an alkali, and it was then called Fowler's solution. This was the first stomach poisoned to death by arsenic that he had seen; none but a rogue or a madman would administer arsenic in so large a quantity as had been found in this stomach by Mr. Herapath; if any medical man had done it, he would deserve to be hanged. In administering Fowler's solution they proceeded with the greatest care; if arsenic were exhibited, they would expect the appearances found in this old lady's stomach, and he felt as confident as that he sat there that her death was occasioned by arsenic; the grave in which she was interred was a deep one for so poor a coffin; in some cases graves were eight or nine feet deep, and from the number buried in them the last body did not probably lie more than two feet from the surface—a very unhealthy and abominable practice.

Dr. Riley was, in a subsequent part of the proceedings, recalled, when he de-

scribed the effects of Fowler's solution as distinguished from the opiment that had been administered in this case; the effect of arsenic when taken in over doses, would be an inflammation of the mucous membrane of the intestinal canal, accompanied with great emaciation and debility, loss of hair, and occasionally of the nails. He had heard the evidence of the girl, Allen, and his opinion was that the deceased had been labouring under a most violent pytalism, because the membrane of her mouth had been stated to be swelled, ulcerated, and bled extremely; she spit blood, and her cheeks and lips were swelled; he was not aware that pytalism was the result of an exhibition of arsenic; he did not mean that it would not produce pytalism, but he had not seen it; he thought it most likely that the pytalism was brought on by taking mercury; he did not doubt it the least in the world that arsenic produced death in the present instance. He never saw a case of death occasioned by arsenic in small doses, taken as Fowler's solution; has seen symptoms produced by it short of the loss of hair and nails, such as sickness and loss of appetite; as arsenic becomes oxidized, it is hurtful; the white oxide is used extensively to preserve birds.

Chemical Evidence.

WILLIAM HERAPATH.—Is Lecturer on Chemistry and Chemical Toxicology at the Bristol Medical School; was applied to on Monday last, the 22d, to examine the body of the deceased; undertook to do so, and to analyse the contents of the stomach; was present during the whole of the time of the disinterment, and the taking out of the viscera in St. Augustine's Church-yard; received them from the hands of Dr. Riley and Mr. Kelson, the medical gentlemen employed; placed them separately in two basins, which had been carefully wiped clean by himself—the stomach and duodenum in one, and the intestinal canal in the other; the stomach was whole, there was no orifice, and no loss of any of its contents worth noticing; tied up the basins with their contents in a cloth, and gave them to a man to carry to the Medical School; never lost sight of him the whole way. The appearance of the body in the church-yard was such as to lead witness to believe that it had been under the influence of an antiseptic; the body was, generally speaking, rapidly passing to a state of animal soap, or adipocere; the stomach and intestinal canal were in an unusual state of preservation, so much so, in fact, that upon seeing the viscera opened, he exclaimed, "This looks like the effects of arsenic;" as it is a well-known fact that that poison has the effect of preserving the parts contiguous to it;

and tends to assist the changing the other parts into adipocere. Upon receiving the parts, witness invited all those who were interested in the case to accompany him, as he intended to operate in public; the Solicitor, and three medical gentlemen employed by the accused, accompanied witness, with many others, to his own theatre, at the Medical School, where he put a new deal board on the lecturing table, and placed on it the stomach, which was still entire, with the exception of two small cuts which must have been made in taking it from the body; witness slit it open with the scissors, and found a great portion of it thickly covered with a yellow pasty matter, looking like wet clay; all the apparatus used by witness was either entirely new, or had been carefully cleaned by him previously. As he was strongly inclined to think this powder was sulphuret of arsenic, he proceeded to treat it as such; he separated a small portion of the yellow substance with the spatula, absorbed the moisture on blotting paper, and then dried it; witness mixed it with a certain proportion of carbonate of soda and charcoal, both well dried, and put the whole into a reducing tube, and immediately sublimed metallic arsenic; this metallic arsenic was made the subject of the other experiments: witness first heated it, allowing the air to enter the tube, and it became oxidized, and sublimed into a white crust; this formed the second test of the presence of arsenic. Witness then introduced two drops of water into the tube containing the white crust, and with heat dissolved it; these two drops were made the subjects of two experiments. Into one he put a minute portion of ammoniacal sulphate of copper, and immediately found the green precipitate of Scheele, or arsenite of copper; into the other drop he put a minute portion of the ammoniacal nitrate of silver, and the yellow precipitate of the arsenite of silver fell. He had thus four tests of the presence of arsenic; it only remained to be brought back to its original state by passing a stream of sulphuretted hydrogen through the arsenious acid; this he did, and obtained the beautiful yellow of the sulphuret of arsenic; he had gone through these experiments four different times, and all with the same results. He next attempted to discover what quantity of the yellow substance there was left in the stomach; there was nothing of any importance in the stomach besides; he inverted the stomach into water, and washed its internal surface; he allowed the yellow powder to subside, and filtered the fluid so as to separate the yellow matter; in doing so he found that certain portions adhered to the internal surface of the stomach, and in two spots an infiltration had taken place

into the substance of the stomach itself; the quantity collected could not be well separated from the filtering paper, on account of the animal matter; the nearest estimate by weighing, and counterpoising an equal sized piece of paper, gave seventeen grains as the weight of the substance and animal matter. To get rid of the animal matter he introduced (taking away four grains for the purpose of other experiments) the paper and its contents into a flask with nitric and muriatic acids, and boiled it till every thing was either decomposed or dissolved, except the fibres of the paper; and next filtered and extracted the whole of the fluid, and then precipitated the arsenic by means of sulphuretted hydrogen; the thirteen grains yielded witness four grains of sulphuret of arsenic. There are but two metals that will give the yellow precipitate with sulphuretted hydrogen; the one is cadmium, which is exceedingly rare, scarcely ever to be met with in this country; he had about half an ounce of it, which he should think is more than there is in all the kingdom besides; the other is the peroxide of tin, which is also scarce, and is not used at all as an article of commerce or medicine, and in this case could not possibly exist.—(Mr. H. then shewed to the jury the matter which had been taken from the stomach, and which had produced the yellow precipitate, or sulphuret of arsenic; and also specimens, in sealed tubes, of the action of all the other tests. The stomach itself was also exhibited, and the yellow spots were very apparent, and some of the yellow matter still adhered to its coats.)

By the CORONER.—He believed there is no well-authenticated case of how much sulphuret of arsenic will destroy life; the quantity will differ with the proportion of the materials used in manufacture; native orpiment is not so poisonous as the fac-titious; it is possible that it might have been swallowed in the form of white oxide, or arsenious acid; arsenic is in common called "white" or "yellow" arsenic, and would be sold by druggists under those names; white arsenic is chemically called arsenious acid, and yellow arsenic, sesqui-sulphuret of arsenic; they are both poisonous, but not equally so; white is the most poisonous; all compounds of arsenic are poisonous; the operation of each is nearly similar. He had never seen a stomach operated upon by arsenic before; should think the yellow spots were caused by the rapid operation of the arsenic suspended abruptly by death; if they had taken place after death, they would, in his opinion, have been as generally extended as the sulphuret itself; both sorts of arsenic are very cheap; he had not the slightest doubt of the nature of the poison found in the sto-

mach; he could stake his existence on the fact of the presence of arsenic in the stomach and intestinal canal; cannot say in what state the arsenic was taken; the process of decomposition sometimes produces sulphuretted hydrogen, which would convert white arsenic into orpiment; that found in the stomach is orpiment; cannot positively say in this case whether sulphuretted hydrogen had been produced, because adipocere was formed, and the decomposition of the body did not proceed as is usual; he was certain arsenic could not have been introduced after death, as the stomach was whole when it came into his possession; witness's attention was first arrested by seeing a small drop of yellow matter ooze from the stomach; the great quantity of yellow substance in the stomach struck him at once that he should find a mineral poison. He observed no bile in the stomach; there was nothing of importance in the stomach; if there had been bile he must have seen it; he was certain there was no bile.

Cross-examined by Mr. PAYNE.—Sulphuretted hydrogen might enter into the stomach from other parts of the body, although there was no orifice; he thinks the yellow spots were produced during life; he had not seen many stomachs that had received poison; he had frequently the contents of stomachs sent to him to analyse; in the stomachs he had analysed he had never met with any arsenic; this is the first, and he hoped it would be the last; this matter in the paper and the tube are both from the stomach; it is the same as is sold in the shops for yellow arsenic; should think that the four grains he reserved, and what adhered to the coats of the stomach, with what he worked off, would yield $\frac{1}{2}$ or 6 grains of the pure sulphuret of arsenic from the stomach alone.

Mr. KELSON was then called, but stated that he was not aware that he could add anything to Dr. Riley's evidence; it was so clear and ample.

Dr. J. A. SYMONDS, lecturer on Forensic Medicine at the Bristol Medical School, was present at the disinterment of the body of the deceased, and at the subsequent operations. His conviction was, that poison (sulphuret of arsenic) was in the stomach and intestines; he had never seen the body of a person who had died from arsenic before; the effects of an overdose of arsenic would be extreme purging. Hahnemann, a German physician, states that two grains of white oxide of arsenic will destroy the life of an adult; the smallest quantity, in an actual well-authenticated case, is four grains; it is recorded by Zittman. Professor Christison, the first authority in this country, says four and a half grains have killed, and

mentions the case. M. Guibourt, a French chemist, states the analysis of artificial opopment to consist of 94 parts of arsenious acid and 6 of sulphur; this analysis is confirmed by Orfila; ordinarily a poisonous dose would operate in half or three-quarters of an hour; it varies with circumstances—it may operate much earlier.

[This was the whole of the medical evidence: we give the following extract from the testimony of the chief witness for the prosecution, as it serves to describe, in some measure, the symptoms attending the death of the deceased.]

Evidence regarding Symptoms.

MARY ALLEN, aged about 16, had been engaged to wait on Mrs. Smith. On the second night of her attendance, the deceased was ill, and drank a quantity of cold water. Mrs. Burdock came up, and asked how she felt herself, and if she would take gruel; to which deceased replied she was very poorly, but did not want any thing, and wished to be left alone. Mrs. Burdock added, "you had better take a drop of gruel; I will make you some, do you take it, there's a good soul." She then went down stairs, and in a quarter of an hour brought up some gruel in a very small half-pint blue basin; it was given to deceased in bed; her pains were dreadful, and she was very ill; the gruel was of a bad colour—of a reddish appearance; the deceased drank about half of it, and then placed the basin in a chair, whence it was removed by Mrs. Burdock; deceased spit thick blood into the chamber utensil, but did not cough or make any complaint. On Mrs. Burdock asking deceased how she felt herself, she said "go along, and leave me alone." The former then turned round to witness and laughed, and sat down at the table near witness, on which she asked her if she had not better fetch a doctor? Mrs. Burdock whispered, "No, she won't have a doctor—what! have a doctor to kill her; no!" Deceased was very ill, rolling about the bed; but after a short time she became quiet, having lifted herself up, and struck her head against the head board. Mrs. Burdock went towards the deceased, saying, "well, I think she is going to sleep now; she is going to be quiet a bit; do you think I had better sit up, or not?" Witness said she had better, and soon after went to the bed-side, and looked at the deceased, observing to Mrs. Burdock she thought she was asleep, and they would not disturb her. On again going to the bed-side, and placing the back of her hand to deceased's cheek, she exclaimed, "La! she is dead." Mrs. Burdock said, "La! come and sit down; don't make thyself a fool; if thee do'st go there, she will grab hold of thee."

Witness then lifted up a hand, and found that life was extinct; she called Mrs. Burdock to come and see if it were not the case, who, on ascertaining it to be so, exclaimed, "Lord, my God, she's dead! what shall I do to bury her?" The latter went down to inform her old servant, Mary Evans, of the fact, who answered, "Oh! she's dead, is she?" Hot water was then prepared to wash the body, in laying out which witness assisted. * * * * Witness thinks deceased must have died between twelve and one at night, and at the time when it was observed she lay so quiet; as the corpse was cold on being laid out. Deceased lay down about five minutes after taking the gruel, and in half an hour was taken very ill; she was not sick at all, but spit blood.

PATHOLOGICAL LECTURES,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

In the preceding lecture, I described the morbid alterations which are met with in the medullary and efferent substances of the brain and spinal marrow, and in the pia mater, arachnoid, and dura mater; and I commenced the description of the symptoms produced by injury or diseases of these organs, and the exposition of the points of structure, upon which those symptoms may reasonably be supposed to depend. The symptoms of deranged function, which have their immediate source in the spinal cord and medulla oblongata, may be considered under nine heads.

1. The cerebral masses, when in certain states of disease or other lesion, are capable of communicating a paralyzing influence, or palsy-shock, to the cord and medulla oblongata; the consequence of which is, that the nerves arising from these parts cease to minister to sense and voluntary motion. In the preceding lecture I have advanced facts which seem to establish this conclusion.

2. When one hemisphere only, either of the cerebrum or cerebellum, is affected, the palsy shock thence produced is transmitted through the decussating fasciculi of the anterior pyramid of that side, to the opposite side of the spinal marrow at its junction with the medulla oblongata; and from this point its influence may extend either downwards to the spinal nerves, or upwards to the lower cerebral nerves, or simultaneously in both directions. The ar-

gument to establish these points is to be found in the preceding lecture.

3. All the parts of the central organs of the nervous system, in vertebral animals, depend, for their participation in the functions of consciousness, upon their physical continuity with the medulla oblongata. Applying this principle to the study of lesions of the spinal marrow, it becomes intelligible how rupture of the spinal cord, or pressure such as to crush its substance at any part, are causes sufficient to produce and to explain the extinction of sensation and voluntary motion, which is observed to occur in such cases, in all the parts supplied with nerves from the portion of the cord below the seat of injury.

4. The spinal cord contains as many integral segments, as there are pairs of nerves arising from it. These segments reciprocally influence each other, and are, to a certain extent, capable of co-operation even when the transmission of impulses from the brain is rendered impossible, and (which is more surprising) when the influence of the medulla oblongata is excluded. These segments are, nevertheless, essentially independent of each other. The destruction of one or more of them does not interfere with the powers of those which are left, even when the destroyed ones intervene between the latter and the medulla oblongata. Softening of the interior of the cervical part of the spinal cord, may thus be attended with palsy or contraction of the arms, while sense and voluntary motion remain unimpaired in the legs. One condition, however, is requisite to enable the part of the cord below the disease to preserve its functions. A certain quantity of sound, or but slightly altered, nervous substance must extend across or through the diseased part, to maintain the communication between the medulla oblongata and the lower undiseased portion of the cord.

5. Palsy may be complete or incomplete, sudden or gradual in its progress. When its progress is gradual, its first invasion is manifested at the remotest part of the limb affected; in the upper extremity, for instance, it attacks first the hand, then the fore-arm, then the upper arm. This phenomenon admits of the following explanation:—I have shewn that the palsy-stroke is carried through the decussating fasciculi of the anterior pyramid to the tracts of the spinal cord and medulla oblongata, in which the nerves originate. Now when the palsy-shock is not forcible enough to overwhelm completely sense and motion, it operates to the extent only

of enfeebling those tracts, which are the sources of the motor and sentient nerves. To follow the effect of this enfeebling cause upon the origins of the motor nerves first:—the source of the voluntary impulse, by the hypothesis, is in this case not extinguished, but weakened; it is therefore, when energizing, still capable of throwing excitement upon the muscles, only less of it than before. That lesser quantity of excitement may be enough to fill (to use a figurative expression) a short nerve, but not enough to fill or to stimulate sufficiently, or in the same degree, a long nerve. The palsy has struck the source of motion; the will energizing through that stricken source can determine a small force of excitement only through the nerves. I suppose, then, that a long nerve cannot be excited by that diminished quantity of nervous influence thrown into it, which still is enough to sustain the function of a shorter nerve. The same hypothesis, *mutatis mutandis*, will account for the commencement of anæsthesia occurring in the hand, or in the foot.

6. The failure of the will to excite the muscles in such cases, is properly termed *paralysis*, or *palsy*; the failure of sensation is properly termed *anæsthesia*. When the spinal cord is completely divided, palsy and anæsthesia simultaneously occur in the parts supplied with nerves given off below the division. This case is termed *paraplegia*. But the consequence of lesser injuries, appear, at first sight, to be capricious; sometimes anæsthesia occurs alone, sometimes palsy; sometimes anæsthesia of one side, conjoined with palsy of the other. The key to these varied phenomena is to be found in Magendie's discovery that the anterior fasciculi of the spinal cord, with the nerves proceeding from them, belong to motion; the posterior fasciculi, with the nerves proceeding from them, to sensation.

7. It has not as yet been satisfactorily explained why, as a consequence of disease of the brain, palsy is much more frequent than anæsthesia; why, when the two exist combined, the palsy is commonly greater in degree than the anæsthesia; why, if the patient recovers, the part stricken regains its sensibility faster than its power of motion. Are we to suppose that this difference is in the nerve, or in the organ in which it rises? Is the organ which gives origin to a sentient nerve, less easily stricken—has it more resistance to the depressing shock,—than the organ which gives origin to a voluntary nerve? or has the sentient nerve an easier office, and one which it therefore performs under greater disease, than a voluntary nerve its own? The following facts render the first hypothesis the most probable.

* The reader to whom the physiological principles assumed in these lectures may be new, will find an exposition of them in my *Outlines of Physiology*.

At the time that I was engaged in the experiments through which I discovered that the facial branches of the fifth are for sensation only, and those of the seventh for each kind of motion, I ascertained the ratio of their functional restoration after division. I found that the *process of reunion* in both these nerves is the same, but that the period of the *return of their functions differs*; sensibility shewing itself on the fifteenth day, motion not commencing till the twenty first. I conclude, from the experiments referred to, that to transmit sensation is easier to a nerve than to transmit the stimulus to muscular action; and that this difference accounts for the greater frequency of palsy than anaesthesia. It does not seem to me a valid objection to this explanation, that numbness of an extremity occasionally precedes palsy. The fact, however, deserves to be well borne in mind, as capable of giving, in practice, an important warning of a contingent danger. It may be variously explained. Perhaps its origin is indirect, and to be sought for in the following facts.

8. The palsy blow upon the cord extends an influence to agitation or organic life. A gentleman, 80 years of age, was smitten with weakness of the left side of the face, and left arm and hand: the left leg was not weakened by the imperfect palsy stroke, but it was extremely cold when examined as he lay in bed, the right leg being warm. Is it possible that this coldness, the result of the lowest degree of palsy, should produce secondarily (as cold often does) any degree of numbness? The lowering effect of the palsy-shock on organic life, is strongly shewn in the feebleness and irregularity of the pulse, as well as in the failure of nutrition which it occasions: a proof of the latter is, that the skin inflames and blisters more readily in anaesthesia than under natural circumstances.

9. I have hitherto considered symptoms, which manifest depression of power; but lesions of the same organs are not less liable to produce excess of excitement. The voluntary nerves, in this state, carry inordinate stimulation to the muscles, which are then affected with spasms, either continued or *tonic*, or intermitting or *clonic*. The nerves of touch, on the other hand, may become acutely alive and sensitive, and communicate sensations of the acutest pain.

As a general rule, it will be found that affections of the substance of the brain, or of its cavities, or of the substance of the spinal marrow—such as hæmorrhages, serous effusions, inflammation; or such external effusions or formations as produce partial compression of the substance of these organs—tend to cause palsy, or anaesthesia; whereas ordinary affections of

the membranes rather excite than depress, irritate instead of paralyzing, and give rise to pain, or spasm, or both.

But through what channel are exciting impressions from the brain carried to the spinal cord? I am hardly prepared with facts at present to enable me to come to a satisfactory conclusion upon this subject. I think that I have often seen, in injury of one hemisphere of the brain, convulsive movements of the *same side* of the body, combined with palsy of the opposite side. On the other hand, I have certainly seen weakness of the opposite side, combined with occasional spasms of the opposite side. In the latter case, I see no reason for doubting that the decussating fasciculi of the anterior pyramids are the channel, which equally conveys the exciting as the depressing influence. In the former case, it is natural to conjecture that the exciting influence is conducted along the posterior substance of the *crura cerebri* to the same side of the medulla oblongata.

Let me now proceed to give an outline of the injuries and diseases to which the spinal cord is liable.

Simple *concussion* of the spinal marrow may produce complete suspension of its functions. In a case given by Boyer, complete paraplegia had been instantaneously produced by a fall into a ditch: the patient died. On dissection, no disease could be discovered either in the head or spinal canal. Frank mentions four fatal cases of concussion of the spine, on the post-mortem inspection of which no change in the spinal marrow was detected, or injury of the vertebral column. Instances of this description throw light upon the nature of those cases of more frequent occurrence, in which persons recover after all varieties of palsy and anaesthesia, that have instantaneously followed blows or falls upon the back. In all such cases, however, there is a threefold risk—first, of the palsy being quickly followed by death; secondly, that the concussion (having been attended or not by ecchymosis of the nervous substance) may give rise to disease of the spinal marrow, vertebral column, or both; thirdly, of the palsy being permanent.

There are some remarkable instances of wounds of the spine, that have been recovered from; which, however, perhaps were but bruises of the cord, the theca not having been certainly penetrated.

A young man was struck on the back of the neck with a poniard, three fingers' breadth below the left ear: the wound penetrating obliquely towards the right. Immediate loss of sense and motion of the whole body ensued, the head alone feeling. During the first few days, there was retention of urine and constipation;

afterwards, involuntary discharge of urine. Towards the eighteenth day, feeling began to return on the left side; on the twentieth, the patient could move the digits of the left hand and foot; and feeling and motion of the left side increased daily. On the thirtieth day, feeling began to re-appear on the right side; shortly after, motion. In three months he was so recovered that he could walk a little; the left side, however, having kept in advance of the right. — *Morgagni*.

A drummer of the National Guard of Paris was struck on the back of the neck with the point of a sabre, which was thrown at him: his limbs bent under him, and he fell. The left arm was palsied. This effect was permanent. The left leg was likewise affected with weakness: but this disappeared on the fourth day. On the thirteenth day it was accidentally discovered that the right side of the body, from the fourth rib downwards, had lost its feeling: this anæsthesia was permanent. — *Boyer*.

Simple pressure or division of the spinal cord above the origin of the phrenic nerves, is instantaneously fatal. The lower the injury, the longer is the period the patient may survive, and the greater the small probability of recovery.

When the spinal marrow is cut across, — as by a musket ball, or lance or sabre wound, at or below the lowest cervical vertebra, — or is torn in fracture of the vertebra, the patient may live from two, three, or four days, to several weeks: if the injury is at the lower part of the back, it is possible that he may recover, but with permanent paraplegia. The fatal turn of such a case is marked by the lining membrane of the bladder becoming inflamed and secreting a thick ropy mucus, which imparts a strong ammoniacal quality to the urine: this change is followed, in a few days, by the patient's death.

The cause of this inflammation of the bladder, I conceive to be the interruption of its supply of nervous influence. Thus, when the pneumogastric nerve is divided, the lungs and stomach become inflamed; when the fifth nerve is divided within the cranium, the eye-ball inflames. So it is likewise with the bladder.

A young man died in the Middlesex Hospital after fracture of the third lumbar vertebra: there was palsy of the right leg, and the bladder had inflamed. The only injury to the contents of the theca vertebralis had been a severe bruise of the right fasciculi of the cauda equina; several of them appeared as if they had been pinched; they were bloodshot at the part, and adhered together by lymph.

Inflammation of the bladder is a symp-

tom liable to be connected with any form of paraplegia.

Pressure upon the spinal marrow operates in two ways: one resembles the effect of a ligature or other strong pressure made upon a nerve. It is probable that pressure of this kind made upon the spinal cord by fracture and depression of the bony arches of the vertebrae, would sometimes admit of being relieved by an operation analogous to trephining. But it is no less probable, that if the injury in such a case were so great as to require the operation, it would likewise be too great to be relieved by it. The other mode in which pressure operates is less explicable; there must be some additional element besides pressure to concur in producing the effect.

A woman, ætat. 48, was attacked, twelve years ago, with pain in the middle of the back, and sickness. There were no paraplegic symptoms, but the spinous processes of three of the dorsal vertebrae became prominent backwards. She was received into St. George's Hospital, and was kept in bed a year, with issues on the sides of the projecting spinous processes. She recovered. Six months ago, this patient having enjoyed good health in the interval, was slowly attacked with paraplegia: after a few weeks, there was total loss of voluntary power in the legs and thighs, and numbness from the loins downwards. This was unattended with any pain of the part of the back before diseased. Nevertheless, I applied caustic issues on either side of the projecting spinous processes, and she was not moved from her bed. A little fever gradually supervened: the belly was hard and obstinately costive; the urine was passed involuntarily; the thighs were frequently drawn spasmodically to the belly, the knees being at the same time strongly bent. She sank, and died.

On examining the body, the spinal marrow and its membranes were found free from disease; but there existed in front of three of the dorsal vertebrae a thick sac, covered by the pleura, which contained about two ounces of what I suppose was inspissated pus: it had the appearance and consistence of putty. This rested upon the anterior surfaces of the bodies of the vertebrae, which had been partially absorbed with the intervertebral substance at the former attack, but now were remarkably hard and firm, and their surfaces covered for the most part with strong fibrous membrane.

The preceding case, with so little to produce the symptoms that attended it, may be well contrasted with the following, which exemplifies the opposite extreme.

Renee Alexon, ætat. 38, had experienced, for a long period, pain at the upper and

back part of the neck: any motion,—that of swallowing, or even breathing,—increased it. The neck became drawn backwards and fixed by the instinctive action of its muscles. She died gradually of phthisis, the cough attending which added to her suffering. Some little difficulty of swallowing and of breathing she had experienced, but no palsy or anæsthesia.

On inspection, the odontoid process and the transverse ligament were found to have perished by caries and ulceration. A displacement forwards of the atlas upon the dens had taken place to such an extent that the articular surfaces of the latter were covered on their anterior half only by those of the atlas.—*Ollivier*.

Inflammation of the substance of the cord.—A gentleman, who was liable to epilepsy, complained of uneasiness of the throat, with difficulty of swallowing, accompanied by acute pain in the neck and occiput, followed by fever, embarrassed breathing, and vomiting; he then was seized with numbness of the left hand, which speedily extended up the arm; the right was immediately after affected in the same manner, and on the following day they were both paralytic. The legs were not in the least affected, nor the functions of the bladder or the bowels. He died on the eighth day, having preserved his intellects to the last.

Inspection.—There was extensive softening of the upper part of the cord, chiefly of the grey matter, which was of a rose colour, with a highly vascular state of the membranes.—*Ollivier*.

In another case, with extensive softening at the upper part of the cervical portion, extending nearly through the whole thickness of the cord, there was palsy of all the limbs.—*Ollivier*.

In a case described by Dr. Abercrombie, the progress of the disease was slow, and lasted from October to the July following; the symptoms being coldness and numbness of the feet, with diminished power of motion; after several weeks, complete palsy of the legs, and inability to empty the bladder; tightness across the abdomen; spasms, like opisthotonos. In the intermediate April, some amendment occurred, with the power of moving the legs when supported by crutches. Two days before death, the right arm became paralytic, and his speech impaired. The loss of sensation was never complete.

Inspection.—The whole cord was of a pale rose colour, and was in every part entirely diffuent. The medulla oblongata was softened on its anterior part, as well as the adjacent portion of the annular protuberance.

A young soldier, after recovering from a petechial fever, was affected with pain in the back, difficulty of moving the legs,

retention of urine, involuntary discharge of faeces. The weakness of the legs increased to perfect palsy, in which the upper extremities were shortly after involved; he then lost his speech; and after lying a fortnight in this state, but in possession of his intellects, he died suddenly. At the lower part of the back the cord was in a state of suppuration, dissolved, and disorganized.—*Breca*.

A woman, ætat. 56, was seized with loss of power of the limbs of the left side, without anæsthesia: voice feeble; speech embarrassed; pulse natural; respiration frequent. Death in a week from the seizure.

Inspection.—The brain sound, but the pia mater injected. In the centre of the right half of the cervical portion of the spinal cord there was a cavity, three inches long, by two or three inches in diameter, full of soft matter, like pus; this became more consistent towards the parietes of the cavity, which were about a line and a half in thickness, and formed by the healthy white matter. In the left column of the same portion of the cord there was a like disease, but less extensive, being about one inch long, and one line in diameter: its contents were less purulent, rather resembling softening of the cord. The membranes of the cord were thickened at this part.—*Velpau*.

The additional features of inflammation of the spinal marrow are, contraction of the limbs (either tonic or clonic), sensation remaining,—or with palsy, the sensibility heightened (with hypertrophy of the posterior fasciculi of the spinal nerves being sometimes added),—the extent and character of the symptoms being dependent on the part of the cord attacked, and on the limitation of the changes to either half, and to the anterior or posterior fasciculi.

Portal describes the case of the Marquis de Causan, in whom, in the space of a year, a gradual palsy of the left side, commencing in a prickling of the fingers, had supervened. Palsy of the right side gradually followed; sight, hearing, speech, deglutition, in succession failed. On dissection, the cervical part of the spinal cord was found to be as hard as cartilage, and its membranes were red, as if inflamed.

Inflammation of the membranes of the cord.—A gentleman, ætat. 26, had been liable for several years to suppuration from the right ear, with occasional severe headaches, which were temporarily followed by a considerable increase of the discharge. The first week in April, 1817, he became ill, with headache, disturbed sleep, loss of appetite, but little or no increase of pulse. About the 7th the pain left the head, and attacked the neck; it gradually moved down the spine, at the lower part of which,

after several days, it became fixed, being more severe at this part than it had before been when occupying the upper part of the neck, and extended round the crests of the ilia, with great uneasiness of the belly, and pain and difficulty in passing the urine. On the 15th, great increase of suffering, under which the patient was continually walking about, grasping the lower part of the back with his hands; repeated rigors. On the 17th, convulsive twitches of the face; difficulty of swallowing; squinting, not permanent; pulse from 120 to 130. After bleeding from the arm, he appeared relieved, and lay down in bed; he soon rose, and became delirious and unmanageable; then threw his head back, fell into a state of coma, and died in two hours.

Inspection.—Brain healthy; gelatinous deposit under the medulla oblongata; the spinal cord covered with purulent matter, which lay betwixt it and its membranes—the matter most abundant near the foramen magnum; substance of the cord itself soft, and in some places much divided into filaments.—*Abscissionable.*

The preceding case is valuable from the general absence of symptoms, which are thus shewn to be in some sort accidental.

The symptoms commonly present are—strong extension or incurvation backwards of the spine, with retraction of the head, the spasm sometimes extending to the limbs; pain in the back, sometimes a prominent feature, sometimes developed on motion only; pain and difficulty in passing the urine; paraplegia is an occasional, but by no means a common attendant.

A child, between three and four years of age, died with symptoms of opisthotonos, difficult deglutition, and coma. There was found, on the post-mortem inspection, a deposition of a red and very consistent fluid in the cellular texture, between the dura mater of the cord and the canal of the vertebrae in the dorsal region; serum within the membrane; and the arachnoid of the cord covered with albuminous secretion for four inches.—*Obituary.*

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CERTIFICATES DEC. 31, 1834.

John Donaldson Potts, Jamaica.
William Robbins, Merton in the Marsh.
Walter Duke, Hastings, Gloucestershire.
Francis Wyley, High Osm, near St. Albans.
Nicholas George Hobson, London.
Edward Baker, Birmingham.
James Trench, Neath, Glamorganshire.
John Hutchinson, Newham, York-shire.
John Dickenson, Wrexham.

JANUARY 8, 1835.

Peter Sampson, Manchester.
Abraham Crisp Gall, Woolbridge.

CHARLES HENRY ADAMS.

MINUTE ANATOMY OF THE LIVER.

In our analysis of Mr. Kiernan's paper in our last number, page 182, col. 2, line 4 from the bottom, the words "called sublobular veins," were by mistake introduced in connexion with the smaller branches of the portal vein, instead of the hepatic vein, to the branches of which the term sublobular is exclusively confined. By merely striking out the above words, the description is rendered perfectly clear.

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE XVI.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

PHTHISIS PULMONALIS.

WE have thus, gentlemen, described the morbid anatomy of tubercles in the lungs; we now proceed to their signs in the usual order.

Local Signs.

1. *Of the accumulation of gray or crude tubercles—Respiratory murmur.*—When but few gray or crude tubercles exist, the pulmonary structure between them is yet healthy, so that the respiratory murmur may be distinctly heard. There is then, in fact, no local sign of their presence; but when they are accumulated in masses, so as to encroach considerably upon the texture of the organ, the respiratory murmur is completely lost at the points of accumulation. I have already stated that tubercles are always primarily deposited in the upper lobes of the lungs; it is therefore immediately below the lines of the clavicles, and in the axillæ, that the absence of the respiratory sound occurs first. When you suspect tubercular disease, examine these regions with the greatest care; apply the stethoscope to the skin itself, press it firmly, and place the

ear upon the instrument, so that no rustling sounds shall be produced, otherwise you may easily be deceived.

Bronchophony.—As the softening process has not yet commenced, the bronchial tubes traversing the tubercular matter are intact; and the consequence is, that when the patient speaks the voice is resounded in these vessels, constituting the bronchophony of Laennec. This sound is to be sought for immediately below and along the lines of the clavicles, in the supra spinal fossæ, and in the axillæ; but if it be heard at the internal and superior angles of the scapulae, no inference should be drawn, because of the presence of large bronchial tubes, which sometimes occasion that sound there naturally.

Percussion.—When the tubercles are isolated, and at some distance from each other, the resonance upon percussion is natural; but as they increase in number, so as to form masses, then percussion elicits a dull sound. The diminished sound extends often from the clavicle to the fourth rib, and is also found in the axilla. Absence of respiration, bronchophony, and dulness of resonance upon percussion, usually co-exist in this stage of the disease at the same parts of the parietes of the chest.

2. *Softening of the tubercular mass.*—The above signs persist for some time, but there is now superadded a slight crepitating sound, varying in duration in different individuals. This crepitation is followed by a gurgling noise (the *gargouillement* of Laennec), as if produced by the movement of a thick matter. As the tubercular mass becomes still softer and thinner, a distinct mucous rattle becomes also daily more distinct.

3. *Tubercular excavation—Cavernous cough and respiration.*—When the tubercular matter is expelled, a cavity is left in the lung. The emptying of this cavity is rendered evident by a cough or a forced respiration; in both cases loud sounds are produced,

called the *cavernous cough and respiration*. While the softened matter is present, these cavernous sounds are accompanied by a mucous rattle. When the cavity is evacuated, these signs give the idea of the cough and respiration being resounded in a capacity of much larger dimensions than usual.

As the cavity empties, it occasionally happens that the sound produced by percussion becomes clearer; the contrary is most frequently the case, because a large quantity of tubercular matter generally surrounds the excavation.

When the softening matter is very near the surface of the chest, a gurgling sensation may sometimes be felt by the hand; this is caused by the rattling of the fluid, especially when the patient coughs: he occasionally even feels it himself. When the anterior parietes of the excavation are very thin, and the patient is much emaciated, percussion elicits a sound something similar to that produced by striking a broken vessel—as a cracked earthenware pot.

If, also, the excavation be very near the surface, the blowing respiration, or “*souffle*,” takes place—that is, whenever the patient inspires quickly, he appears to draw the air from the ear of the observer, and on expiration he seems to drive it forcibly back again; every time he speaks, the same sensation is felt, although it rather immediately follows the voice than accompanies it. To distinguish this well, the patient should be made to speak in monosyllables. The modification of the blowing respiration, called the “*souffle voilé*,” is also given when the anterior parietes of the cavity are very thin, soft, and not adherent to the costal pleura. It appears, then, that every vibration of the cough, voice, or respiration, agitates a moveable partition between the excavation and the ear of the examiner.

When the cavity is completely empty, the cavernous cough and respiration are rendered perfect; the mucous rattle now disappears, sometimes to recur slightly, in consequence of the secretions going on in the parietes of the excavation.

Pectoriloquy.—The most interesting of all the signs of an evacuated cavity is the pectoriloquy. It may, however, exist in an imperfect state before the evacuation is complete. I have already endeavoured to account for this sign, but this is the time to describe the circumstances by which its varieties are produced. I shall present to you Laennec's observations upon this subject.

We should conclude nothing from doubtful pectoriloquy, when it occurs in the interseapular regions, in the axilla, or at the union of the clavicles with the ster-

num, or even from the clavicles to the third ribs. The sign is doubtful if it exist equally on both sides of the upper part of the chest. The cause of all these doubts is, that the upper lobes contain a larger proportion of bronchial tubes, of greater diameter than the rest of the lungs, and some of them frequently take a superficial course; so that what is really bronchophony may be mistaken for a doubtful pectoriloquy.

If, too, the stethoscope be applied perpendicularly upon the upper surface of the clavicle, between it and the superior edge of the trapezius muscle, the resonance of the voice from the trachea and larynx is sometimes very similar to pectoriloquy.

But if a doubtful resonance of the voice be found below the third or fourth rib, or on one side only, there is then a strong presumption that it is pectoriloquy. If the sound does not exist at the same time at the points of the chest corresponding to the upper lobes, the sign is certain. The conclusion should then be, that the cavity is deeply seated, or that it is yet partly filled with incompletely softened tubercular matter.

On whatever part of the chest the voice is resounded more loudly than on the corresponding part of the opposite side, and particularly if it be so intense as to appear stronger and nearer to the ear of the observer than that which proceeds from the mouth of the patient, the sign is then as certain as if the articulation were heard distinctly passing up the tube, and the pectoriloquy is *imperfect*, but not *doubtful*. Between perfect and doubtful pectoriloquy there are many intermediate degrees, which practice alone can teach, and which it would perhaps be impossible to describe.

The pectoriloquy is always most evident in persons having acute voices, as in women and children.

In men whose voices are very grave, the pectoriloquy is often imperfect and doubtful, even when the excavations are in a proper state to produce that sign. The voice then appears agitated and trembling; it seems to be unable to introduce itself into the stethoscope, but resounds loudly at its extremity, and is heard as if through a speaking-trumpet. But it is a perfect sign of a cavity, especially if no such sound be audible on the opposite side of the chest.

The most evident pectoriloquy may present differences; thus the voice may pass continually through the tube, it may be intermittent, or some acute tones only may be heard: this intermittence occurs when the communicating bronchial tubes are temporarily obstructed by mucus. By making the patient cough, the pectoriloquy is easily reproduced.

In relation to the voice itself, the pectoriloquy may vary: the articulation of the words may be more or less distinct, the nature of the sound more or less altered; usually the voice is a little stilled. Sometimes the sound is fuller than from the mouth; it is, however, commonly stronger, and the patient occasionally speaks through the tube as if he placed his mouth to your ear.

Laennec observes, that when the voice is reduced to a mere whisper, still the pectoriloquy exists.

The thinner the parietes of the excavation, the better is the phenomenon produced.

Moderate-sized unilocular cavities give the pectoriloquy best: small ones, however, occasion it to be very distinct. In a multilocular cavity the articulation of words becomes stilled and confused.

In cavities whose upper parietes are thin, and can collapse, the pectoriloquy may be entirely lost.

If the pectoriloquy be continued, evident, well articulated, and unaccompanied by any other sound, the excavation is complete, and its bronchial orifices are large.

When a cavity is very large, and is but little anfractuons, the pectoriloquy is entirely lost, but then the amphoric respiration and the metallic tinkling become evident; the first occurs most frequently. Laennec states that the Hippocratic fluctuation rarely co-exists with the metallic tinkling in these cases. I have tried to produce it in above twenty different instances, and have never succeeded.

It is necessary for the production of the metallic tinkling, that the cavity should be exceedingly large, and that it should contain a certain quantity of fluid. If the quantity be very slight indeed, the phenomenon will not appear, but the voice, the cough, and respiration, are accompanied by the amphoric sound.

When an excavation bursts into the pleura, the pectoriloquy is usually lost; we shall advert to this again, in speaking of the combination of *Pneumo-thorax with Emphysema*.

Functional Signs.

Dyspnœa.—The degree of dyspnœa is often extremely variable. The patient, at the commencement of the disease, experiences more or less difficulty of breathing, which usually augments as the tubercles soften. The causes of the dyspnœa are not only the presence of tubercles, but also of catarrh. It might be supposed that the intensity of this functional sign depended upon the quantity of tubercles in the lung; but such is the general wasting of the body, such is the diminished quantity of blood in the system, the proportion sent into the lung is so small compared to the healthy state, that the necessity for respiration becomes extremely diminished also, so that frequently towards the termination of the disease the patient suffers less from dyspnœa than might be expected from the organic lesions existing in the lungs.

Cough.—This symptom is present in all stages of the disease; it is slight and dry at its commencement, but as the tubercles soften, and the accompanying catarrh supervenes, it is attended by a more or less copious expectoration. The most violent coughs depend upon the co-existence of ulcerations of the larynx, epiglottis, and rima glottidis.

Expectoration.—It had long been thought that phthisis depended upon inflammation of the lungs, and that the matter expectorated was pus. Under this supposition, it became a subject of importance to determine the difference between pus and the yellow secretion, or mucus, arising from inflammation of the bronchial tubes. The following differences were pointed out:—

<i>Pus.</i>	<i>Mucus.</i>
Dissolve both pus and mucus in sulphuric acid;	
pus precipitates,	but mucus does not.
Oxymuriate of mercury does not coagulate pus; ..	it coagulates mucus.
The microscope shews pus to consist of semi-opaque globules	mucus—of flakes.
Pus sinks in water;	mucus floats.
Pus evaporates to dryness without first coagulating;	mucus coagulates first.

But the examination of these differences is of no use whatever in forming our diagnosis of phthisis, for the disease is not the result of inflammation of the lungs, and consequently the fluid expectorated is not pus, but a mixed matter derived from different sources.

The sources whence the expectoration is derived, are, 1st, the irritated bronchial tubes and trachea: catarrh is formed, and

the mass of the sputa is constituted of mucous or pituitous matters, or a mixture of both. 2dly. The softened tubercular matter itself: this may put on a puriform appearance, or, what is still more common, it consists of whitish, curdy, irregular, small pieces, or flakes, mixed up in the catarrhal secretions. You should be careful, however, in examining whether they are not really curds of milk, for they are

not unfrequently the causes of this appearance. Certain curdy productions will also occasionally result from chronic inflammation of the amygdalæ; these glands should therefore be examined.

The quantity of the fluid expectorated is sometimes very considerable; for though it may not ordinarily be more than a tea-cupful, yet it occasionally amounts to more than a pint in a day. The mass of these secretions arises from the bronchial tubes. The softened tubercular matter can only be in very small proportion, since an excavation of the capacity of a pint measure is often many months in forming and evacuating its contents. The quantity, therefore, of softened tubercle contained in the matters expectorated, has been supposed to be scarcely a thousandth part.

The third source of the expectorated secretions is from the parietes of the excavation; but the nature of this has not been sufficiently studied. It is probably but small in quantity, and if it be like the matter which may be scraped from the surface of the cavity, it is of a pituitous nature.

Blood in small quantity may be expectorated in any stage of the progress of tubercular matter. I have met with it before any expectoration had taken place, or, indeed, before the development of any local signs. It is commonly seen in streaks, or spots, in the expectoration. Hæmoptysis is rarely considerable; I have met with but few instances of its being the immediate cause of death; in one of them the bleeding arose from a ruptured vessel opening into the excavation.

Small quantities of ossific matters are sometimes mixed up with the expectoration; I shall shew the sources of these when I speak of ossific concretions.

Pain—Oppression.—The patients rarely complain of pain, except slight pleurisies occur; they have not commonly, either, any sense of oppression in the chest, or, if present, it is but slight.

Paraphonia.—The voice, especially towards the close of the disease, often becomes hoarse, and reduced to a whisper; this, though partly arising from the exhaustion of the patient, is principally caused by the ulcerations in the larynx and trachea.

Such are the signs which may be referred to the lesion of the functions; we now proceed to those arising from the sympathetic disorder of the general system.

General Signs.

That general condition of the system known under the appellation of *hectic fever*, prevails in all the stages of this disease. It is least manifest during the crude state of the tubercles, most evident during the

period of their softening, and diminishes when the excavation is completely formed.

Hectic fever has been classed among the remittents; it is said to have two accesses in the twenty-four hours, the one being in the middle of the day, and the other towards the evening; the latter being the longest. From long observation, I can say that the meridian access is rare. The access generally commences with horripilations (according to Louis in five-sixths of the cases), accompanied by great sensibility to cold, although the skin may feel warm to the observer. The hot stage soon begins, and lasts usually for many hours, terminating in the morning in perspiration.

These perspirations, or, as they are commonly called, *night sweats*, are highly characteristic of phthisis. The quantity is sometimes enormous, completely wetting the head and the whole body, the night-clothes, and sheets; they have been seen penetrating deeply into the mattress or bed on which the patient is placed. These sweats often occur when the other symptoms of hectic fever are not marked. I have seen them in so early a stage of the disease, that the local signs were not present; indeed, their presence, if combined with frequency of pulse, is often alone a sufficient indication to the experienced practitioner of the approach of this fatal disease. There seems to be some relation between this sweating and sleep, for the profuseness of the one often depends upon the completeness of the other: even if the patient sleeps at any part of the day, he almost always awakes in a state of perspiration.

The urine is usually high coloured, and deposits a furfuraceous sediment. The thirst is rarely great, even during the febrile access. The tongue is often healthy at the beginning, but towards the termination of the disease becomes dry, of a deep red colour, and its edges and point, and then its surface, and the throat, are covered by aphthous vesicles, leaving sores which distress the patient, and prevent free deglutition.

The lesions of the stomach are often shewn by anorexia, nausea, and even vomiting; frequently these signs are absent, and the patient preserves a tolerable appetite to the last.

The ulcerated condition of the intestinal tube almost always causes *diarrhœa*: this is one of the most prominent and common signs of phthisis, and exists in every stage, but most frequently during and after the period of the softening of the tubercular matter.

The catamenia are usually diminished at first, and totally cease as the disease progresses. Females are apt to attribute

the whole of their symptoms to this irregularity; but it is an effect, and not a cause.

The pulse is accelerated at all periods of the disease, but most during the hectic paroxysm.

Debility prevails from the commencement; yet this varies considerably. Some will take to their beds early, not to leave it; I have met with others who have been walking in the streets on the day of their deaths.

If the disease be slow and chronic in its course, extreme marasmus is produced. Aretæus gives us the following picture of it:—

The nose becomes thin, especially at its point; the malar bones project, and the skin covering them is of a brilliant red colour, of a circumscribed form; the conjunctivæ shine, and are of a light pearly blue; the eyes are large, although somewhat sunk in their orbits; the cheeks are hollowed; the lips retracted, presenting often the appearance of a bitter smile. The neck is oblique, and as if oppressed in its movements; the shoulders are elevated; the ribs project; the intercostal spaces are depressed; the scapulæ are elevated like the wings of a bird; the belly is contracted and flattened; the articulations appear large; the nails are curved; and the hairs gradually fall from the head. No disease produces such great marasmus, excepting cancers, empyema, and fevers of long duration.

During the whole course of the disease all the mental faculties are perfect. If there be any thing anomalous, it is in the strong hope, nay certainty, which the patient has of his ultimate recovery.

Having, gentlemen, described the symptoms of this formidable disease, let us now throw our observations into one point of view, by tracing a patient throughout its course.

I will imagine an individual of from 18 to 22, or 24 years of age, a female, brought to you perhaps by an anxious parent, whose solicitude is increased by having already lost some of her children by this insidious malady. You examine your patient; you perceive the eye to be of a bluish tint, and of a somewhat pearly lustre; that the cheeks are coloured with a red and unhealthy bloom, irregularly circumscribed; that her form is attenuated, the nails curved, the hair thinned and falling off, and the pulse frequent. Upon questioning her, she smiles at her mother's fears, and denies the existence of any ailment. You perceive she coughs slightly; that there is no expectoration, or merely a little pituitous matter—occasionally, perhaps, tinged with a spot of blood. She accounts for all this by attributing it

to a recent cold; she admits that her respiration is somewhat quickened; even now there are frequent night sweats, irregularity of bowels, sometimes costiveness, sometimes diarrhœa. The catamenial flow is diminished in quantity, or irregular in its return.

Examine the local signs at this period: there may be none, for the tubercles may be yet gray, or crude, and not great in quantity; or there may be absence of respiration, bronchophony, and dulness upon percussion below the lines of the clavicles, or in the axillæ, indicating the presence of tubercular masses yet unsoftened.

I will suppose that a few weeks have passed, and you are now called to visit your patient, for you are told she cannot leave her room.

The eye has still further assumed the pearly lustre I have described; the redness of her cheek is still more vivid, or there is a deadly paleness; the malar bones project; the cheeks have lost their rotundity; the dyspnœa is at its height; the cough constantly torments her; the expectoration is copious, consisting of a mixture of pituitous and mucous matters, with shreds of a curdy substance floating in it, and often also small spots or threads of blood. The hectic is now completely formed; in the evening a slight horripilation is succeeded by heat, which continues during the night. The patient sleeps nevertheless, if the cough does not torment her, and awakes in the morning bathed in perspiration. Now the urine deposits copiously a furfuraceous sediment; the diarrhœa is constant; the catamenia have totally ceased; the pulse beats from 100 to 130, or 140, in the minute; the weakness is great, but her never-failing hope still buoys her up; she is yet certain that she is labouring only from the effects of a common cold, from which she will soon recover.

This period coincides with the softening of the tubercular matter; the local signs evince it; for if you apply the stethoscope, a distinct crepitation, or the still louder sound of gurgling (*gargouillement*), is heard at the parts corresponding to the upper lobe of one or other of the lungs; an imperfect pectoriloquy exists, and the cough and respiration are becoming cavernous at the same points.

Let us now suppose that the third and the last period has arrived; you will now find that the change is still greater; the malar bones are still more prominent; the cheeks still thinner; the lips are retracted, and give the bitter smile. The neck now appears somewhat awry, the ribs project, the intercostal spaces are deep, the scapulæ are elevated, the abdomen is flat and contracted, the flesh of the whole body is ex-

traordinarily reduced in quantity, the articulations appear large, and the nails more incurved.

At this period the dyspnoea frequently diminishes, but the cough is often unceasing; not so much from increased fluid to be expectorated, as from the irritating ulceration of the larynx and parts adjacent. From the latter cause, also, the voice becomes hoarse, and reduced frequently to a whisper. The mouth, tongue, and fauces, become exceedingly tender from the aphthous eruptions.

The hectic fever now frequently becomes less; the night sweats even often cease, as if from diminished materials; the diarrhoea continues, and is colligative. Hope, however, still clings to the patient; she often will not hear of doubts of her recovery, but is constantly forming projects for the future. At last the pulse gradually sinks, the voice is lost, the power of expectorating fails, the head falls forwards, or laterally, by its own weight, and the patient frequently expires so quietly, that the attendants are for some time unaware of it.

If you examine the patient during the progress of this stage, you will find the excavation, or excavations, complete; the pectoriloquy becomes, therefore, evident, and the resonance of the cough and respiration in the cavity cavernous. In some instances I have met with ravages so extensive, that nearly the whole of the lung on one side has been destroyed. In these cases the *bourdonnement amphorique*, and the *tintement métallique*, were perfectly distinct.

The three successive periods of the disease which I have just attempted to describe were denominated by the older writers—*phthisis incipiens*, *phthisis confirmata*, *phthisis desperata*.

Causes.

1st, *Remote causes*.—Individuals of all temperaments are subject to tubercular deposits, but it most commonly occurs in those of the nervous and sanguine lymphatic. Persons thus constituted have the skin of a brilliant fairness of colour, and fineness of structure; the cheeks of a lively red; the neck narrow and long; the transverse diameter of the chest often diminished; the shoulders high; the scapulae projecting; and a general thinness of the whole frame. Phthisis attacks all ages, and both sexes, as I have shewn you in the preceding lecture. There is perhaps no disease which results from hereditary predisposition so frequently as this. Moral causes, such as distress of mind, great seclusion, &c. may also be classed among the strongly predisposing causes.

The external causes are—1stly, Cold, especially if combined with humidity. Phthisis is thus most common in the north

of Europe and America; it is a frequent disease also in France, Italy, and Greece, but generally less so in the meridional parts of Europe, and least of all in the tropics. In speaking of localities, it is found to be more frequent in large towns than in small ones, more common in the interior than on the coasts. It is rare on board ships. 2dly, Too slight clothing may be assigned as a cause of phthisis, by permitting the influence of atmospheric variations to act too suddenly upon the body. 3dly, All debilitating causes, as venereal excesses, long courses of mercury, continued fevers of considerable duration, habitual intoxication, &c. 4thly, Some trades have a tendency to produce the disease, as that of knife-grinding. Very sedentary occupations have a similar effect, as those of the milliner, tailor, weaver, &c.

It is thought, particularly in the south of France, that phthisis is contagious. I have seen no proof whatever of the correctness of this opinion. It is true the disease may occur in several individuals of the same family, about the same time; but this circumstance is much more readily accounted for from hereditary predisposition than contagion.

Proximate causes.—Although we shall be able to throw no light upon the proximate cause of phthisis, yet it will be of some advantage to refute the erroneous opinions that have been entertained upon this subject.

Thus, it was the opinion of the ancients that this disease was a consequence of an acute or chronic inflammation of the lungs; and this notion has been renewed by Broussais.

Can phthisis arise from inflammation of the lungs, or peripneumonia? It is difficult to suppose so, since peripneumonia does not co-exist with phthisis in a greater proportion than one-tenth of the cases. Are the products of ordinary inflammation any thing like tubercles? Certainly not. Peripneumonia principally attacks the vesicular texture of the lungs, and often leaves the interlobular cellular substance intact; and yet in the latter tissue the tubercular matter is most commonly deposited. Peripneumonia attacks primarily the inferior lobes of the lungs, in almost every instance; tubercles as frequently are placed in the upper lobes. The reverse should take place if tubercles were consequent upon inflammation of the organ. Tubercles are often seen imbedded in a perfectly healthy tissue, where there is no evidence whatever of inflammation. I have seen [shewing a preparation] the lungs of a fetus studded with this deposit; was this from previous inflammation?

It is true that inflammation may accidentally accompany, or even be caused by,

the irritation which the tubercular matter may produce; but it cannot be admitted to be the proximate cause of its deposition.

Can *catarrh* occasion the tubercular secretion? The latter is commonly attended by the former, but large tubercles have been seen without co-existing *catarrh*.

There is scarcely an individual in this country who is not even annually affected by *catarrh*. Phthisis, if depending upon that disease, should therefore be infinitely more common than it now even unfortunately is. *Catarrh* is most common on the coasts; phthisis in the interior. This order should be reversed if *catarrh* were the cause.

If tubercles depended upon *catarrh*, these deposits should not be found in the interlobular cellular tissue, since the bronchial tubes do not open into it; but they are commonly formed there.

But *catarrh* and phthisis are two very distinct diseases—the first is an inflammation of the mucous membrane of the air tubes, having for its result a secretion, varying in character; the second is the consequence of a peculiar adventitious deposit; and, as Laennec expresses it, no one has yet, scalpel in hand, shewed the conversion of *catarrhal* into tubercular matter.

Pulmonary apoplexies have never been seen converted into pus or tubercles. *Hæmoptysis* often, indeed, seems to precede phthisis; but if the patient be carefully examined, it will commonly be found that the local signs of the latter disease are present at the same time. Tubercles frequently, by their pressure upon the vessels, cause spitting of blood; but the quantity is usually small, and is derived from the bronchial tubes. This hæmorrhage must be considered as a consequence, and not as a cause.

Tubercles have been supposed to be a modification of hydatids. This opinion, I believe, has met with no supporters. I see no relation between the hydatid, even in its earliest budding state, and tubercle.

All we can say upon the subject of the proximate cause is, that this formation is a deposit from the blood-vessels. I am quite aware that this is no explanation, for all adventitious matters arise from the same source. To determine the proximate cause, would be to determine the reason why the blood-vessels should deposit tubercle in one case, medullary sarcoma in a second, melanosis in a third, &c. The cause would probably be found in certain conditions of the system, or of the blood, peculiarly favourable for each particular deposit; of the nature of which conditions we are as yet perfectly ignorant.

Treatment.

I now arrive at the least satisfactory part of this subject — I mean the treatment of phthisis; for I am convinced that art has done little more than to palliate this disease, and that when a cure has been effected, it has been by nature's efforts alone. I have shewn the possibility of a cure by the cicatrization of the excavation; but I do not believe that this event occurs without the formation of a fresh crop of tubercles in one case in two hundred—perhaps not so frequently.

The following indications, which are proposed to be fulfilled by means sufficiently doubtful in these effects, have been laid down by authors.

1st indication. To prevent secondary crops of tubercles.—Bleeding has been employed from remote antiquity, but it is rarely useful except in intercurrent pleurisy or peripneumonia. I use the lancet only when there is considerable dyspnoea, and the patient yet possesses a certain degree of power, and when the pulse is full. Cupping, or leeches, may be applied under similar circumstances; but I do not believe that bleeding can prevent the formation of a secondary crop of tubercles; I think it would rather tend to their production, by increasing the general debility of the system.

Counter-stimulants have also been extensively used, particularly by the ancients. Hippocrates applied the actual cautery at once to the axilla, back, and breasts; Celsus recommended it in six places—under the chin, on the throat, on each breast, and at the inferior angle of each scapula. These violent remedies have now subsided into blisters, setons, caustics, and occasionally also the moxa. Expectorants relieve temporary pains and feelings of oppression in the chest, but cannot prevent the fresh formation of tubercles.

2nd indication. To favour the softening of the tubercles.—This indication was supposed to be accomplished by the use of certain medicaments believed to have a solvent power: among these were lime-water, sulphureous waters, either in baths or potations; the muriate of ammonia, the sub-carbonates of potash and soda. But these are very inert medicines. I have tried mercury, barytes, and iodine, extensively, but with no satisfactory results.

3rd indication. To cicatrize the excavations.—A great variety of remedies have been recommended with this intention, as the following list will shew:—Antiscorbutic and aromatic plants, balsams of tolu, Mecca, and Peru, turpentine, and camphor dissolved in volatile oils; artificial atmospheres formed of the vapours of emollient, carminative, narcotic, and balsamic plants; also of certain substances burnt upon

heated iron, as myrrh, benzoin, petralem, tar, resin, and wax; sublimations of zinc, of sulphur.

Various gases have been employed: oxygen was recommended by Caillé, hydrogen by Beddoes; even sulphuretted hydrogen by Körtin, carbonic acid by Beddoes also; the vapours arising from stagnant pools, from stables; the smoke of snuffed candles, heated air. The vapour of iodine, and chlorine gas, have been the latest remedies of this class proposed.

I have tried many of these remedies, and often with temporary advantage; but I have no doubt that advantage has arisen from the relief they have afforded to the catarrh which accompanies the tubercular disease; for with a tolerable large field for observation, I must say that I never yet have seen a case whose *cure* could be attributed to any one of these medicaments. Most relief, I think, is produced by the inhalation of tar vapour, and of chlorine gas.

Many other means have been proposed, with the view of giving strength to the general system, or to relieve dyspnoea. Thus a milk diet is of very common use, and is often advantageous. The milk has been obtained from women, cows, asses, and mares; perhaps that from asses is the best. Charcoal, champignons, the boletus suavelens, frogs, vipers, snails, oysters, chocolate, large doses of sugar, wine, &c., have all been lauded in their turns, although principally as articles of diet fitted to this disease. Electricity, ciêuta, aconite, digitalis, ipecacuanha, and hydrocyanic acid, have been also successively extolled; but practical men have unfortunately experienced that their beneficial effects, if any, are rarely more than temporary.

Gymnastics, if not carried to excess, are excellent prophylactics, especially rowing and riding on horseback.

In the very early stage of phthisis, when it is yet incipient, or when the patient manifests a tendency to the disease, I believe a long journey, by such easy stages as the patient may not be fatigued, is of the greatest advantage; and I always recommend patients to travel whose means permit it. Sea voyages also frequently produce excellent effects. There is no doubt, too, but that sojourning in a warm climate during the winter season is of great utility; I will not say that it cures the disease, but it often protracts life. I speak here only of the earlier periods of the affection; for I firmly believe that when a tubercular excavation is once formed, no means have yet been discovered which affords the patient any thing but palliation.

The object you should have in view in

relation to climate, is to choose a locality where the winter season is temperate, and subject to the least vicissitude. The late Dr. Young observed, that the mean temperature, from October to March, was, from the year 1790 to 1794, as follows:—At London, 43 deg. 5 min.; Penzance, 48 deg. 1 min.; Lisbon, 55 deg. 1 min.; Madeira, 63 deg. In this point of view, therefore, Madeira is the most preferable spot. There is the least vicissitude in the weather in England, at Undercliff, in the Isle of Wight, Torquay, and Penzance; and abroad, at Lisbon, Madeira, Hyères, Nice, in some parts of Italy, and at Montpellier. I refer you for an elaborate account of this subject to Dr. Clarke's excellent work upon Climates.

My plan of treating phthisis is generally as follows:—

If I meet with an individual in the earliest stage of the disease, or in whom only a predisposition to it exists, I place him upon a very moderate animal diet, allowing him no wine or stimulants in any form; I permit moderate exercise, as walking, riding on horseback, or sailing. As the month of September advances, I advise him to change his position entirely, and to winter in a warm climate; if in England, at Undercliffe, Torquay, or in some sheltered valley in the south. If his circumstances permit, let the change be still more complete, by sending him to Madeira, Lisbon, Hyères, or Nice. If the means of the patient do not allow him to effect this, I then recommend him to be confined during the winter months in chambers in which the temperature should be regulated according to his feelings.

At this early period of the disease, if the dyspnoea and cough be troublesome, and the pulse somewhat full and hard, I abstract a few ounces of blood occasionally; but this, gentlemen, should not be too often repeated, as you should preserve the strength of your patient as much as possible. The digitalis, under such circumstances, is of use; blisters, or the tartar emetic ointment, may now be employed. I commonly administer a combination of ipecacuanha, squills, and hyoscyamus, as an expectorant, and endeavour to alleviate the cough by emulsions and other demulcents.

You will often, very often, find, that such is the weak state of the patient, even from the beginning, that he will bear no depletion. In those cases, support him with a bland and non-stimulant diet—as milk, the white meats, jellies, &c.; and you may administer the ordinary tonics, combining them with the acids, if there be night sweats and no diarrhoea.

When the tubercles soften, and the exa-

vations commence forming, I should recommend you, gentlemen, not to send your patients abroad: it rarely, if ever, is of any service, but is often highly disadvantageous; for they are removed from the comforts and attentions at home at the moment they are most required, and they too often, unfortunately, expire in a foreign land, without a friend to afford the last consolations.

As the disease advances, the remedial means diminish daily in their effects: the distressing symptoms alone can be attended to. Thus the cough may be somewhat allayed by demulcents—as emulsions, the lichen islandicus, the Irish moss, &c.; the two latter also serve as articles of diet. Opium produces often the greatest relief in procuring sleep and abating the cough. The hyoscyamus and belladonna have been used with the same intentions, but rarely with such good effects.

I am satisfied that it is injudicious to permit the diarrhœa to continue at any period of the disease, since it produces great exhaustion. It often yields to the ordinary chalk mixture. I sometimes use small doses of the sulphate of copper, combined with opium, if the relaxation of the bowels be very obstinate.

A gargle, composed of borax, honey, tincture of myrrh, and infusion of roses, often relieves the aphthous state of the mouth, tongue, and fauces.

I recommend the inhalation of chlorine gas if the concomitant catarrh be extensive and considerable; and I think with occasional advantage.

Such is the general plan by which phthisis may be *paliated*; but I repeat again, that I believe the disease to be not *curable* by any means proposed up to the present time.

PATHOLOGICAL LECTURES,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

PATHOLOGY OF THE SPINAL CORD— (continued.)

Of Serous Effusion in the Spinal Canal.

THE observations of Magendie have taught pathologists that a sensible quantity of serum exists in the space between the arachnoid and pia mater of the cord in health. An increased secretion of this fluid is not a common form of disorder. The following cases, however, may serve to exemplify it.

A man, ætat. 40, was affected with acute

pain and weight in the lower dorsal vertebræ, the pain occasionally extending upwards or downwards to the top and bottom of the spine. After eleven days, he was seized with palsy of the right lower extremity; and in three days more, with retention of urine. The pain was now so acute as to prevent him from lying down; and was soon after accompanied by dyspœa, vomiting, and tonic convulsions of the trunk and arms, which recurred at intervals, and continued for about fifteen minutes. The left inferior extremity then became paralytic, and he died suddenly. His intellectual faculties had continued entire, except during the paroxysms of convulsion. On inspection, much fluid was found in the cavity of the spine, but the cord was sound; there was also fluid on the surface of the brain, but none in the ventricles.—*Morgagni*.

A child, ætat. 12 months, after appearing to be in much pain, lost the use of the inferior extremities, and died in three days. The spinal canal was found full of bloody serum.—*Chevalier*.

Of Spinal Apoplexy, or Hæmorrhage of the Spinal Marrow.

A man received a violent blow on the three inferior lumbar vertebræ from a log of wood which fell upon him: he died in four hours. Extravasated blood was found in the spinal canal, but the vertebræ were entire, and the cord was healthy.—*Morgagni*.

A lady, ætat. 40, had headache and pain of the back. After a few days, the pain of the back became very acute, and violent convulsions took place, which were fatal after continuing five or six hours. All was sound in the brain, but extensive extravasation of blood was found in the spinal canal, which was most abundant about the seat of pain.—*Ollivier*.

A gentleman, ætat. 61, had just arrived in Paris from a long journey, when he complained of pain of his back, extending from the cervical vertebræ to the sacrum. After a few hours, he was seized with paraplegia, and incontinence of urine, and fever; and he died while the physician was talking to him, who had been sent for on the occurrence of the palsy. There was extensive extravasation of blood in the spinal canal, under the membranes of the chest. At the lower part it formed a mass like a bouillie of bullock's blood, in which the substance of the cord could not be distinguished as far as the third dorsal vertebræ; and above this, where the cord was entire, it was of a deep colour, and very soft.

Of Deposits between the Membranes of the Cord.

These consist of small thin flakes of

cartilage, or phosphate of lime, which form in the cellular membrane between the arachnoid and pia mater. They are often met with where no symptom of spinal disorder has occurred. They are likewise occasionally met with in combination with the most severe. To this subject I shall presently recur; in the meantime, let me give an instance of this deposit complicated with a growth of another kind in the same situation.

Velpau relates the case of a woman, *ætat.* 36, who had first some convulsive motions, which soon ceased; then acute pain of the left arm, with headache: the arm became weak, and gradually completely paralytic. She then had convulsive motions of the lower extremities, which also became completely paralytic. The right arm next became painful, and the motion of it was impaired, but not entirely lost. The inferior extremities became oedematous; the inferior half of the thorax, and all the parts below, were completely deprived of sense and motion; and the right arm at last became entirely paralytic. Sloughing of the integuments of the sacrum then took place, and death ensued at rather more than three months from the commencement of the paralysis.

On inspection, there was found between the body of the cord and the arachnoid a tumor, of a reddish-yellow colour; it was about three lines in thickness at the thickest part, and covered the anterior surface of the cord, from the sixth cervical nerve to the third dorsal: the cord was flattened by it. The tumor was of a firm fleshy consistence, and of a yellowish-white colour. On many parts of the arachnoid of the cord, cartilaginous scales were observed.

Of Tumors exterior to the Theca.

There are three preparations in the King's College museum of tumors external to and pressing on the theca. In two of these the morbid deposit looks like tuberculous matter; is oblong, about two inches in length, half an inch in breadth, and a quarter of an inch in thickness. In the third, the tumor is somewhat longer, of a white colour, and half an inch in thickness; it was situated at the upper part of the back; the spinal cord, otherwise healthy, is narrowed through absorption at this part. In each of the three cases, there was more or less complete paraplegia. An interesting case, in which the pressure of a fatty tumor in the vertebral canal had caused the entire absorption of an inch of the cord, leaving the membranes only, is given by Mr. Roberts, in the *MEDICAL GAZETTE*, for March 22, 1834. The fatty tumor lay beneath the bony rings of the tenth, eleventh,

and twelfth dorsal vertebrae, was about the thickness of the middle finger, and between two and three inches in length.

Aneurism of the aorta is liable, after producing partial absorption of the vertebral column, to press as an external tumor upon the theca. Dr. Abercrombie describes a case, something of this description, in which the arms, for a short period before death, were entirely deprived both of motion and feeling, the head and legs being in constant motion. There is in this case a want of agreement between the part of the spinal marrow softened from inflammation, excited by the carious vertebra, and the parts affected with palsy.

Of Malignant Disease of the Spinal Cord.

A youth, *ætat.* 14, fell from a window in the second story of a house into the street: his back was bruised, but without fracture; but he afterwards continued to walk, with his body bent forwards. After three years and a half, he was seized with violent pain in the back, thighs, and legs; and a tumor began to form on the lumbar vertebrae, which increased gradually, till it attained to a very great size. The prominent part of it was red; and repeated attacks of hæmorrhage took place from the apex of the tumor. He was then affected with complete paraplegia, incontinence of urine and feces, and extreme emaciation; and at length died, gradually exhausted, about six years from the accident. On dissection, the tumor was found to consist of a large fungous mass, resembling the medullary substance of the brain, which took its origin from the spinal cord, and had extended itself upwards and downwards from the third dorsal vertebra to the os coccygis. Many of the vertebrae, both dorsal and lumbar, were extensively carious on the posterior part; and some of the lumbar vertebrae had nearly disappeared.—*New London Medical Journal*, 1792.

The plan which I proposed to myself in my pathological lectures, and which hitherto I have traced in outline only, comprehends three objects. One, the simple description of the morbid changes which have been observed in different organs; a second, the examination of the symptoms which attend these changes, and an explanation of the manner in which the two are connected, as cause and effect; a third, the display of those successions of structural alterations, with their groups of attendant symptoms, which constitute the natural families of diseases. It is, indeed, in the more complicated and important organs only, like those now under consideration, that each of these elements of study deserves to be considered separately. In

organs of this importance, however, there even remains another, a fourth branch of inquiry, which fully equals in interest the preceding. What, it may be asked, are the groups of symptoms which display themselves, unattended by any appreciable alteration of structure? What are the diseases of these organs, which are at present without a morbid anatomy? With what additional families of diseases are pains and spasms, palsy and anaesthesia, grouped by nosologists, who can find no lesion of the texture of the spinal cord and brain, with which to associate them?

These affections form so large a class as to claim the most attentive study. At present their locality alone is satisfactorily identified; they may possibly, in time, be traced home to sensible changes in the condition of tissues, that our present means are insufficient to discover; or they may always remain as instances of derangement purely functional—examples of the disordered action of healthy structure. Without it be coupled with a knowledge of facts, such as I here advert to, and which I am about to sketch, pathological anatomy, instead of uniformly guiding aright, would as often mislead the medical practitioner; it would form that half knowledge which is proverbially more dangerous than ignorance.

To prove that such disorders exist, I have only to make one or two additional extracts from Dr. Abercrombie's most valuable "Practical and Pathological Researches on the Diseases of the Brain and Spinal Cord."

A medical gentleman, ætat. 30, who had been for several years in the navy, returned home in perfect health, and was living in Edinburgh, when he was observed by his friends to drag his legs awkwardly in walking. He was not himself at first sensible of it, but soon perceived a weakness and want of command over both his legs, which gradually increased to nearly perfect paraplegia. Some time after the affection of the legs took place, he began to lose the power of his arms; and this also increased till he retained in them only a very feeble and unsteady power of motion; they were also frequently seized with convulsive startings, so that any article which he attempted to hold was thrown from him with violence. The legs often started in the same manner, and were thrown about with considerable violence, especially when he attempted to move them while he was sitting up. No disease could be discovered in the bones of the spine, and he was otherwise in good health, until about two years after the commencement of the complaint, when he was seized with phthisis, of which he died in September 1822. Dr. Abercrombie examined the body with the

utmost care, and could not discover a vestige of disease either in the brain or spinal cord.

A woman, ætat. 35, was first affected with numbness of the thumb of the left hand, which gradually extended over the whole hand and arm. The limb was thus partially paralytic, and was likewise affected with involuntary motions, exactly resembling those of chorea: this continued several weeks, and then gradually ceased, and the arm recovered its healthy state. Almost immediately after this, the right hand and arm were affected in the same manner, and after some time also got well. The legs then became affected with starting, involuntary twitches, and a feeling in walking as if they would fly from under her to one side. The complaint went on in this manner for some time, and then terminated in complete paraplegia, with retention of urine, requiring the constant use of the catheter. She was now confined to bed for nine months, and died of extensive gangrene of the sacrum and tops of the thighs. For some time before her death she had recovered the action of the bladder.

No disease could be discovered in the brain or spinal cord, except that the cauda equina was of a very dark colour, as if it had been soaked in venous blood, and there was some bloody fluid round it.

Dr. Abercrombie gives several parallel cases to the preceding, where death ensued; and others, bearing a strong analogy to them, in which the patients recovered.

The classes of diseases which are to be grouped under this head, "as genera of diseases of the spinal cord and medulla oblongata, unattended with any discernible change in the structure of these organs," are the following:—

1. *Chorea*, to which disease each of the two instances I have quoted display an affinity. It is evident that a step is made towards explaining the phenomena of this disease, by separating the functions of the double cord, which originates pairs of nerves, from those of the hemispherical masses of the encephalon; the former part containing the organs, or forming the sources, of sensation, volition, and the simple impulse which connects them; the latter being the organs in which the sensations excite apprehension, reflection, and desire; and from which the deliberate impulse to action is, in return, derived.

In chorea the former parts are preternaturally irritable. Common sensation, in this case, telling upon the irritable cord, causes the voluntary nerves to stimulate the muscles forcibly and uncontrollably; this effect (consistently with the hypothesis) is heightened when a deliberative impulse comes down from the brain, to

involve the will to energize. I recollect the instance of a lady who was affected with chorea: when she kept herself quiet and composed, there was but little jactitation; but when, happening at dinner to drink wine with any one, her brain sent an impulse to the spinal cord to determine one gentle action of the muscles of the neck; the cerebral mandate found the segments of the spinal cord exquisitely irritable, and off parted a thousand impulses among all the muscles, which made her nod for a minute, in every direction, with astonishing rapidity, omitting, however, generally, the right one.

2. Tetanus and trismus evidently have their seat in the spinal marrow and medulla oblongata. After wounds of tendinous and ligamentous parts, these affections follow in a small proportion of cases. Those so affected are persons in whom the spinal cord is unusually sensitive. In the museum of St. Thomas's Hospital, Mr. Green informed me that there are two specimens of the spinal cord, the membranes of which are studded with little cartilaginous and earthy flakes, taken from patients who died of tetanus. These small deposits did not, it is to be presumed, produce the tetanus, but they probably had made the spinal cord preternaturally irritable. In general, no morbid appearances are found in the spine after death from tetanus.

3. Hydrophobia is certainly nearly allied to tetanus, but it is differently produced,—not by a particular kind of wound, but through the introduction of a specific animal poison; it is further characterized by the acute morbid sensibility which attends it, by the spasms being clonic, and affecting the respiratory muscles alone; principally those of the glottis. It is a pity that, in these fearful cases, medical men content themselves with trying over and over again the practice which experience has proved to be inert. There certainly should be formed in London a board of medical men, for the express purpose of examining into this disease, and part of some hospital should be appropriated to the reception of hydrophobic cases. The opportunities of study being thus concentrated, it is conceivable that in time some curative method might be found which would control the disease.

In human beings, the experiments which at present most deserve repeating, or trying, are—cauterizing the cicatrix, and opening the larynx freely (to neutralize the frightful and exhausting laryngeal spasm), in combination with the use of the most powerful sedatives; or the injection of water into the veins, in combination with abstraction of blood. *Upon rabid dogs*, the latter experiment of Magendie certainly

should be repeated; and Mr. Sewell's marvellous experiment (made by him in tetanus) might be tried. Mr. Sewell's experiment was this:—A horse, suffering from a severe attack of tetanus and locked-jaw, the mouth being too firmly closed to admit the introduction of either food or medicine, was inoculated on the fleshy part of the shoulder with an arrow-point coated with the wourali poison. In ten minutes apparent death was produced. Artificial respiration was immediately commenced, and kept up about four hours, when re-animation took place: the animal rose up, apparently perfectly recovered, and eagerly partook of corn and hay:—with which he unluckily was too abundantly supplied during the night. The consequence was over-distention of the stomach, of which the animal died the following day, without the slightest recurrence of tetanic symptoms.

The local congestion, or inflammatory appearances, which are discovered after death from hydrophobia, are singularly capricious, and have evidently been results of the disturbance of the nervous influence, not causes of the disease or of its symptoms.

4. The varieties of convulsive attacks of infants—spasms of the hands and feet—spasm of the glottis, characterized by the crowing inspiration which attends its departure—spasmodic tension of the back and neck,—are clearly results of irritation of the spinal cord and medulla oblongata. Great discrimination is required to distinguish when these attacks flow from irritation alone, and are to be so relieved; or indicate vascular action, and a different treatment.

5. There are classes of affections which are called neuralgic (acute local pain in a joint may be of this nature), which may be caused by spinal irritation. A patient in St. Bartholomew's Hospital requested, after years of painful affection of the knee, to have the leg amputated: the operation was done, but the pain was not removed. On her death, at some interval afterwards, the spinal cord was examined. The posterior surface of the cord was found covered with flakes of cartilaginous deposit.

6. Finally, there is much in hysteria to shew that the central organs of the nervous system are occasionally implicated in its production. Dr. Abercrombie evidently inclines to this opinion, which has found advocates in more than one useful practical writer of the present day.

ON CLUB-FOOT.

By PHILIP M. LYONS, M.B. A.M.

Physician-Accoucheur to the Brighton Lying-in Institution, &c. ; late one of the Physicians to the Brighton General Dispensary.

[Concluded from p. 474.]

I HAD purposed to inquire into the pathological relations of reel-foot, both as to cause and effect ; but as I find I have already extended this paper to almost too great a length, I shall proceed to relate the cases I have already alluded to as illustrating the mode of treatment which appears to me most desirable, as combining great facility with comparatively short confinement and little suffering on the part of the patient, while on that of the surgeon it requires common manual dexterity, with that degree of anatomical knowledge devoid of which he were unworthy of a place in his profession.

John Callaghan, æt. 10, 62, Nottingham Street, Brighton, was recommended to my care by Major Stewart, one of the governors of our institution, in July 1831, on account of a pair of club-feet. Having twice examined them, I stated it as my conviction that one or both feet might be restored to their natural shape ; and on the 6th of August had casts taken from the limbs. He was one of six children, all perfect except himself ; both feet were inverted at birth, and the midwife who attended his mother having pronounced his complaint incurable, no pains were taken to remedy the defect until he was two years old, when the inversion was perceived to be considerably increased by any attempt to place him on his feet. His father being in Salisbury at the time, carried him to a surgeon there, who braced down the left foot, to what, from the description given of it, appears to have been an iron sandal, armed with straps and buckles. This the child wore for three weeks, and during that period the limb appeared to improve ; but the parents leaving the town, and the straps being broken, the shoe was laid aside. From this time he was unable to walk, or even stand alone, until four years of age, though both his health and appetite were extremely good, and he did not seem to suffer from any debility of back or loins. His first

pair of shoes were put on when he was six years old, and he was enabled shortly after to accompany his parents on foot to the extent of five miles a-day, their employment, as hawkers, compelling him to do so. This life he continued until a year and a half ago, when, on the decease of his father, his mother settled in Brighton. Present state :—General appearance that of a strong stout-built boy, his legs excepted, which are very much emaciated, the circumference of each leg, about an inch and a half below the patella, being $7\frac{1}{2}$ inches, with hardly a trace of muscle. When standing *at ease*, the base of the metatarsal bone of the little toe supports the right limb, while the left one rests on the mere point and the whole outer side of that bone. These, with the metatarsal and phalangeal bones of the other toes, have their apices turned towards those of the opposite foot, while their bases, being twisted on themselves, are set at right angles with the tibia ; thus the metatarsal and phalangeal portion of each foot appears to overlap the other, their coronal surface presenting an anterior, while their plantar assumes a posterior aspect. In progression he enjoys no voluntary power over his lower joints, the hips excepted ; he therefore advances with a waving kind of motion, which is caused by the heads of the thigh-bones being rolled outwards and backwards when he attempts to advance. The flexor muscles of the leg at the same time contract powerfully ; but as they are thrown out of their line, their tendency is to draw the toes upwards and inwards towards the ankle, thus thrusting the basilar extremities of the outermost metatarsal bones from their connexion with the ossa cuboidea, making these points the fulcrum of each foot, and consequently of the entire body, while they render the foot a more perfect club in appearance. The consequence of this is, that the cataneous and muscular coverings of these parts have become enlarged, thickened, and indurated, from constant pressure, and assume the appearance of a false heel. On a more careful examination of the right foot, I found the tibia apparently twisted to a considerable extent, but not really so ; the external malleolus being directly perpendicular to the base of the external metatarsal bone, while the internal ankle cannot be discovered. The superior portion of the head of the astraga-

lus is pushed downwards and forwards, with a slight inclination outwards. The calcaneum, with the os cuboides, is drawn upwards and backwards against the posterior surface of the tibia, while the ossa naviculare and cuneiformia, with the metatarsal bones, appeared at right angles with, but below, the tibia, as has been already described. In the left foot was a deformity of a similar character, but not to the same extent; the false heel of the right being double the size of that of the left, and the space between the great toe and internal malleolus a third less than in the other; consequently, the heel of the latter is much more perceptible, and nearer its proper situation. When he makes the slightest motion with either foot, the abductor pollicis is brought most powerfully into play, and so completely separates the great toe from the others as to give the intermediate space the appearance of an expanded crab's claw.

August 10, 1831, I procured the necessary apparatus, consisting of some very soft tow, two yards of yard-wide calico split into nine lengths, and rolled into two firm rollers; also two long straight leg-splints, and a foot-board for each limb. The leg-splints were made to extend from half-way up the thigh to a little below the foot; the sole-board was somewhat longer and broader than the foot, rounded at one extremity and square at the other. I commenced by softening the feet in water, and extending them between my hands as much as could be done without causing pain: to aid this, the foot was well rubbed with the hand moistened with sweet-oil, from which some advantage was evidently derived. The roller was now applied in the figure-of-eight fashion, and, the foot being completely enfolded in the bandage, the angle between the internal malleolus and great toe was filled with padding: the roller being then drawn with a firm pressure over both padding and false heel, was made as tight as could be comfortably borne. The foot and ankle being once more covered with a layer of bandage, the foot-splint was placed beneath the roll, to which it was bound, and then a leg-splint fixed along the inside of the limb. I now found that the foot had allowed of a very slight degree of extension, to secure which I loosely bandaged another splint on the outside.

From this time they were opened

every other day, and given each three-quarters of an hour's gradual extension, care being taken each time to draw the bandage tighter, and to bind the foot more firmly against the inner splint.

At the end of ten days the improvement in the left foot was perceptible to every one, the great toe being brought nearly parallel to the inner edge of the patella. I now commenced my endeavours to flex the joint, first by moulding it, and then by bringing the foot-board as near to a perpendicular as the feelings of my patient would permit; this I accomplished in a dozen visits, carefully observing each time to push the pulley of the astragalus upwards, backwards, and inwards, and the base of the metatarsal bone directly inwards. To keep these in their places, a piece of sheet-lead, adapted to the size of the projection, and lined with padding, was bound on each prominence. The effect of this gradual compression was not only to aid in replacing those protrusions, but also in causing an absorption of the callous and thickened integuments, without exciting ulceration.

Sept. 8th.—The left leg is restored to its proper shape, but the weakness of the extending portion of its muscular and ligamentous structure renders it incapable of retaining that shape unless it be supported by some mechanical contrivance, although the muscles of the leg and calf are becoming remarkably developed. I therefore had made for him (as recommended by Dr. Harrison, in his work on Spinal Curvature) an iron plate, which should run along the inner side of the foot, with a horizontal one attached, and extending under the sole of the shoe, to which it was sewed; it had also a flat rod proceeding along the inside of the limb, as high as the centre of the thigh, and provided with two joints, one to correspond to the knee, the other to the ankle. Attached to this was a plain flat-heeled boot, which was fastened in front by means of buckles and straps brought from certain points, by means of which the pressure on the irregular prominences might be very much increased.

After a few days' trial, I found that the resistance being altogether from the inside, the foot gradually swerved to the outer, and that nothing but a similar plate in that direction would keep the limb in its proper position. The right foot, which had not been handled by

any one before me, and which, consequently, was considerably more *fixed* than the other, at first appeared inclined to resist extension; but having overcome this difficulty in the course of two months, I began to bend it, when it became necessary to apply strong and continued pressure with the thumbs to the pulley of the astragalus, which was at last restored to its proper cavity. The foot was now rendered capable of being placed in a boot, similar to that last described, and secured in an iron frame, which consisted of a full-sized flat sole-plate screwed on the bottom of the boot: to this were attached two side-plates, each extending from one extremity to the other, and rising so high at the sides as to be almost equal with the ankle behind, and a little above the metatarso-phalangeal articulation in front. From each of these plates extends a flat steel rod, passing up two-thirds of the thigh on the inside, and to the hip-joint on the outer. The inner one is provided with two joints, one to correspond to the ankle, the other to the knee; to these the outer one adds a third at the hip, to which is attached an oval concave plate for the great trochanter to lie in; this shield is pierced with holes, and has a button on its outer side, that it may be the more easily padded, and in order that a belt, which is secured round the waist, may be attached to it.

Dec. 11th.—The boots and irons being finished and padded, they were placed on the feet, and found to fit comfortably. Orders were then given that he be not allowed to leave the house until his feet became accustomed to them.

16th.—This evening he walked a distance of 800 yards, and found his only difficulty lay in not knowing how to raise his feet in progression.

17th.—Was able to come to the Lyngby Institution, a distance of some hundred yards, with a very firm and steady step. The right foot is perfectly straight, and flat in the shoe; but the metatarso-phalangeal articulation of the great toe of the left one projects considerably upwards and inwards. In order to remedy this defect, two longitudinal slits were made horizontally in the inside plate of the instrument: one of these was placed directly parallel to, and opposite, the metatarso-phalangeal articulation of the great toe; the other about three-eighths of an inch above, and two inches behind it; a third, in the outer plate, occupied

the space midway between both. A strap then passed through those slits and over the foot, was drawn tight, and the ends buckled together; by this means all parts of the foot were kept equally pressed down in the shoe. The same apparatus was also necessary at a subsequent period in Triller's case.

Shortly after the above notes were completed, I ceased to attend this boy, partly from his engaging more of my time than I could spare from my other avocations, and partly because, as soon as he was released from his temporary and necessary confinement, he could not be kept under control by myself or his mother. He was therefore left completely to his own management, his instruments broken or dashed out, and his limbs allowed to assume what shape they might. In spite of all these unfavourable circumstances, the limbs are both at this moment strong and serviceable; and when covered with its shoe, &c. the deformity of the right one, which is much the worst, is scarcely noticeable.

During the whole of this boy's confinement he did not require any species of medicine, with the exception of a single dose of rhubarb and magnesia, in consequence of a slight diarrhoea, though his food during a large part of that time was extremely bad. The only difficulty I had to encounter in the whole course of my treatment was his inability to bear pressure on the metatarso-phalangeal articulations of the great toes—an inconvenience which I was enabled to remedy by placing small soft pads on either side of the articulation, and thus removing the pressure from it. Each of his legs had increased a full inch from the commencement to the termination of the treatment.

CASE II.—George Triller, son of a stucco-plasterer in the employment of Mr. Wilks, the architect, *ætat.* 9, one of twins, the first a breechling, and still-born. The second, the subject of these notes, came into the world naturally. Immediately after birth, his feet were perceived to be considerably inverted, as much, in his mother's opinion, as they are at this moment. When about twelve days old he was taken to a surgeon, who bandaged them. There being no perceptible improvement at the expiration of a fortnight, and the child's health re-

quiring country air, his parents ceased their attendance. When six months old he was brought to St. George's Hospital, and placed under the care of Mr. Brodie as an extern patient, by whose direction each limb was enveloped in a roller bandage, and had a leg-splint placed on the inside. This mode of treatment was persevered in for six or seven weeks, at the end of which time he was placed under the management of Mr. Callum, then a student of St. George's, and son of the instrument-maker of that name, who resided in Great Queen-Street, Lincoln's Inn. This gentleman strapped the feet with plaster and bandages, and then placed them in machinery, which the child continued to wear for fourteen months; and during this time the limbs appeared to be greatly improved while confined by the instruments, but as soon as they were removed the deformity again became quite perceptible.

At the end of this time the father removed to the country, but continued Mr. Callum's mode of treatment until the boy was four years old, when, in consequence of the inconvenience attendant on the procuring Mr. Callum's apparatus, they ceased to make use of it, and had recourse to the machinery of other persons, lastly of Mr. Revel, St. Martin's Lane, whose instruments caused so much pain, and so abraded the integuments, as to compel the boy to throw them off altogether at the age of seven, since which time he has had nothing more than common shoes on his feet. While he wore instruments his health was always deranged, particularly his bowels, which were constantly hard and costive.

October 10th, 1831.—Present state: general health good, but complains of pain and weakness in his loins when he walks, which he does in the same manner as Callaghan, though he can run extremely fast, and with comparatively less inconvenience. Height three feet nine inches; body well made, and moderately covered with flesh, except his legs and feet, which are very much emaciated and curved. When sitting, or in the recumbent posture, and the condyles of the femora in juxta-position, the phalanges of one foot overlap the metatarsal bones of the other. In running or walking he rotates the thighs inwards, and moves with a waving kind of motion. When he places his foot on

the ground, he rests on the external plantar arch of the left foot, nearly through its whole length; this gives a considerable obliquity to the leg, while the arch is much more flattened than in the right limb, and is brought nearly to a right angle with the tibia, whose internal malleolus appears to be inclined forwards to a considerable extent, while the astragalus projects more outwards, and the base of the calcis is drawn more upwards and backwards than in the right one. The foot resting completely on the outer side, the integuments of that part are consequently become very callous, and there is a hard ridge running along the upper surface of the cuboides, forming the outer edge of this unnatural planta. Right leg: the anterior spine appears twisted in such a manner as to give an oblique direction to its anterior inferior triangle, and thus throw the internal malleolus more forwards, and the external one more backwards, than natural, while the head of the astragalus projects directly forwards. The base of the calcis is drawn up by the gastrocnemii, whose tendon is long, tense, and rigid. The flexor muscles of the toes throw the os cuboides and base of the metatarsal bone of little toe into a prominent arch, on the inferior and external portion of which, along with the external part of the same metatarsal bone through its entire length, he seems to rest.

The space between the great toe and one next is greater than natural; the two following are much distorted, particularly that nearest to the little toe, which is completely twisted. The boy possesses some power over the toes, and can incline them towards the internal malleolus, but is unable either to extend the foot, or flex the ankle. In the left foot, also, he possesses the power of bringing the phalanges nearer to the tibia; and thus, when he stands, of resting himself on the parts already mentioned.

On trying to extend the foot, I found it could be done but for the resistance offered by the soft parts. The tendons and ligaments were particularly tense and rigid; I therefore ordered them to be well rubbed with olive oil, for at least an hour; after this I again tried extension, and being provided with a nine-yard calico roller, of three inches wide, applied it in the same manner as in Callaghan's case, taking care that in

each fold of the bandage the pressure should come upon the os cuboides. Having attached a foot-board and a side-splint to the inside of the limb, and having filled up every hollow with tow, as in the former case, taking care to keep the great toe, and consequently the whole foot, as nearly parallel with the anterior edge of the perpendicular portion of the foot-board as was possible, without inflicting considerable pain, I observed the same rule at the upper portion of the limb, with respect to the anterior surface of the patella and corresponding edge of the splint. I then proceeded to place another splint on the outside of the limb, but found that a pressure merely to keep it in its place caused such acute pain, from the stretching of the limb which it produced, as to induce me to lay it aside for the present.

On calling the following morning, I was informed he had suffered no inconvenience from the novelty of his situation until evening, when he said his

ankles and toes felt stiff; but on being put to bed went to rest, and though he cried occasionally in his sleep, did not, on being awakened, complain of suffering pain. The limbs had been unbanded previous to my arrival, and well rubbed with oil. I proceeded to examine if any part had been fretted by the splints or bandage, and found that the metatarso-phalangeal articulation was the only part which had been in the slightest degree irritated; but here a slight vesicle was raised. As this prominence had caused me some annoyance in Callaghan's case, I determined to try what effect would be produced by enveloping the entire toe in a pledget of soft lint spread with spermaceti, and sufficiently thick to remove all pressure from the joint. I then used gradual extension for half an hour with each foot, and enwrapped them in the bandages as before, slightly increasing the pressure. This mode of treatment I continued for a week, when, having

Apparatus referred to in the Paper.

brought the limb into a more direct line, I put a splint on the outside of the right leg, the left one being still too much curved to admit of one. After this I proceeded to apply pressure with my thumbs to each unnatural prominence, particularly of the os cuboides and astragalus, directing each bone at the same time into the line of its proper situation. To aid me in those endeavours I made use of the warm bath, and pressure directly on the part by means of a piece of sheet-lead fitted to it, lined with wadding, and over which the bandage was tightly drawn.

Saturday, Oct. 22d.—The left foot being considerably more capable of extension, I have put a splint on the outside of the limb. He complains sometimes of cramps in the legs, and, as I am informed, suffers most from it at night, the pain being sufficient on some occasions to make him call out in his sleep, though not to awaken him.

Dec. 26.—After some delay on the part of the trades-people I have been able to get a boot finished for his right foot, which is now capable of being put into one without pain: the ankle-joint can also be flexed to a certain extent.

Jan. 6th.—The second boot was put on this evening, both exactly similar to those of Callaghan. These being secured, he was enabled to stand erect for some minutes, by the aid of his stick, and with the assistance of a pair of crutches to move some steps. He has considerable command over his joints.

8th.—He can stand alone, with his toes everted, and without any support, but cannot advance, recede, or turn, without his crutches; but with their assistance can make all these movements, though very slowly, and complains of pain and weakness in the loins after he has used a little exercise. The feet lie fairly in the boots, and do not experience the slightest pain on pressure, except on their being first introduced. During the whole length of his confinement his mother has not found it necessary to give a dozen doses of syrup of poppies in $\mathfrak{z}\text{ij}$. doses, while formerly, during the time he was under the care of Callum, Revel, &c. she has administered to him to the extent of $\mathfrak{z}\text{ij}$. of this medicine within the 24 hours, without it producing on him the slightest soporific effect.

To these two cases I shall briefly add one more, with which I purpose concluding this essay: as, though it was

not brought to a termination, I think it affords satisfactory evidence of the reasonableness of the opinions advocated in the preceding part of this memoir, and of the success which may rationally be expected, even at very advanced periods, from a steady perseverance in the mode of treatment pursued in the cases of Callaghan and Triller.

Being in Dublin about the 30th of last June, I was requested to see and give an opinion as to the curability of a young girl, *æt.* 14, the daughter of Mr. Holmes, a respectable shoemaker, in Castle Street. On examining the feet, I found she was affected with a double congenital club foot, of a character very similar to that of Triller, but which, from being taken in hands at a very early period, being subsequently fitted with shoes according to a plan of her father, and perhaps from a peculiarity in her constitution, or *in the original formation of the muscles and ligaments of her lower extremities*, were capable of being more easily and rapidly restored to a right line with the limb than in either of the other two children. I therefore commenced a similar mode of treatment with her, with the hope that if I were enabled to accomplish the rectification of the deformity to a certain extent, some person might be found who would undertake the completion of the task. With the addition of the nightly use of the knee bath, I had, at the expiration of ten days, the satisfaction of seeing both feet brought to a right line with their respective limbs. I was then necessitated to leave Dublin and return home instantly, and since that time have not heard any thing farther concerning my patient, nor have had any opportunity of making particular inquiries.

Note.—Since the completion of this essay, which has been unavoidably withheld from publication for a period of several months, the medical world have, through the medium of the various professional journals, become generally acquainted with the opinions and treatment advocated by MM. Stroemeyer and Dupuytren; but as it is not the object of the *present* paper to enter into the consideration of their advantages and disadvantages, it is sufficient for the present merely to have noticed them. In conclusion, the author has recently had an opportunity of examining a beautifully executed instrument, made by Mr.

Tailor, of the Strand, which, with that adaptation to particular cases always necessary in such instruments, is a most admirable substitute for his (the author's) more rude contrivance.

Brighton, Dec. 28, 1834.

ON THE ANTERIOR MEMBRANE OF THE CORNEA.

By RICHARD MIDDLEMORE,

Lecturer on Diseases of the Eye at the Birmingham Eye Infirmary.

In the Medical Gazette for February 1834, it is stated by Mr. Wallace that the cornea is not covered by the conjunctiva, and that the latter membrane terminates at the corneo-sclerotic junction*. It is also asserted that the corneal covering "resembles the cuticle," and that it overlaps, and is inserted into, that portion of the conjunctiva immediately surrounding the cornea. The author's reasons for arriving at the preceding conclusions are stated to be chiefly derived from carefully conducted dissections; from, in fact, the very method which has long since been employed, and, as I think, successfully employed, to correct the errors Mr. Wallace attempts to renew. This mode of reviving exploded doctrines is, I fear, too much practised by writers of the present day, without an adequate examination of the grounds on which their former refutation rested.

Writers on diseases of the eye usually consider the affections of the cornea as they occur—1st, in its conjunctival covering; 2d, its lamellar and connecting cellular texture; and 3d, its serous lining. This is the plan adopted by Mr. Wardrope†, and all succeeding systematic writers on the pathology of the eye.

* It is stated by the learned Porterfield, that "the conjunctiva is extended over the whole front part of the globe, till its termination in the edge of the sclerotic adjoining to the cornea, where, of consequence, it forms a large hole for the transparent cornea, through which the iris and pupil are seen."—A Treatise on the Eye, and the Manner and Phenomena of Vision, chap. 2, sec. 2, page 60.

† The Morbid Anatomy of the Human Eye, vol. i. page 3. This mode of discussing the diseases of the cornea, by arranging them according to a correct anatomical division of the textures which enter into its composition, would appear (I cannot say more than this), to have originated with the philosophical Leeuwenhoek. At page 316 of his "Arcana Nature Detecta," he says, "atque etiam in tunica cornea oculorum, quam antea examinans constare censui ex tribus distinctis membranis coacervatis."

An important part of the pathology of the cornea has been founded and received under an impression that it was covered externally by a continuation of the membrane which covers the other part of the outward surface of the eye; and it becomes us to hesitate ere we consent to renounce this opinion, approved and confirmed as it has been by the labour and research of so many distinguished anatomists*.

I shall now attempt to condense a small portion of the mass of evidence which may be brought forward to prove that the conjunctiva, in a modified form (suited to the part it covers), is continued over the cornea.

1. If the eye of an ox (I select the eye of this animal simply because it is large, and is precisely the same as the human eye, as respects the point at issue) be kept for a few days, so that putrefaction may have commenced, the conjunctiva may, by a careful dissection, be removed from the whole anterior surface of the eye; but it will not certainly be found equally dense, &c. throughout its whole extent, though it will still be ascertained to be a *continuous membrane*.

2. For my present occasion I do not lay much stress upon the removal of an entire pellicle from the surface of the eye in those animals which "cast their skin" at stated periods; for at best this circumstance can do little more than prove what was long since stated by Porterfield (op. cit. vol. i. p. 63), namely, that the cuticle is detached not only over the cornea, but over the whole anterior surface of the eye.

3. When the surface of the eye is in-

* "Ipsa autem conjunctiva non hic subsistit, sed porro per corneam, sed pellucidissima nunc facta producitur."—Descriptio Anatomica Oculi Humani iconibus illustrata; auctore Johanne Gottfried Zinn. Göttingen, 1755, p. 24.

"Firmior cum cornea, quam cum albuginea tunica adnata coheret. Licet intinuis igitur nexus utramque intercedat tunica, cultro tamen et maceratione conjunctivam a cornea sepi. rari posse, sæpius expertus sum." Clemens in Scriptores Ophthalmologici Minores, vol. i. p. 105.

"Parvenue sur le globe de l'œil, la conjunctive adhère lâchement à la sclérotique. Sur la cornée, elle prend plus de ténacité et une adhérence beaucoup plus forte, mais que peut être détruite par la macération."—Traité d'Anatomie Descriptive; par Xav. Bichat, tom. ii. p. 428.

"There is a pellicle, or exceedingly thin coat, which, by maceration, can be taken off from the surface of the cornea. This is the conjunctiva continued over it. In the fœtus calf I have forced the blood in the vessels of the conjunctiva into the vessels passing over the surface of the cornea."—The Anatomy and Physiology of the Human Body, by John and Charles Bell. London, 1823. Vol. iii. p. 31.

flamed for a long period, and particularly if that organ be exposed to some prolonged source of irritation, vessels sometimes pass over the cornea, and are found to be developed in its external covering, and to be continuous with tubes which ramify in the texture of the sclerotic conjunctiva. Pustules occasionally form near to, or at, the margin of the cornea, and by their increase—by the augmentation of their fluid contents—they elevate the tunica which covers them, which is then seen to be a continuous membrane covering the whole of the pustule—that is, the part which is placed upon the sclerotic, and the other portion which is situated upon the cornea. The vessels of the conjunctiva are sometimes extended upon the cornea, for the purpose of repairing a superficial ulcer of its texture. It may be said that these vessels are formed in a sort of lymph track, and that they are merely so developed for a temporary occasion; but as they are observed to be continuations of the same vessels which are noticed within the sclerotic conjunctiva, I apprehend that if that membrane really terminated at the corneo-sclerotic junction, these vessels would terminate there also, and would not, if I may be allowed the expression, push through the mucous membrane at the point of its attachment. The disease termed pterygium is a morbid production developed in the subconjunctival cellular membrane. It is always of a triangular figure; and this circumstance has been found to depend on the gradually increasing strictness of adhesion which subsists between the conjunctiva and sclerotic, as they approach the cornea*. This triangular figure is still preserved as the diseased production passes over the cornea, though not so perfectly as when placed upon the sclerotic; and the surface of the pterygium is covered with conjunctiva wherever situated. The slowness of its growth affords a favourable means of securing the gradual elevation of the conjunctival covering of the cornea; and that this actually takes place,—that both the sclerotic and corneal portions of the conjunctiva are raised by the pterygial growth,—is, in my opinion, a most unquestionable fact. I have once or twice witnessed an arid state of the conjunctiva, in which that membrane

has been shrivelled, of a pale brown appearance, partially detached from its natural connexions, and quite dry, having lost its secreting property. In this condition of disease, the anterior membrane of the cornea is affected in the same manner as the immediately surrounding parts; and the connexion of texture—the continuity of surface—is then very distinctly marked. Similar states of disease have been noticed by Travers, by Mackenzie, and also by Wardrop.

4. The effect of various chemical substances upon the external part of the eye appears to be pretty much the same upon every portion of its surface. If, for instance, a weak solution of lime be applied to the eye for a short period, so as to lead to any appreciable change, the same alteration, whatever may be its extent, is visible on every part to which the slightly caustic matter has been applied.

In making the preceding statements, I do not mean to say that the conjunctival covering of the cornea exhibits, in perfect purity of type, all the characters of mucous membrane; on the contrary, I am confident that the qualities of such membrane are much modified, and that it may with perfect propriety be classed (like the part it covers), among the anomalous tissues. But I am desirous of stating my belief, that the surface of the eye is covered by a *perfectly continuous membrane*.

Fearful of encroaching upon your limits, I will not adduce the mass of evidence I am prepared to add to that I have already advanced in support of the latter statement.

Mr. Wallace asserts, that—1, “were the anterior membrane (of the cornea) a continuation of the conjunctiva, the chemosis in severe catarrhal (?) ophthalmia would not stop at the edge of the cornea, but would proceed over its surface.” I apprehend this will depend on the degree of firmness of the adhesion subsisting between these parts. When those effused matters which constitute chemosis elevate the sclerotic conjunctiva, it readily yields, and is raised above, and overlaps the edge of the cornea, in a way which tends to prevent the elevation of the membrane which covers it. 2, “Were it (the anterior membrane of the cornea), a mucous membrane, the mucus secreted would impede vision.” I am only anxious to

* See, upon this subject, the opinions of Scarpa, Wardrop, Demours, and almost every modern writer on ophthalmology.

assert that the anterior surface of the eye is covered by a *continuous membrane*, which is emphatically denied by Mr. Wallace.

The concluding sentence in Mr. W.'s communication is peculiarly unfortunate for his argument. Should he ever visit this part of the country, I shall be happy to convince him that what are usually termed pustules may not only form upon the cornea, but at almost any part of the surface of the eye-ball.

TREATMENT OF RINGWORM WITH PYROLIGNEOUS ACID.

To the Editor of the Medical Gazette.

SIR,

ABOVE a year ago I received the enclosed circular letter from Mr. A. L. Wigan, of Brighton; and I have since made, as I supposed, a fair trial of the remedy for ring-worm which he recommends. I have, in common with others, been disappointed in the result, and I think it due to Mr. Wigan to express my belief that the acid employed was not of the strength he recommends.

The disorder in question has been so obstinate, in some notable cases at public establishments, and is often so perplexing in private families, that it seems to me worth while to make known a method of cure which is said to have proved so successful.

Mr. Wigan has, it may be said, already done so, by circulating among the members of the profession his printed letter; but as this failed to convey his instructions with sufficient precision, I would request that you publish either the whole or a part, as you think more eligible, of his former communication, and of that which he now particularly addresses to myself. I have the honour to be, sir,

Your obedient humble servant,

B. G. BABINGTON.

16, Aldermanbury, Jan. 2, 1835.

CIRCULAR.

"SIR,—The disappointment and annoyance so generally experienced in the treatment of ringworm, induce me to believe that the suggestion of a safe, speedy, effectual (and I believe *new*) remedy, will be acceptable to the profession, although

the form of this communication be unusual.

* * * * *

"It would seem superfluous to say that before any attempt is made, the disease should first be strictly identified; but I am constantly seeing cases where, from a too cursory inspection, or from a too ready acquiescence in the report of the friends, continued disappointment has arisen. Several other eruptions are occasionally confounded with it by men perfectly capable of distinguishing them, if they would give themselves the trouble of an attentive examination, but this should invariably be done in a strong light, and with a *very powerful lens*; an examination with the naked eye is worth nothing at all.

"Ringworm is not only frequently mistaken for, but is often actually complicated with, porrigo, psoriasis guttata, and many other tettery eruptions; but I believe it is never modified by them. The two eruptions may still be distinguished, even when mixed together. The additional diseases may be cured by their respective remedies, without advancing the cure of the original malady a single step. Nay, the specific remedy for the others will often aggravate ringworm; although cases sometimes occur in which the means adopted for the cure of the latter entirely dissipate the former.

"The most frequent combination is ringworm and porrigo favosa, which is easily and invariably cured by a week's steady use of the ung. hydr. precip. albi, freely applied at bed-time: but it is occasionally necessary to conjoin therewith a mild alterative course, such as a grain of calomel and ten of chalk every night.

* * * * *

"In the majority of cases the disease is obvious enough. Whether simple, then, or complicated, I will suppose it clearly ascertained, and its concomitants, if any, entirely removed; and proceed to speak of the remedy which I have found so extraordinarily beneficial.

* * * * *

"In the beginning of the treatment it very much simplifies the affair to insist, in the first instance, on shaving the head—for the skin is contaminated long before the disease is cognizable. This is, however, sometimes very obnoxious to the patient or friends, and there are cases in which it may be omitted—of which I will speak hereafter.

"The head, then, being shaven, and time given for any slight cut of the razor to be healed, I apply all over it (by means of a short soft shaving brush) the strong pyroligneous acid prepared by Beaufoy, diluted with one-third of its volume of

water—keeping the head thoroughly wet with it for the space of two minutes. Some slight and very transient pain is given at the spots, *which we immediately rendered visible, though they could not previously be distinguished*,—they become instantly of a very bright red, while the healthy scalp is not at all affected, except in some rare cases, where the skin, being exceedingly thin and delicate, it is advisable to use the acid in a more dilute state.

“The complete detection of every infected spot makes our further progress easy and satisfactory, as we know the extent of the disease.

“I now continue to *soak* the affected parts with fresh applications of the acid in its full strength for a quarter of an hour; and if this be done carefully and steadily, a second or third application (with intervals of three or four days) will always complete the cure. Once is sometimes sufficient, but I do not like to trust to it.

“A thick scab is generally the result of this process, and this should not be hastily removed. At the end of a week or ten days it is seen gradually rising from the scalp, supported on the new hair which grows rapidly under it, and soon raises it high enough to admit a pair of scissors, when the whole is cut off, and the skin shews clear and healthy. Should this not be the case, which can very rarely occur, the same process must be repeated; but I again urge that the *examination be always made by the lens*.

“The most embarrassing cases are those wherein various applications have been already tried, many of which being of an irritating nature, produce an appearance not ‘in the books.’

“If on the first examination (after the test of the acid) there be found only a single spot, and of slight extent, and if (as in the case of a school) it be of importance to prevent even the *possibility* of communicating the disease to others, it is better at once to touch the surface with the *kali purum* so slightly as to give no pain. This is effectual. A slight eschar is formed, and when the slough separates, no hair appears for some time; but there is no fear of its being re-established in a few months, and in the meantime all apprehension is at an end.

“*The important thing is, however, in all cases, that the surgeon should do all this with his own hands*—the only mode of knowing whether the failure or delay arise from the inefficiency of the remedy or from the imperfect mode of applying it. No dependence whatever is to be placed on the punctuality of the child’s friends in this respect.

“Ringworm on any part of the body except the head *never* requires more than a single application of the acid.

“When the hair is very thin, and the disease of recent origin, it is unnecessary to shave the head. The acid must still, however, be first applied as a detector.

“I have the honour to be, sir,

“Your obedient servant,

“A. L. WIGAN.

“Brighton, Nov. 10, 1833.”

To Dr. Babington.

MY DEAR SIR,

MANY applications have been made to me by London practitioners, to know if I still retain my good opinion of pyroligneous acid, as a remedy for ringworm, and asking if any error in the mode of using it can have led to results in their hands so different from those stated in my letter.

Allow me to request the favour of you^a to give publicity to my answer, in any mode you may think best adapted to the object.

I would premise that the hasty letter I addressed to the leading members of the profession, was printed solely to save myself the trouble of answering so many applicants; but owing to some errors of the press (such, for instance, as the omission of *favosa* after *porrigo*) it failed of giving a clear idea of my meaning.

The main cause of disappointment was, however, my omission to state the absolute strength of the acid employed; as I find that almost all the gentlemen who have addressed me have used it as usually sold to apothecaries—viz. two parts acid and one part water, make the “distilled vinegar.”

Now that which I use makes a liquid of the same strength, on mixing one part acid and eleven parts water; consequently is just *eight times stronger*. It is no wonder, then, that disappointment has arisen, for the fluid they have used is not strong enough even for the “preliminary test.”

The acid is furnished to me by Messrs. Beaufoy, and is called *eleven acid*: but I believe it is sold in all intermediate strengths, down to simple distilled vinegar.

Further experience does but confirm me more and more in the absolute efficacy of the remedy. Whether the local atmosphere of Brighton may aid the cure, I know not; but I can safely as-

sert that I have hitherto met with no case of failure.

It is obvious that this malady may occur in conjunction with constitutional ailments requiring medical aid, and which may modify the appearance of the eruption. I shall take an early opportunity of offering to the public, through some of the medical journals, the results of a very extensive experience in this and analogous diseases, in the conviction of saving much trouble to practitioners who only see such cases in private practice, at intervals which do not allow of drawing accurate inferences—except, indeed, with men who have the advantage of an extraordinary memory.—I am, sir,

Yours very truly,
A. L. WIGAN.

INVERSION OF THE UTERUS SUCCESSFULLY TREATED.

To the Editor of the Medical Gazette.

SIR,

As there appears to be some doubt among obstetrical writers as to the practicability of returning an inverted uterus, after the inversion has continued some hours, perhaps the record of the following case may not be without practical utility. Should such be your opinion, you will oblige me by inserting it in your valuable publication.

I am, sir,

Your obedient servant,
W. B. DICKINSON.

Macclesfield, Jan. 3, 1835.

On the 24th of December, 1834, about ten o'clock in the morning, I was called upon to see, in consultation with a medical gentleman, Mrs. Bingham, a married woman, aged 30 years, of a very weak and delicate constitution. The account given was, that Mrs. Bingham had been brought to bed of her fourth child, about ten o'clock in the morning of the previous day. Her labour was a natural one, and the placenta was expelled entire, without traction of the funis having been used, and unaccompanied by subsequent hemorrhage.—During the whole of the day in which

her labour occurred, she appeared to be pretty well, except that she had sharp after-pains, which returned about every five minutes till three o'clock in the afternoon, when she became a little easier; but from this time she felt a forcing down, and a continued desire to micturate, till nine o'clock in the morning of the 24th, when a large tumor was protruded from the vagina. When her medical attendant, who was immediately sent for, arrived, he at once discovered that this tumor was the uterus completely inverted.

When I saw her she was in a state of great depression. Her pulse was very frequent and feeble; her face deathly pale; her lips without colour; her eyes half-closed and languid, and her extremities cold. On examination I found the uterus lying externally, inverted, and feeling to the touch rough, elastic, and resisting, and about the size of a new-born infant's head. I could pass my finger round the cervix uteri, and could feel the part which I judged to be the os tincæ, closely drawn up. Though extremely faint, as described, she was not sick, nor was there any sickness at any subsequent period. She had some wine and water given to her; and after exertions continued for more than a quarter of an hour, by pressing the knuckles against the inverted fundus, the uterus was returned within the vagina, but further attempts to reverse the viscus were at this time ineffectual. The woman now became still fainter than before, and the pulse was scarcely perceptible; it was therefore resolved to wait a little, and in the meantime to refer to different authors who had written upon the subject, and to consult our medical friends as to what they conceived would be the best course to pursue.

During this rest, the application of cold wet cloths to the parts was directed, and the internal exhibition of cordials. Upon reference to authors, it appeared to be their general opinion, that after an hour had elapsed from the inversion, the reduction was scarcely possible; but a medical friend, Mr. Fleet, said that the late Mr. Kinder Wood, of Manchester, had returned an inverted uterus after the lapse of two days from the accident; and Dr. Swanwick stated, that he had seen a case of partial inversion reduced after seven days from its occurrence. It was therefore determined to make a second attempt at reversion.

At one o'clock Dr. Swanwick was kind enough to see the patient with the medical attendant and myself. Though still greatly depressed, she had in a slight degree rallied. Previous to a renewed attempt at reduction, a small dose of laudanum, and sp. ammon. aromatic. was given. At first I could only introduce the points of the fingers, well oiled, into the vagina, but by gentle steady efforts the hand was passed, carrying the inverted uterus before it. Pressure with the knuckles was then made upon the fundus, and afterwards the inner surface of the point of the thumb was pressed against the part, till slowly, and almost imperceptibly, the uterus was restored to its natural state. I could distinctly feel the inner surface of the uterus soft and irregular, like the surface of torn flesh, the cavity being not larger than would contain a full-sized orange. The hand was kept in the vagina some time, till the os tincæ contracted to its usual size, after which it was slowly withdrawn, and a tampon, formed of a well oiled silk handkerchief, was cautiously introduced.

No hæmorrhage of consequence occurred during or after the reduction; but upon subsequent examination, the flock bed was found saturated with blood to a considerable extent, which no doubt had been lost during the inversion, and which accounted for the bloodless appearance of the countenance. The pulse at this time was 140 in the minute, but the woman did not seem worse than before the reversion. Nutriments and cordials were ordered to be given, and the most perfect rest enjoined. No bad symptoms ensued, the only discomfort having arisen from headache, and the woman at the date of this communication (January the 3d) is going on in the most satisfactory manner.

That the complete or partial inversion of the uterus took place at, or immediately after, the expulsion of the placenta, there is every reason to believe. The uterus, if such was the case, was inverted twenty-seven hours. If the uterus was inverted by the continuance of after-pains—a most improbable circumstance—it was inverted at least from three o'clock of the afternoon of the 23d of December, or twenty-two hours. In either case the effectual return of the uterus points out the possibility of reduction at a period when it has usually been considered impracticable.

ON PERCUSSION, AS A MODE OF DISCRIMINATING CERTAIN ABDOMINAL SWELLINGS.

To the Editor of the Medical Gazette.

SIR,

THIS subject appears to me to deserve more attention from medical practitioners than it at present possesses. In many cases the diagnosis of abdominal swellings is rendered less difficult by the employment of percussion. Taking the following outline of the abdomen as a guide, we will proceed to mention some of the diagnostic marks of certain swellings occurring in its cavity.

e, the epigastric region—*l l*, the two lumbar regions, forming a part of *u*, the umbilical region—*h*, the hypogastric region.

Diagnosis of Non-encysted Ascites by Percussion, the Patient being in the recumbent posture.

In every case of non-encysted ascites which I have either seen examined, or examined myself, percussion produced resonance in some portion of the region *u*, in consequence of the floating intestine. If percussion be made laterally, in the direction of *l l*, the lumbar regions, there will be dullness, in consequence of the gravitation of the fluid. In order to proceed a step further in the diagnosis, we should percuss the lumbar regions, directing the patient to change his or her position, viz. supposing the *right* lumbar region to be dull on percussion, the patient lying on the back, if the patient be directed to lie on the left, the right lumbar region will become resonant in consequence of the fluid gravitating to the left side. If the patient be in the erect posture, dullness will be produced by percussion in *h*, the hypogastric region, in consequence of the gravitation of the fluid,

the level of which may be ascertained by percussing in the direction of *u*, until resonance is obtained. Encysted ascites will of course form an exception to this rule.

Diagnosis of Ovarian Dropsy by Percussion, the Patient being in the recumbent posture.

The sounds produced by percussing in ovarian dropsy, the patient being recumbent, are the reverse of those produced in non-encysted ascites; for there will be dulness in the direction of *u*, occasioned by the tumor (allowing the disease to be somewhat advanced), and resonance in the direction of *l*, from the situation of the intestine below the ovarian swelling. Similar sounds are produced in pregnancy, so that difficulty arises in distinguishing between ovarian swellings and pregnancy, from percussion alone. Ovarian swelling and ascites may co-exist; in such a case there will be dulness at both *u* and *l*, the former varying with the change of posture.

I am, sir,

Your obedient servant,

C. J. B. ALDIS,

Member of the Royal College of Physicians.

13, Old Burlington-Street,
Jan. 3, 1835.

SUCCESSFUL CASE OF LITHOTRIPSY.

To the Editor of the Medical Gazette.

SIR,

I HAVE read, in your number of the 20th December, a letter from Dr. Arrowsmith, of Coventry, relating an unsuccessful case of lithotomy, wherein he says, "if the various cases in which lithotomy has been, or may be, performed, were detailed from the commencement to the termination, a series of facts of considerable practical value would be obtained; nor could the pages of our medical periodicals be more fitly occupied than in furnishing the grounds for correctly estimating the value of an operation of such great importance."

As I entirely coincide in the opinion expressed above, I am induced to send you the following successful case of *lithotripsy**, performed by the Baron

Heurteloup, on a little boy belonging to this Institution, in March last.

George Hunt, aged 6 years and a half, was in the habit of wetting his bed every night, and was also observed to make water very frequently in the day; on which account he was brought to me. I passed a sound, and soon discovered that he had a calculus in his bladder. The child, though rather puny and delicate, was in apparent good health, and suffered very little from his complaint, only a frequent desire to make water, with some pain after voiding it. The urethra being unusually large for a child of his age, it occurred to me that lithotripsy might be tried, and, on the 17th of January last, I consulted Baron Heurteloup as to the practicability of the operation. He examined the boy, and was of opinion that, the stone being small, the operation might be successfully done, and in the most liberal and handsome manner offered gratuitously to perform it. As there was no urgency, the child appearing to suffer so little, the Baron recommended the previous introduction of sounds into the urethra, for several weeks prior to his operating, in order to ascertain its capacity, and to accustom it to the presence of instruments. This was done by the almost daily introduction of elastic gum and metallic bougies, until a steel sound, No. 12, could be introduced with facility. The chief difficulty we had to contend with was in quieting the fears of the child, who, of course, by resistance and struggling, might have rendered the operation very difficult; but this was overcome by a little management: by the frequent introduction of bougies and catheters, and by injecting the bladder with warm water occasionally, the young patient was familiarized with the use of the instruments: he was also naturally of a docile temper.

On the 19th March, Baron Heurteloup performed the operation, in the presence of several medical gentlemen. The stone was seized with great skill and celerity, and with blows of the hammer was broken. The operation was over in about two minutes, and the child did not appear to suffer any thing beyond the fear natural on such an occasion.

The same evening, he passed with his urine much sand, and several minute fragments of the stone. On the following day there was some inflammation

* Baron Heurteloup so calls his operation, in contradistinction to *lithotomy*, which, he says, merely signifies breaking the stone by perforation; whereas *lithotripsy* indicates, in a general sense, the breaking down of the stone.

and swelling of the *meatus urinarius*, with slight mucous discharge from the urethra, and several fragments of stone were seen sticking within the urethra for about half an inch down the canal: by means of small forceps these were easily extracted. He had slept well, and made no complaint. He continued to pass sand and small fragments until the 25th March, when he complained of a want to make water, but could not void any. On introducing a catheter, it could not be passed beyond four or five inches, a fragment of the calculus being evidently impacted in the canal of the urethra. Baron Heurteloup happened to call very soon after this occurred, and aftersome time, by injecting warm water, and a little manipulation with sounds and catheters, succeeded in pushing back the fragment into the bladder, and the urine flowed freely; but even on this occasion, when more force was used than during the whole of the treatment, not a drop of blood was passed, although it might have been expected, from the urethra being scratched, or wounded, by the fragment. The following day (March 26th) a *second operation* was performed, and the Baron crushed two or three remaining fragments in a similar short space of time as in the first operation, and with as little pain to the child. For three or four days subsequently, sand and minute portions of the stone were voided; after which period his urine became quite clear, he ceased to wet his bed, and has continued to the present time quite well. Within the last two months a sound has been passed several times, but not a vestige of his former complaint apparently remains.

The only medical treatment employed was occasional enemata, with small doses of castor-oil, in order to keep the bowels free. He was allowed his ordinary diet, and played about with the other boys in the hospital.

The calculus appeared to be composed of the triple phosphate, and the amount of the *détritus*, or dry fragments, collected (exclusive of much sandy matter necessarily lost) weighed forty grains. Whether, in children, *lithotripsy* can generally be employed as successfully as *lithotomy*, future experience can alone determine, as no general deduction can be made from a few isolated cases; more especially as, I believe, hitherto lithotripsy has rarely been per-

formed in children of so early an age as the case above related.

I cannot omit this opportunity of mentioning what I think a curious fact. Children are well known to be much more subject to stone than adults; yet, in nearly 7000 children of both sexes, between the ages of five and fourteen years, who have been admitted into this Institution during the last thirty years, the above has been the only case that has occurred.—I am, sir,

Your obedient servant,
S. G. LAWRENCE,
Surgeon.

Royal Military Asylum, Chelsea,
December 31, 1834.

OBSERVATIONS ON THE PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and
the General Lying-in Hospitals.

[Continued from page 513.]

Morbid Excitement of Nerves.

ONE other remote consequence of arterial excitement remains to be noticed. This is, a proneness to inflammation from slight causes, and a corresponding difficulty of cure. Two instructive examples of this have lately presented themselves to my notice.

CASE.—A lady, the mother of several children, had, after one of her labours, severe suffering in her back, extending to the abdomen, which was exquisitely tender to the touch. Violent pain afterwards occurred along the course of the great sciatic nerve, so as in sitting to prevent her from resting upon that side of the nates. It was obvious that the very respectable practitioners under whose care she then was, and continued for a lengthened period, considered it as an affection of the origin of the sciatic in the lumbar and sacral nerves; for their principal treatment consisted in the application of leeches, and repeated blisters alternately to each side of the lower part of the vertebral column. In a subsequent pregnancy, for three months previously to her delivery, she was unable to leave her house, and scarcely even her chamber, on account of violent suffering a little to one side of the lower lumbar vertebrae and of the

sacrum, extending to the abdominal muscles of that side, to which it was so strictly limited that its extent was defined accurately by the *linea alba*. This greatly increased after her delivery, was of that hyperacute kind which denoted its neuralgic character, and was liable to fearful aggravation from the slightest movement or pressure. Upon the other side of the abdomen the deepest pressure produced no suffering; and it was evident that there was no tension in any one part of the abdominal cavity. As a matter of precaution, lest there might be any lurking subjacent inflammation, I suggested the application of leeches to the abdominal parietes, although my patient assured me that on the former occasion they had been tried without success. She yielded, however, to my recommendation, when they were followed by an aggravation, rather than any subsidence, of the symptoms. They produced erysipelatous inflammation, followed by little ulcerations around the orifices from the leech-bites, which were exquisitely sore and sensitive, and weeks elapsed before they assumed a healthy character, or showed any disposition to heal. The great sciatic nerve, which had not altogether escaped during pregnancy, now became more violently affected; pains shot in the direction of its more superficial sensitive branches in different parts of the limb; and one of her most prominent symptoms was a very severe pain, accompanied with throbbing, under the ankle. When I pressed upon the nerve as it here passes upon the side of the *os calcis*, she suddenly drew away her foot, on account of a lancinating pain which darted under the sole of the foot*.

CASE.—Whilst in attendance upon this lady, I was consulted by a patient

* This is the second instance which has fallen within my observation of neuralgic suffering referred to the heel from irritation, perhaps some accidental inflammation, about the roots of the sciatic nerve. In the other case, the lady was subject, at distant intervals, to attacks of such agonizing pain as to confine her to her chamber—often to her bed; and for some time afterwards she could do no more than hobble about her house on crutches. I have seen little of this lady for some years, but have reason to believe, that since two great causes of additional excitement have been removed by time—menstruation and child-bearing—she has been entirely free from her former attacks. She bore with stoic fortitude the sufferings, which she more than once described to me as like those which she supposed the violent driving of a large iron screw into the heel would produce.

in Chelsea, who, being about five months advanced in gestation, had small oblong, hardish, and circumscribed tumors under the integuments of the leg, close to the inner edge of the tibia. These were exquisitely tender, and were allied to, if not identical with, the disease described by Mr. Wood* under the denomination of painful subcutaneous tubercle, as well as some very interesting cases detailed with great minuteness by the late Mr. John Pearson†.

All exertion, and the slightest pressure, as from a stocking or the bed-clothes, produced intense suffering in the part, darting towards the foot. A very respectable practitioner had applied leeches to the part, but without the slightest relief. They produced surrounding inflammation, and the leech-bites festering, remained unhealed, ulcerated, and exquisitely sore, for many weeks. The symptoms at length yielded partially to confinement to the bed, the leg being protected by what was equivalent to a fracture-cradle, to the sedulous application of cold evaporating lotions, with opium, gentle aperients, and an abstemious regimen. She, however, continued for some time subject to a recurrence of her symptoms, and was obliged therefore to be very cautious as to exertion. A long walk, too long continuance in the erect posture, produced such uneasy feelings as powerfully to warn her of the necessity of recurring to the horizontal position.

If any excuse be requisite for the introduction of these cases, I can but plead their interesting nature, their connexion with the symptoms of morbid excitement of individual nerves, and the conclusion to which they lead. They seem to inculcate this practical precept—that where painful symptoms arise from some cause of irritation, as inflammation or tumor at the origin or in the course of a nerve, the symptoms, however, manifesting themselves at some distance from the seat of the disease, then, as in Sir Charles Bell's case, communicated to the public by Dr. Cooke, “by repeated leeches along the course of the nerve, together with some other remedies, the patient may be restored to health;” but leeches applied to the part in which the symptoms appear,

* Ed'n. Med. and Phys. Journ. vol. viii.

† Med. Facts and Obs. vol. vi.

seem more frequently to add a new and painful disease, without corresponding relief to the original malady. They do more harm by the irritation they excite, than they do good by the abstraction of blood.

What is the precise condition of a nerve in a state of excitement, characterised by pain or convulsive movement, or the combination of the two in the part which it supplies, is a question which, in the present state of our knowledge, or rather ignorance, of the nature of nervous influence, it is far from easy to determine. Until we have ascertained what is the natural state of a nerve in the exercise of its function, it is impossible to understand in what a morbid excess of that state consists, and of both we are profoundly ignorant. We recognise them only in their effects.

It is scarcely necessary for me upon this point to advert to the different theories which have been advanced to explain the functions of nerves. The doctrines of the circulation of a fluid in tubes, there being no sufficient proof of the existence either of a fluid or of tubes, as well as that which referred the phenomena of nervous influence to certain vibrations, have had each its advocates; but they have now given place to the more recent dogma, that the exercise of nervous energy depends upon galvanic influence, and, indeed, that they are the same in essence. The evidence, however, upon which it has been alleged that this important vital function is dependent merely upon galvanic agency, is, in my estimation, far from conclusive. Galvanism may indeed excite the action of a nerve, and re-establish a communication between the extremities of a divided nerve, and produce a renewal of its powers; but, with the utmost deference to the opinions of those who by their talent and exertions have won for themselves golden opinions, their experiments and observations appear to me to be totally insufficient to establish the identity in essence of nervous energy and galvanism. A metallic tube may be divided and re-united by a leather hose; the office of the tube is restored, but the communicating medium is not a metallic tube: so, divided nerves are brought in contact or communication by a metallic body passing from one cut extremity to another, or from one nerve to another, and nervous influence is

supposed to be generated—I should rather say excited or produced. But this is no sufficient proof that the metallic communication is equivalent to nerve in all its offices and attributes, or that galvanism is nervous energy. I believe galvanism to be to the nerve in these cases what venous blood is to the right, and arterial to the left side, of the heart; or, to come nearer to our own subject, what arterial blood is to the brain.

Mr. Swan has, in his work upon the Diseases of Nerves, reproduced the doctrine of vibration, though somewhat modified. He does not, indeed, assert that in the production of the phenomena of nervous energy the nerves vibrate like a musical chord, but he inclines to the opinion that there is “action, so as to produce motion for the ordinary functions of the nerves;” that “from the great retraction after their division, and the sometimes straight and sometimes waved or tortuous appearance of the fibrils, it is most probable that their state is not altogether passive*.” The transition from this opinion, as to the ordinary function of nerves, supposing it to be established, to that which would refer an excited state of the nerve to an inordinate and anomalous degree of this “movement,” is natural, easy, and obvious, and accordingly Mr. Swan arrives at that conclusion, as appears from the following passages in his works:—“I conceive,” says this generally judicious and practical writer, “that in some cases there is a contraction of the nerve itself, which produces pain;” and again, “I conceive that contractions of the nerves may take place and produce pain in the same manner as those of the muscles during their violent action in cramp or tetanus†.” “When pain has been excited in any distinct and previously healthy part by a disordered organ, and has arisen in the first instance merely from a contraction or *spasm of the nerve*, it may have been so often repeated as to have produced sufficient action of the nerves and blood-vessels for making the surrounding parts irritable and liable to be affected with a variety of fresh causes, even when the organ that first produced the pain has resumed its healthy functions‡.” Lastly, “Tic

* On Diseases of the Nerves, p. 4.

† Ibid. p. 1, 5.

‡ Ibid. p. 17.

douloureux in the nerves of the head and face may arise from a *spasm of the nerve*, through sympathy with a distinct part*."

I am fain to acknowledge that these statements produce no very definite impression upon my mind as to the exact pathological condition of an excited nerve; or if it is really meant that the state of the nerve under such circumstances is identical with that anomalous condition of a muscular fibre in a state of convulsive contraction, there is at least a deficiency—perhaps I may venture to add a total absence—of proof. It is, indeed, within the bounds of possibility that such may be the case, but we are at least ignorant of the fact; and the statement, if it be intended to be taken literally, rather than as a figurative or illustrative expression, is at best but an incautious application of a term hitherto devoted exclusively to an anomalous condition of muscular textures, and is calculated to lead to confusion and error, rather than to the elucidation of that obscurity in which this intricate subject is involved.

Defective Nervous Energy.

Having now considered the symptoms and consequences of morbid excitement of nerves which consist of violent paroxysmal pain, excess of vascularity, of heat, and of secretion in the parts supplied by those nerves, together with a proneness to inflammation, which is little disposed to yield to remedies, I am next to consider the evidences and consequences of defective nervous energy. The direct results of this "*effect defective*" need not detain us long: they are the converse of those of excitement. If it exist in a nerve devoted to sensitive organs, the sensibility will be impaired; if in a motor nerve, paralysis of the muscles which it supplies will be the consequence; if in a compound or symmetrical nerve, which ministers both to motion and sensation, as in the extremities, local or partial paralysis will be the result; and this may exist in its various degrees, from mere imperfect motive power and impaired sensibility, up to complete paralysis of the muscles, and anæsthesia of the surface.

To this general law, however, there is an exception in those cases where para-

lysis has been the result of the destruction of the continuity of a nerve by an inflammatory process. The inflammation in these cases rarely continues in the part below the injured part, or if it exist, the communication with the sensorium being cut off, mechanical violence done to it produces no sensation; but inflammation is apt to linger in the upper portion of the divided nerve, and this may occasion pain in parts upon which it should be distributed, although no nervous communication remains.

The other collateral effects of defective nervous energy will require at least a brief consideration. One of the most common of these is wasting of the muscles of the part affected. This can scarcely be from any increase of absorption; it is too gradual for the operation of such a cause, and there is no proof of such increase: on the contrary, the puffy ankle often observed in paralytic patients, would seem to indicate that the lymphatics are impaired in their action, as well as the nerves of the limb. It is much more probable that this withering of the muscles arises from defective supply by the nutrient vessels in the last process of assimilation. It has been already seen, that in an excited state of nerve the arterial circulation is increased; so in cases of defective nervous energy, all the actions which depend upon nervous influence are diminished. The vessels of the capillary circulation much under the influence of nerves, are enfeebled; the paralytic limb is consequently defectively nourished, and the general results are well, though briefly, enumerated, by Dr. Cooke, in his observation, that "paralytic limbs often become more soft and flaccid than natural; they waste and shrink, and sometimes appear œdematous."

Another necessary consequence of defective arterial action, is a diminution of temperature in the paralysed part. Upon this branch of the subject it has been already seen that Mr. Earle has entered much at large, and has deduced from the negative evidence which such cases afford, the general and positive principle, that "vital heat is the result of arterious action on the nerves," and this, "notwithstanding there is no apparent diminution in the circulation of the blood;"—a conclusion, however, with which the ingenious writer himself is

* On Diseases of Nerves, p. 39.

not altogether satisfied, as a consideration of the experiments of Dr. Davy obliges him also to "consider the circulation of the blood as *one* source of animal temperature." I have already stated the grounds upon which I am disposed to dissent from Mr. Earle's views upon this subject, in the case of an excited condition of nerves; and the same reasons, *mutatis mutandis*, will apply to his explanation of the diminished temperature in parts deprived of nervous influence. The evolution of animal heat takes place in the capillary vessels, and is commonly in proportion to their activity; in paralysis, the wasting of the limb shews that these vessels have their function impaired; it is "soft, flaccid, wasted, and shrunk;" the calorific function "is proportionately impaired, and, as a general result, the limb is colder than the other."

This conclusion derives material confirmation from one of the experiments of Mr. Earle. He applied to the back of a paralytic hand a blister, which he "was obliged to repeat several times before it would act; at last, however, a vesication was produced. During the time that the blister was acting, there was no alteration in the thermometer placed immediately contiguous to the edge of the plaster; but on removing the bladder, and applying the bulb to the denuded cutis, a rise of three degrees took place. The blistered surface was not in the least sensible to any injuries, and healed very readily." The explanation of this is obvious, but seems at variance with Mr. Earle's opinions. There is here no evidence of any direct impression upon the cutaneous nerves, so as to increase their energy; "*the blistered surface was not in the least sensible to any injuries;*" and yet there was an increase of temperature of three degrees. But the action of the capillaries was increased, the cuticle was separated by the effusion from inflammation of the subjacent texture; secretion, therefore, went on with energy. Those changes occurred, under the influence of the blister, which usually accompany the alteration of colour in the transition of arterial to venous blood. Amongst the most important of these is the diminished capacity for caloric, in consequence of which "vital heat" is evolved, and the thermometrical temperature consequently increased.

The amount of this change of capacity has been somewhat variously estimated by different chemical philosophers. The specific heat, according to Crawford, of arterial blood, is greater than that of venous, in the proportion of 114.5 to 100; and according to three experiments out of four by Dr. Davy, who placed more reliance upon the results of the three, which constitute the rule, than in the single exception, is in the relative proportion of 913 to 903. Since, then, in the experiment of Mr. Earle, there was no cognizable change in the state of the torpid nerves of the part, while the action of the capillaries was increased, it is natural to infer that the increase of temperature was owing to the augmented activity of the arterial circulation, of which there was ample evidence, and not of any increase of nervous influence; with respect to which, as there was no evidence, we may apply the logical axiom—"de non apparentibus et non existentibus eadem est ratio."

It appears to be a proof and consequence at once of the influence of the capillary arteries in regulating the temperature of the human body, a principle which has acquired almost universal belief, and of the extent also to which these vessels are subject to nervous influence, that if, in consequence of diminished energy of the nerves, the capillaries are weakened, the power of resisting sudden, though what to others, or to a sound limb in the same individual, would be inconsiderable alternations of temperature, should be lost. That this is in reality the case has been fully ascertained, and has been well illustrated, by Dr. Yelloly, whose patient, though insensible to the heat of boiling water, or the vesication which succeeded the inadvertent exposure of the limb to it, yet "on putting his hand, at the desire of a friend, into a pail of hot grains, into which his friend, to convince him that it was not too hot, had thrust his own hand, there was an extensive vesication produced." "His hands were never free from blisters, which he got by inadvertently putting them too near the fire; and he had met with several severe burns without being aware of it*." This remark has been also amply verified by Mr. Earle, in the interesting

* Med.-Chir. Trans. vol. iii.

case of Thomas Anderson, who was "advised to place his hand in a tub of warm grains, having previously ascertained with his other arm that they were not too hot." He retained the arm in the pail for nearly half an hour, and, on withdrawing it, found the whole hand blistered in a most alarming manner; and at the extremities of his fingers, and underneath the nails, sloughs had formed. It would be unnecessary, even if it were within the compass of my intention in this sketch of the principles of the pathology of nerves, to dwell upon the most important practical precept which these facts inculcate, of putting a patient upon his guard with respect to his paralytic extremities, which are so liable to serious consequences from such slight causes: the knee near to a fire may be vesicated, or even sphacelated, when the clothes which cover it have suffered nothing.

It has been shewn that the results of defective nervous energy, when it amounts to a paralytic affection, are, in addition to the immediate effects, want of nervous power and of sensibility, a wasting of the limb, a proof of enfeebled action of the capillaries, diminished temperature of the limb from the same cause, and a want of power to resist sudden changes of heat. It now remains that I mention another consequence of long-continued paralysis—namely, the withering of the nerves themselves. Upon this point, Dr. Cooke has the following observation, part of which has been already quoted, for another purpose:—"Paralytic limbs often become more soft and flaccid than natural; they waste and shrink, and sometimes appear cedematous. Mr. C. Bell has observed, that in these cases the nerves themselves lose much of their substance*." This is the "atrophy" of modern continental writers; a subject which has been somewhat elaborately considered by one of the greatest ornaments of the French pathological school—M. Andral. He describes it as a state "which we have rarely an opportunity of seeing, unless the parts upon which the nerve is distributed has its nutritive powers, or other functions, impaired;" and he illustrates this more especially by reference to the optic nerve, which he considers as the type of "atrophy" of all

other nerves, quoting (with complete and deserved confidence in their accuracy) the observations and experiments of Soemmering and Magendie, to prove that atrophy of the optic nerve is the general result of the destruction of the eye; that it occurs more slowly in man than in other mammiferous animals, and more quickly in birds than in either; and he concludes with the expression of his belief that the rapidity with which atrophy of the optic nerve is produced, depends upon the greater energy of vision in the being deprived of it. He further remarks, that the compression by tumors in their vicinity, will also occasion atrophy of those nerves, and mentions, in illustration of this, an instance in which the pneumogastric and phrenic nerves were subjected to compression, and consequent atrophy, from a schirrhous tumor, situated near or about them, and producing such *distress in breathing* as to have led to the suspicion of the existence of heart-disease*. Other instances are recorded, and amongst them, one of atrophy to the extent at last of the total disappearance of the optic nerve, from an osseous tumor seated in the situation of their decussation, which had entirely disappeared†. The olfactory nerves have disappeared in consequence of compression by a tubercular disease at the base of the cranium‡; the trunk, and most of the branches of the portio dura of the seventh pair, have disappeared under the pressure of a fatty tumor, occupying the region of the carotid§.

It thus appears that, in cases of paralysis, the nerve generally withers, and this may arise from the pressure upon the part of the nerve by a foreign body, as in the case recorded by M. Sanson, in which the decussation of the optic nerve was completely destroyed, or from the removal by interstitial absorption, the subsequent supply of the nutritive vessels being imperfect, in conformity with a general law of the animal economy in parts which have been little used, or from accidental cause have become useless. For years I was subject to a painful affection of the soles of my feet, which prevented my walk-

ing without intense suffering. In consequence of the inactivity of the muscles of the legs, these withered and lost their firmness; the right foot recovering more speedily and completely than the left, the muscles of the latter remained smaller than those of the former. A lady, walking in the street, had her foot violently bruised by a piece of coal falling upon it from a height. She was unable to use her foot for some time, on account of the pain from inflammation, and at the end of a fortnight, to use her own expression, "her leg had gone away to nothing." It is the same with a nerve which has been rendered useless. Nature, conscious apparently of its inutility, removes it either by some increase in the activity of the absorbents, approaching in its character to ulcerative absorption, as in cases in which the nerve is destroyed at the point where the pressure is employed, or, as more frequently occurs, by diminishing gradually the action of the nutrient vessels, so as to withhold from the nerve the usual supply of blood for its growth and nourishment; as in those instances where the nerve withers beyond the seat of injury, or between an organ whose structure or office has been destroyed, and the sensorium commune.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

The Dublin University Calendar. M.DCCC.XXXV.

WE notice this work chiefly with reference to the new arrangement respecting medical degrees. In the University of Dublin it was, and is, the practice to take the Bachelor of Medicine degree in three years after graduating A.B. The period was lessened when the student, immediately after his matriculation in arts, entered on his attendance of the medical classes: he could then become M.B. in six years, instead of waiting for seven and a half. But the regulation adopted in March, last year (1834), facilitates still further the attainment of the same object, under cer-

tain conditions. The resolution of the Provost and Senior Fellows runs thus:—"That in addition to the usual modes (just described) of obtaining medical degrees, a Bachelor of Arts shall be entitled to a *licent ad examinandum* for the degree of M.B. on his producing certificates of having attended the eight following courses; provided the certificates shew that, during each of the four medical sessions, he has attended at least one, and not more than three, of the courses which begin in November. The degree may be conferred at the July commencement of the middle Bachelor year. The courses to be attended are, 1. The six courses of lectures delivered in their respective departments by the professors of the school of physic. 2. One year's attendance on the practice of Sir P. Dun's Hospital, including six months' clinical lectures in that hospital. 3. A course of lectures on midwifery, by the professor of midwifery of the Royal College of Physicians."

No alteration has been made in the time appointed for the attainment of the Doctor's degree; though we think that, in that respect, some change suited to the present state of things might be very fairly ventured on. The M.D. of the Dublin University must be an M.B. of five years' standing; his exercises are one opponyency and a printed thesis in Latin.

One attractive feature in the volume before us is its giving the questions proposed to the candidates for fellowships, mathematical and divinity premiums, medals for science and classics, and even the prize questions at the quarterly examinations. We are thus presented with a fair criterion for estimating the average attainments of the better order of students in Dublin College. Might not a selection from the questions for *medical* honours be added with advantage—especially as the chief part of the examination is now conducted in English? Such an arrangement, we think, would be acceptable to a large class of readers.

We are much pleased with the "getting-up" of this Calendar; those of last year and the year before (for this is the third of the series, and we hope they will have an uninterrupted run) were favourably mentioned in this journal, and the present one is not less valuable than its predecessors, though it comes

out, we believe, in a less expensive form. The editor has evidently profited by his experience.

Traité complet de l'Art des Accouchemens, ou Tocologie théorique et pratique, avec un Abrégé des maladies qui compliquent les Enfants nouveau-nés. Par A. VELPEAU, Professeur à la Faculté de Paris, &c. Deux tomes. 1835. Bailliére.

THE first edition of this work was comparatively meagre, and only intended for students: in its present form it embraces fully all that it announces in the title-page, and is adapted not merely for pupils, but for practitioners, teachers, and professors. M. Velpeau defines midwifery, or, as he chooses rather to call it, tocology, as the *ensemble*, or combination of human knowledge relating to the reproduction of the species; and from an examination of his work, we must say that we do not know where a larger or better arranged assemblage of facts connected with midwifery can be found, than in the present two volumes.

Among the more novel and interesting chapters which attracted our attention, were those on obstetric auscultation, extra-uterine pregnancy, and superfœtation. On this latter subject we shall extract the recapitulatory passage. "I am surprised," says the author, "that modern physiologists, and even certain medical jurists, should assert that superfœtation is possible up to the moment when the ovulum reaches the uterine cavity, while they dispute its possibility subsequent to that epoch. It ought to be rejected equally in both cases. The effused lymph, or the decidua, is just as capable of preventing its occurrence in ordinary circumstances, as the ovulum itself. The four cases quoted by Millot are otherwise explicable; so are the two instances reported by Dewees: the example, indeed, given by Dr. Matton might be difficultly explicable, were it not that there is a defect in the details. Perhaps, on the whole, we should conclude that superfœtation is not possible, except—1, In case the pregnancy is extra-uterine; 2, when the uterus is double; and 3, where the female has had intercourse on one and the same day with two different men, or, after a short interval, with the same man. There is, however, nothing repugnant to reason in admitting the pos-

sibility of superfœtation, as long as the uterine cavity is not occupied with any substance, nor the orifice of the tubes closed; and all the cases that have been hitherto reported on the subject are perhaps admissible, on the ground of their forming only certain varieties of multiple births."

The arrangement of M. Velpeau is natural and easy. After an historical and statistical introduction, drawn up with much ability, he enters on the main business of his treatise, by the anatomy and physiology connected with obstetrical science. In the third book he treats of gestation and its varieties, true and false; in the fourth, of the embryo and the fœtus; the fifth book is devoted to the practical subject of labour; and the sixth and last contains the author's views of the diseases connected with the puerperal state. There are sixteen useful plates annexed.

But the reader who is interested in midwifery practice, or teaching, will do well to examine the work for himself; he will not meet with a chapter in it which is not touched with the hand of a master; and, perhaps, if we except some little redundancy of style, and certain passages which might no doubt be more condensed, it will be agreed that no production hitherto issued from the press merits more praise, as affording an ample fund of obstetrical knowledge combined throughout with so much variety of learned illustration.

MEDICAL GAZETTE.

Saturday, January 17, 1835.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

COLLEGE OF PHYSICIANS.

THE government does not seem disposed to wait for Mr. Warburton's scheme of reform—at least as regards the College of Physicians—but has already had communication with the magnates of Pall-Mall East, in reference to some plan of their own. There are, we suspect, two reasons for this—first, a desire to do *something* as speedily as possible,

and secondly, an impression that the honourable chairman of the medical committee has shewn himself to be rather too much of a partizan against the College. The present prime minister was nominally a member of the committee, but being dissatisfied with the spirit in which the investigation was carried on, he proposed some changes, which being rejected, he declined to attend—"he left the room, and never entered it again." We stated this circumstance before, and now repeat it, because the *honourable* (!) member who represents the Jew clothes-venders of Finsbury, and *mis*-represents the medical profession, had the impudence to state that Sir Robert Peel concurred in the proceedings alluded to, before he was in power, and was therefore likely to do so now that he is in office.

However, our present object is this: having ascertained that a Committee is now sitting, to consider the expediency of certain changes in the College, we are naturally led to inquire what changes ought to be made?

The first and greatest grievance is the separation of Physicians into two sets, or orders—viz. Fellows and Licentiates; and the first and most popular change would be its abolition. The license ought not to be granted to any one who cannot shew that he has had the highest medical education, and attained the highest standard of professional acquirement; and if he does, no one has a right, as a physician, to rank above him. In the College of Surgeons all belong to the same order; there is not first a list of those who have been educated in London, and next of those who have been educated elsewhere, but there is one common list, in which the only distinction is seniority. So we think that the hearthburnings and dissensions among physicians will never cease till the distinction between Fellows and Licentiates be done away, and some common designation (such as that of

Members) substituted—the present lists being blended into one, in which the order of the names shall indicate merely the date of the licenses. The Fellow of the College, be it remembered, is a Licentiate, and it is only as such that he is entitled to practise; while it is in right of the Fellowship that he belongs to the governing body. Now, for ourselves, we think the Licentiates might well compound for the present Fellows continuing their privileges in this last respect, provided the obnoxious distinction as to the name were laid aside, and provided also they had yielded to them the *right* of being present at all lectures and orations, as well as of admission to the library and museum. So long as the Licentiates are excluded from these last, so long have their complaints a plausibility which we feel satisfied will obtain for them a favourable hearing in parliament, and which will prevent the permanency of any arrangement which falls short of the one we have suggested.

Another very important change, too, and one on which we have on former occasions insisted, is the establishment of a course of study for physicians, which curriculum, and not the possession of a degree, ought to be the passport to examination for a license to practise, and for admission into the College.

Formerly a degree was required, because, when the present regulation was made, Universities were the only places at which the necessary education could be acquired, while the diploma was the test of such opportunities having been turned to due account. But now it is otherwise, and more especially with regard to medical science; for whereas formerly the education of the physician consisted exclusively in reading books, it now consists in reading nature also. But this last not only cannot be done best at the Universities, but can scarcely be done at all, owing to the limited field of observation which

is afforded. It is high time, therefore, that the possession of the degree should cease to be looked upon as a necessary preliminary to entering the College of Physicians; and the College ought, in its place, to require proofs—1st, of a sufficient time having been devoted to literary and scientific pursuits; 2d, of sufficient means of studying medicine having been possessed (for anatomy, chemistry, and an acquaintance with disease, can no more be acquired without bodies, apparatus, and patients, than can literature without books); 3d, the use made of the “time” and “means” referred to, ought to be tested by an adequate examination.

If these preliminaries have been established, the admission into the College ought to constitute the individual a physician, and to carry the doctorate with it. We are aware that at present the College has the power of licensing persons who have no degree; but the privilege has fallen into abeyance, and never can become available, unless it be extended to the conferring of a degree in physic.

There is, we believe, even now some project in agitation for admitting persons without degrees, with a view chiefly of relieving the dissenters: but we do not like the principle in which it seems to have originated, nor which seems likely to guide its adoption. It appears too like a temporizing piece of expediency on the part of the minister, to quiet certain political opponents, rather than a liberal and well-digested plan to improve the profession. Dissenters are not admitted to degrees at the Universities; but it is thought, as regards medicine, this might be remedied by inducing the College of Physicians to take them without degrees. Now either such admission will or will not carry with it the doctorate: if it does, the College, we presume, will either make the new doctors Fellows or Licentiates (for we have not heard that the abolition of the distinction which we

recommend is contemplated); if Fellows, then all the present Licentiates would, of course, at once claim admission on the same terms; nor could they with any shew of justice be denied. If, on the other hand, they make the new Pall-Mall doctors, Licentiates, then do the London College of Physicians acknowledge that *their* degree in medicine is inferior to that of Oxford, Cambridge, and Dublin. Again: if the admission does not carry with it the doctorate, but merely a license to practise, then are the Dissenters not relieved, as they will not be regarded as physicians;—while the present Licentiates would have to complain, that though the College had compelled *them* to procure degrees, yet did they hold that distinction in such light estimation, that, in an English dissenter, it was regarded as quite indifferent whether he had obtained it or not.

No change short of abolishing all distinctions of grade among physicians, as practitioners, will now avail; one common list must contain all, under one common designation, and ranged according to the dates of their admission. Any distinction among the members ought to be merely an additional and separate list of office-bearers; and it would be no more than reasonable to let those now in possession—viz. the present Fellows—continue to be the governing body. But we are quite satisfied that if any patching-up be attempted—any sacrifice of principle to expediency—anything less broad and liberal than we have suggested—then will the object in view not be accomplished, and therefore it were better to do nothing. We assume that the object of any change originating in the College is either to gain a direct advantage, such as the power of conferring medical degrees, or to get rid of the irritation which the constant “pressure from without” at present produces. But we do not believe that the new government (and certainly none such

as would be likely to succeed to it), would confer on them the power in question, unless accompanied by such modification of their regulations as should open a direct road for the dissenters—and if for them of course for others—to the highest honours in medicine, without passing through Oxford or Cambridge. Neither, we are convinced, would any more restricted measures free the College from the hostility of the Licentiates, or from their persevering efforts to force the gates of the sanctuary—efforts which, though hitherto unavailing, the most sanguine of the Fellows must feel will probably be successful at no distant period, changed as the whole aspect of public affairs has within a few years become. We repeat, then, what we said before, either “do nothing, or leave nothing for others to do.” Half-measures will but entail the mortification of having yielded, without securing the repose of pacification.

Now we know very well that most of the Fellows who read this will say “the GAZETTE is becoming radical;” but we say nay—we do but argue for the adoption of measures which, or something analogous to which, must be adopted, or else, in our humble judgment, will there be soon no College of Physicians in existence, and its only remnant be seen in a highly-educated and exclusive, but yearly dwindling, club of English graduates.

ADVERTISEMENT EXTRAORDINARY.

WANTED, at the Valetudinarium, a few cases fit for the knife. Rare and striking diseases would be preferred, but the most trifling contributions will be thankfully received, and all the minor operations will be admitted as *capital*, and published in the weekly journal of the University.

As it has been ascertained, on the most competent and disinterested authority, that the London surgeons are lamentably deficient in “the science of operating,” it is expected that they will avail themselves of the opportu-

nity now afforded them of improving their manual dexterity, particularly Messrs. Astley Cooper, Keate, Bell, Brodie, Key, Green, Scott, and Stanley (vulgarly reputed to be our best operators), the whole of whom, we understand, have agreed to send those cases to Gower-street—which they cannot operate upon themselves. Hitherto, the only displays of the “science” have consisted in the successful extirpation of a large tumor from a plaster-of-Paris bust; but real operations will be *done*, and the casts laid aside, as soon as living subjects can be found.

N.B. A liberal commission given for damaged noses; and any gentleman consenting to be trepanned, will receive a London University share *gratis*,—being 25 per cent. under the market price.

[WE have been not a little amused with the following specimens of clinical instruction just now tendered to the surgical pupils in Gower-Street. We are sorry our space is so limited, or we should certainly cull more of those flowers of delicacy and good feeling:—]

DESCRIPTION OF A “SCIENTIFIC SURGEON.”

“I KNOW the animal calling itself a ‘scientific man’ in our profession full well, and never wish to see one of the species again. It does not exist, I presume, on this side of the Tweed. It looks wise and dignified, and pretends to see further into the heart of a millstone than its neighbours. He (shall we give it a sex) is naturally deficient in dexterity; ‘all his fingers are thumbs,’ to use a common expression in the north. He has never been at the trouble to acquire any use of his hands; he has thought it beneath his notice. He has, moreover, such a plentiful lack of judgment, that he is totally incapable of devising or executing any operation of consequence, without committing a gross outrage on the feelings and sympathies of the spectators. He pretends to great sanctity, is an adept in cabal and intrigue, and is prompt in depreciating the talents of those in his own line who may be ‘struggling for life against the waters.’”—*Mr. Liston’s Clinical Lecture.*

CONTRAST PRESENTED BY THE “KNIVESMAN.”

“It is only those who are themselves lame and impotent in such works as can be judged of by ordinary observers, that declare operations to be beneath the notice of scientific men, and they, forsooth, these bunglers in their trade, would wish to be

thought the *only pure scientific*. * * * Was it ever alleged that an accomplished leader of an instrumental band, because by intense study he had acquired a fine touch, great dexterity in fingering his instrument, and by his style of bowing could give grace and expression to his performance, was ignorant of music. * *

The advantage of having an operation well planned, was, I believe, never better exemplified than in the removal of the tumor which this painting and wax cast represent."—*Ibid*.

[Here the lecturer proceeded to operate UPON THE CAST.]

CLINICAL LECTURES,

Delivered at the Middlesex Hospital, 13th and 20th December, 1831,

By SIR CHARLES BELL.

DYSPHAGIA.

[The case was read from the hospital-book.]

"Robert Linan, 43 years of age, came here on Tuesday the 9th of December. He had not been able to swallow even a drop of liquid since the preceding Friday; he is a little, spare, sallow man; he speaks in a whisper, that conveys the idea of disease in the larynx. In May last he was admitted into the Physicians' ward; he had difficulty of breathing, cough, and some hoarseness; he got considerably better at the end of three months; he had never spit blood. In the beginning of October he first felt difficulty of swallowing, and came here for relief. Two blisters were applied to the throat, and these almost immediately relieved the dysphagia.

"He has returned again. He lost the power of swallowing on Monday; the difficulty continued with little abatement till Thursday. He appears to have taken almond emulsion, and vinum ipecacuanhæ, with some relief; but he always found it necessary to take a little fluid after every solid mouthful, to get it to pass an obstruction just below the cricoid cartilage. On Friday he had eaten his dinner as well as usual, but at supper he found that he could not swallow even a cup of chocolate. Suffering no pain further than that of thirst, he allowed it to go on till Monday night, in the hope of its getting well of itself, and followed his usual avocations. At eight o'clock that night he came to the hospital, and had half a dozen leeches put on his neck. On Tuesday the œsophagus was examined with the soft wax bougie, but the instrument did not pass; and it was observed on withdrawal to be flattened on one side. He now attempted to swallow a little

milk and water: it seemed for a little to be swallowed, but it brought on a fit of coughing; and after a little, a sort of eructation brought it all up again. He was sent into the ward. On inquiry, it was found to have been the belief that his disease was ulceration of the larynx, and spasm of the lower part of the pharynx. A solution of nitrate of silver, eight grains to the ounce, was applied with the sponge of the probang. After this he attempted to swallow some warm milk and water; it remained for a minute in the œsophagus, but soon brought on a fit of coughing, and then it was brought up by eructations as before. The pulse was getting weak for want of sustenance, and an injection of a pint of strong beef-tea was administered, after which he felt greatly refreshed. He had a liniment of camphorated oil and tinct. opii rubbed on the sides of his throat. He was furnished with some beef-tea, and Reid's injecting apparatus, to use in the night, as he was obliged to go home to attend on a helpless wife, who could not undress herself without his assistance. He returned in the morning very faint. He was now seen by the surgeon, who attempted to introduce an elastic catheter, No. 4 or 5, and after a little hesitation at the termination of the pharynx, it passed freely down its whole length. The precaution of passing the instrument through paper, and holding a lighted candle to it, was taken, lest by any chance it should have passed into the larynx. A mouthful of milk was now squirted through the tube. It went down, but there was evidently resistance; and on removing the lips the milk returned spouting from the catheter: this was again repeated with the same results. The catheter was withdrawn, and he attempted to swallow, but in a minute or two the coughing and eructation came on as before, and what he had seemed to swallow returned. He was so weak that the fatigue of the operation made him faint. He was now put into the warm bath to relieve the thirst, which he said was such as almost to madden him at the sight of liquid. After the bath he was more comfortable than he had been since the attack began, and fell asleep. The linimentum hydrargyri was rubbed into his neck; and he had some mucilage and tinct. opii, of which he was occasionally to sip a little, and to let it lie in the pharynx as long as possible. During the day he was nourished with frequent injections of beef-tea and mutton-broth. In the afternoon the bath was repeated, and attempts made with a small catheter similar to those described in the morning. The catheter was again passed by the house surgeon, but with no advantage; it did not pass the stricture, which appeared to be in the commencement of the œsophagus. As he sat at the fire he

brought up what appeared to be a piece of meat.

"11th.—This is the sixth day since a drop of liquid has been swallowed; he does not complain of hunger, but of intolerable thirst. He says he has experienced great comfort from the mucilage and opium, which was the only thing that did not immediately bring on a fit of coughing and eructation. He has brought several little pieces of meat, which look like shreds of boiled beef, which he spat up in the night. At half-past twelve he met the surgeon at the door of the ward in great joy, having at length succeeded in swallowing some milk. Beef tea was now given him, which he swallowed with considerable ease.

"*L'espero*.—The nurse has been too kind to him, giving him more than his allowance of broth, which was ample; the pulse is a little excited; his thirst is still great, but he was ordered to take nothing more than a little nutriment, and to have a spoonful of castor-oil in warm milk."

COMMENTARY.

I am sure this is a case that must go to your hearts. There can be nothing more touching than to see a man actually starving, and suffering from excessive thirst; exhausted, misery in his looks, and absolutely fainting from inanition; and the conviction at once arises in your minds that something must be done immediately. Now I do assure you that I came to the hospital that morning very uncomfortable in my feelings, expecting to find him worse, and that an operation of great danger and difficulty must be done for his life; for I saw no alternative, although the circumstances were altogether new.

You will have reflected on the appetites which nature has implanted in us for important purposes, silent monitors which urge us to the necessary supplies. You think not of thirst but as a source of enjoyment, and so it is; but you see here with what an urgent and painful demand it gives token of the wants of the system: "He was maddened by the sight of liquid."

Next I beg you to notice, as connected with your general studies, the extraordinary fact of the violence of the symptoms of muscular parts, produced by apparently slight causes; and on the other hand, as contrasted with it, the almost entire absence of symptoms, when, on dissection, you find there has been great disorder. For example, your practice will furnish you with instances of affection of the stomach, and violent action consequent upon it, while in the dead body there is no morbid appearance whatever; on the other hand, you will find great ulceration of the stomach, extending through one-half of

the organ, with comparatively no symptoms. You will find, again, a man breathing with excessive difficulty, with the circulation exceedingly disturbed; and on dissection there is nothing to be found amiss in the heart; and, contrasted with this, I have found a tumor surrounding the whole heart, or ossification of the actual substance of the heart, without any train of symptoms corresponding with this obvious defect. The same circumstance occurs in every part which has a muscular action, as the bladder and the rectum, and the duodenum and gall-bladder, &c.; and therefore you might be led to expect something similar in the pharynx and larynx, irritable muscular parts. There is on the table a preparation sent down by Dr. Wilson*, which I understand has already been the subject matter of three lectures by three different professors. My whole object is that you should exercise your own good sense, and that nothing important should escape you. I have no desire to employ the hour with a subject which, so far from being overlooked, has seriously occupied the attention of our physicians; but still, is it not remarkable that such a thing should come from the interior surface of the œsophagus, and that the physicians can hardly say whether it is part of the original and proper structure of the tube, or a secretion excited by inflammation? It signifies not to my argument which it is; there is the proof of extraordinary destruction, and the woman not suffering half so much as we find in many hysterical girls who are incapable of swallowing at all. I have examined the œsophagus of such a patient, after an inability of swallowing of eight months' continuance, and found the only circumstance at all remarkable to be the paleness of the fibre of the tube, and which is consequent, as you know, on inaction in any muscle of the body.

The impression left upon us with regard to the case under review is, that it is an instance of the effect of remote disease on the muscular tube, probably of phthisis laryngea. I will relate an odd circumstance. Some time ago I went into a private family, and they were very full of admiration, and warm in their applause, of a practitioner who had just come to town, and who had found some new disease to be very common, and very much mistaken by the profession; and had also discovered the means of curing it. It was disease of the larynx, and the remedy was the application of lunar caustic in solution. I have the happy faculty—and to me it is a very happy one—of forgetting what I have

* It was a case of poisoning with sulphuric acid, an account of which is contained in our 14th volume, page 429.—*REV.*

written; but just at the moment I had a sort of recollection that I knew something of this practice before, and, after a time, I remembered that, in the hospital reports, I had described the disease, had given many dissections of it, and had recommended and practised this very remedy. I mean you to understand by this, that I have seen a great deal of disease of the larynx; and, as anatomists, you cannot be surprised that when the larynx is diseased, the muscular coat of the pharynx should be spasmodically affected. You find my colleague, Mr. Mayo, saying that, in a case which occurred the other day, where there was an incapacity of swallowing, and the patient died, there was nothing the matter with the pharynx, but only with the larynx. Have we, then, a key to the explanation of this man's condition? The notion of disease in the larynx corresponds with his whole aspect; he is a phthisical looking patient; his voice corresponds with the idea of ulceration in the larynx; and then you find that he is seized with spasms and difficulty of swallowing, and symptoms usually attendant upon this disorder of the larynx.

But there is another view of the case, another circumstance of interest—the rejection of a piece of meat like boiled and macerated beef or mutton. When this was rejected he had immediate relief, and expressed his thanks energetically, as if I had been the means of saving him. It seems somewhat strange that he should not have known of this sticking of the food in the throat until it is brought up; and it is no less remarkable, that the rejection of these portions permitted him to swallow, by relieving the spasm in the pharynx.

The case, then, being represented to me, and having all the appearance of stricture, I said to the man, “Now answer me distinctly this question, when did this extraordinary difficulty come on?” and he replied, “On a certain day I swallowed perfectly well, and the next day I could not.” That does not look like stricture of the œsophagus; for when there is real stricture, the person begins his narrative by saying, “O! I had always a very narrow swallow.” They invariably tell you that they have had a difficulty in swallowing large pieces, and a facility in swallowing liquids. When there is a spasmodic difficulty, it is the very reverse of this: a person can swallow a smooth morsel more easily than a few drops of liquid.

[The house-surgeon here intimated that the patient had been subject to difficulty of swallowing for six months, and had been obliged to wash down his food.]

That still (continued Sir Charles)—that corresponds sufficiently with what I presume to be the condition of the neighbour-

ing parts—a spasmodic difficulty, and a necessity of washing down his food: there is in this fact nothing contrary to the hypothesis I have proposed. However that may be, it is distinctly stated that he swallowed one day, and the next there was a total obstruction. The truth is, we cannot trust to the narrative of a patient; we are poor creatures ourselves when we are patients; and a man seeing, as it were, the approach of death, cannot be conceived to be very good evidence in his own case. Hence it is that we take all possible precaution; and before any thing else was to be attempted, I conceive I was right in passing a small catheter through the stricture at the bottom of the pharynx, and squirting in some warm milk: and I think that the repetition had the happy effect of getting a little fluid down; and when vomiting came on, and the action of the throat was restored, a little portion of meat was brought up, and after that another portion, which relieved him completely, he being now left in the hands of the physician, who, I hope, will be successful in relieving the original disease, to which all you have heard is merely accessory and symptomatic.

The subject continued:—

ANEURISM.

Delivered on the 20th December.

If we possessed eloquence, we should have no occasion for it in the present instance, because the legitimate object and use of eloquence is to prepare the heart for a certain impression; to remove the prejudices which prevent us seeing clearly or reasoning justly; and to fit us to understand and fully to appreciate a plain story told by a plain man. But I am quite sure that what you have lately seen in this hospital has opened your understanding, in the first place, to the importance of your profession; and, more than that, to the severe and anxious duties that you have to perform. It is said that a General arranges his troops, and infuses into them a spirit of conquest; but deep in his own breast rests the possibility of defeat, and for which he prepares secretly. So ought a surgeon to go forward to his operation with the confidence which knowledge produces; but in all capital operations he should also revolve, in his own mind, every possible disaster. Now you have seen an operation of great difficulty performed, and you have seen the most disastrous accident taking place during the operation, and you have witnessed, and must, I am sure, fully appreciate, that manly decision and vigour of mind which give calmness and promptness in these circumstances.

Our subject is aneurism; and there cannot be two more interesting cases than those I have to place before you.

You remember certain points connected with aneurism, and I am sure you recollect its definition; for this is especially necessary to a comprehension of the subject. It is an abrupt tumor of the artery,—not an enlargement of the vessel in its proper coats; and the consequence of such abruptness is the formation of a coagulum, the presence of which coagulum comes to be the essential character of aneurism. I doubt not but that you remember the reason of this coagulum forming—that the interior surface of the artery is burst up or destroyed. Now there is a relation established in nature between the blood that is flowing in the tube and the interior of that tube. This relation, like many of the influences of the life of the body, we want words to define and describe; but of the effect we cannot be ignorant—viz. that the blood is kept fluid in that *living* vessel: instantly, however, and most happily, when the interior surface of the vessel is chopped or broken up, that moment a coagulum is formed. Here, then, is the combination of circumstances—the abrupt tumor is attended, or rather preceded, by a rupture of the inner coat of the vessel; and this disruption is attended with the formation of a clot.

With regard to the cause of aneurism, it becomes a most important matter for you to consider it; for unless you understand it, you will not comprehend fully the merit of Mr. Hunter, nor how the rule of practice is laid down by that gentleman who is supposed to be his most successful commentator—Sir Everard Home. There is, as we advance in life,—and I am speaking to dissecting-room pupils, who cannot be ignorant of the fact,—a general change taking place in the arteries of the body; and during that change, before the period of old age arrives, and whilst yet there is vigour and strength both in body and mind, aneurism is apt to take place. The condition is this: the arterial coats lose their pliancy—that elasticity which is necessary to resist without obstructing the heart's action—and they become thick and firm, and acquire an inert resistance. Sometimes there is a deposition of fluid in the interstices of the coats, the fluid becomes concrete, and what is called *ossification* takes place; but it is not ossification, it is merely a deposit of earthy matter. The earthy matter thus deposited takes the shape of the artery; and if any sudden change by exertion, or twisting, or violent action of the heart, stretches the artery where it has been curved, or bends it where it has been straight, breaking the coats of the vessel where the deposit has

taken place, rupture ensues. This is generally the commencement of aneurism, and therefore of course you see at once the importance of the fact; for it is continually taking place under your eye. In this last operation, the coats of the artery burst upon the edge of the portion that was ossified.

Aneurism of the Arch of the Aorta.—Ulceration into the Œsophagus.

The first case I have to mention is one with which you are as familiar as myself; and I know not what this gentleman, whose pen runs so fast, may tell of us, for we have misunderstood the case sadly. The dissection is now before us, and we must acknowledge that we were wrong. “Il n'est rien de tel que d'être honnête homme,” say the gentlemen on the other side of the channel; or, according to our homely expression, “Honesty is the best policy.” I allude to the case which we conceived to be an obstruction of the œsophagus by a piece of meat; and I really think the explanation given by the house-surgeon is better than any thing I have offered—viz. that it was not a piece of meat, but a portion of compressed coagulum from an aneurism, which came up. You will no doubt examine the morbid parts carefully: they are before you. The poor man suddenly died; some blood passed out of his mouth; and upon dissection, his stomach was found full of blood. On further investigation, it was seen that there had been an aneurism of the arch of the aorta; that the aneurism had come in contact with the œsophagus, adhered to, and ulcerated into it; and there is every probability that what was brought up by the act of vomiting was a portion of the white firm coagulum that always forms in aneurism, and prevents the blood for a time from bursting out of the sac.

This being the case, we have some difficulty—and yet not much—in reconciling the symptoms with what you now see before you. For example, you remember I stated that I passed a tube through the part where I conceived the obstruction to be; that I was much surprised, on injecting tepid milk into the tube, to find that it did not pass freely into the stomach; and that when the lips were withdrawn from the tube, the milk came spouting out of the tube again. Now on the dissection, it was found that there was a stricture, but of a spasmodic nature, just behind the larynx—such a stricture, that the point of the finger could not pass; but upon being pressed, the fibres dilated completely: implying that it was not a permanent, but a spasmodic stricture. The tube, it appears, had been passed through this spasmodic stricture opposite the cricoid cartilage;

but when the fluid was injected, the aneurism mechanically pressed on the lower part of the œsophagus, and so the fluid distended the space between the mechanical compression below, and the spasmodic stricture above. This explains the filling of the throat, and why, as soon as the lips were withdrawn, the milk returned by the tube.

You may infer, then, that the observations were not applicable to the circumstances of the case; yet, allow me to say, not altogether remote or foreign. I argued that the piece of meat sticking in the œsophagus had increased the spasm, the spasm occurring where there was no actual disease; and now we find that the aneurismal tumor, pressing on the œsophagus in the posterior mediastinum, was the formidable cause of obstruction, and of the spasmodic difficulty higher in the tube.

You are aware that this patient came from under the care of the physician; and I suppose you know that he was examined by percussion and the stethoscope; respecting both of which I am accused of being very sceptical. Here we have the fact before us, that the aneurism was not discovered. Now there is something in the mass of aneurismal clot occupying the chest,—something also in the manner of the circulation of the blood through an aneurism, the whiz of the current of blood through the narrow opening,—that we might have reasonably expected an indication through the instrument. If it were very effectual in any case, one would naturally suppose that it would be so in this. But practitioners at home seem to contradict this; and the authorities abroad say that it is exceedingly difficult to discover aneurism of the arch of the aorta. This would imply that the stethoscope discovers slight effects of disease, but not material and important changes.

Aneurism of the External Iliac.

The second case to which I have to call your attention, is aneurism of the groin. It is an awful thing, indeed, to see a person dying from internal aneurism; but it is a still more fearful thing when you see a person dying of an aneurism, and you have let slip the opportunity of affording relief; or when relief from art is possible, were you capable of ministering the resources of art! When you see an aneurism of the groin, such as has lately come under your notice, with very slight symptoms, no great tumor, no pain, no lameness, no imperfection at all, you would be almost inclined to hazard the opinion, and say that such a case is too trifling to call for a formidable operation. But then you must cultivate the knowledge of this subject;

you must anticipate and know what is about to occur;—that when an artery has once given way, spontaneous cure does not take place in one case in a hundred; that the tumor increases; the circulation becomes obstructed; the tumor bursts, and bursting, produces the most lamentable effects. It is only when you reason, and the imagination presents the latter stage—the final close of the scene—that you feel a conviction of the necessity of the operation which you have seen performed.

I hope you perfectly well understand to whom you are indebted for this operation—for this enlargement of your field of usefulness—viz. Mr. Abernethy. In the early part of his life, he was just the example that you should take; but in the latter part of it he became more negligent. When I first knew him, he was a most intense student: he had a great desire for improving his profession; he was possessed of the highest possible faculties of mind suited to the accomplishment of his object, and the greatest zeal in its prosecution. One of the circumstances for which you are indebted to him is the power of saving life in the condition in which the man is. I can imagine him thinking about it, and revolving the principles of Mr. Hunter, and the evidence of free inoculations brought forward by Mr. John Bell; at last performing the operation; but failing in it—failing in it again—and then at last successful. If he had been a man of common understanding, he would have said, “I shall imitate Mr. Hunter here, and tie the external iliac above the tumor;” and when it had failed, he would have resigned it. But what I most admire in Mr. Abernethy is, that although there was no man with whom I have been acquainted in my walk through life, who had less desire of doing great operations, yet in this he had encountered every unfavourable circumstance—such as the communication between the incision and the sac—the bursting of a vessel—and the death of the patient—yet did the acuteness and philosophical cast of his mind enable him to see that the failure was from an accidental circumstance, and not a necessary consequence of his method: he saw the causes of failure, and by avoiding them, established the operation of tying the external iliac artery in the inguinal aneurism as one of our regular operations—one which you may be called upon to perform.

Perhaps I should here point out the circumstances that are to be attended to in this operation. In all operations for aneurism, the leading rule is to take care that you do not interfere with the tumor: it is not that the operation should be performed, as Sir Everard Home said, upon a part of the artery free from disease, that we ope-

rate high. You must know that an artery is more diseased the nearer it is to the heart, and, therefore, if you tie the artery nearer to the heart, you will be going more on those trunks which are apt to be ossified, rather than removing the ligature from the diseased part. This idea of securing sound artery to operate on is not the object; it is that you should, with a neat, decided incision, cut down upon the artery with the least possible disturbance of the circulation of the limb, and without engaging the aneurismal sac in the inflammation which must necessarily arise. As sure as inflammatory action is excited in the aneurism and surrounding parts, so surely do you lose the advantages of Mr. Hunter's operation; for then the limb becomes tumid, effusion takes place, pressure affects the collateral vessels, coldness supervenes, and a want of circulation in the foot: and on this subject I have to repeat what I said lately, on tying wounded arteries—tie the vessel neatly, without disturbing the circulation, and the circulation will certainly be re-established by collateral arteries; of which we have an extraordinary proof in the present case.

In performing the operation, the incision is made from Poupart's ligament, in a direction upwards, along the course of the artery, as if you were about to cut into the abdomen, which you are careful not to do. Having made the incision something more than three fingers' breadth in length, you may come to the aponeurosis or external tendons of the descending obliquus; you then separate the fibres of the tendon a little, cutting between the fibres, so that you may introduce the point of the directory below and across the fibres of the tendon; so that running the bistoury along the directory, you may divide the tendon in the direction of the first incision. Having done this, you find the internal obliquus and transversalis muscles exposed, and under them you place the directory again, and divide them. The next part of the operation is difficult and hazardous; you are not cutting into the abdomen, as would appear at first, but, having cut through the abdominal muscles, you are to take care that the fat and cellular membrane external to the peritoneum, together with the peritoneum itself, shall be pushed up. Now the fingers of the operator go deep below the peritoneum and behind Poupart's ligament; you see no farther—you conjecture how the operator is engaged—you remember that a strong fascia still covers the artery. The great error which, on former occasions, I have seen committed, is that of forgetting this fascia, and attempting to pass the needle round the artery before the fascia was sufficiently opened. The fascia,

then, is to be *scratched* with the silver point, not cut; and by repeated scratching, it is at last opened, and when opened, though it was impossible before, it is now comparatively easy to put in the point of the fore-finger and thumb, and lay hold of the artery, disregarding the nerve which is on the outside and is removed from you, but being especially careful of the vein which is on the inside.

So far I speak of what you have seen, and I must now acknowledge, upon the very principle with which I set out in addressing you, that it is especially necessary to be honest—that I never had so serious an alarm in my life as at this period of the operation, when I saw the blood welling out from the bottom of the wound. I cast about as to what was to be done, because I knew that if this were venous blood the vein must be tied, and I believed that death would have been the indirect consequence of tying it. I never was more relieved than on seeing that the blood was arterial, and of course came from the artery, and I was pleased beyond measure with my friend and colleague, when I found that the very circumstance which would have cowed and rendered useless the hand of many men, only shewed you, and shewed us all, the vigour of his character—the resolution and decision which enabled him at once to lay hold of the vessel, and to continue to hold it till it was tied above and below. Dexterity of hand, and ingenuity, possess no value compared with that manliness of character which enables the surgeon to summon up all his resolution on a trying occasion; indecision at such a moment would have been disastrous to the patient, and would have brought disgrace upon us all*.

This you saw, and the source of the blood was the cracking or bursting of the artery close to the portion of ossification.

There are other circumstances in this operation to which I must more particularly draw your attention. After the ligature was applied above, the hæmorrhage continued; and I hope you are fully aware of the importance of that fact. On reflection, you will see with what advantage you come to the study of this subject, compared with those who investigated it thirty, forty, or fifty years since. The idea was, that an artery threw out its blood with an uncontrollable degree of violence—that is, men saw an artery, for example, in the wrist, bleeding furiously, and with difficulty suppressed it; and so they imagined that an artery at the groin, more especially the external iliac, must bleed with an uncontrollable force. Some most ingenious members of our profession were deceived,

* Mr. Arnott was the operator.

and I will tell you how. In an operation upon the thigh, they compressed the artery at the groin. I have seen a man bearing upon the artery, and another bearing upon the top of him, yet the blood flowed; and so the idea was still entertained that the artery was so exceedingly active as to overcome all this accumulated pressure. It was no such thing; it was only a proof of one of the most important circumstances, and one which should, if properly understood, have given the members of the profession perfect satisfaction and freedom to tie any artery they chose. The blood was returning from below; it was not coming through the main vessel; but the vessels of the hip, of the thyroid hole, were returning the blood circuitously into the vessels of the thigh, and so back by the wounded artery. I need not go into the circumstances that first convinced me of this, but I may state the following case. A man was wounded in the artery of the groin, and he (a resolute fellow) took hold of the integuments, and so held the wound together with his own hands, and sent for a surgeon. When the surgeon arrived, he said, "My good fellow, what can I do if you hold the wound in your hands?"—"Oh," replied the man, "if I let go, the blood will spout out all over you, and I shall die." The surgeon at last prevailed upon him to let go, and presently the blood spouted out; and as you are aware that a few ounces of blood, lost direct from the heart, will cause a man to faint, while a pound or more may be taken from a remote part, without any such effect, so when this great vessel threw out its blood, pressure was suddenly taken off the vessels of the heart, and instantly the man fell back in a faint. What was wrong on the part of the surgeon, was insisting on the poor fellow, who had most sense of the two, letting go his hold before matters were arranged for action, and much blood consequently lost. The artery was at length tied, and the surgeon went away. You anticipate what did occur: presently hæmorrhage came on again. The surgeon was not aware, as you are by the very occurrence of to-day, that the inoculation is so free that the blood must flow by regurgitation where there is an open wound. This second hæmorrhage decided the poor fellow's fate.

You perceive, then, gentlemen, how knowledge and presence of mind have been happily combined in our operation on this occasion. By laying hold of the artery at the point where it burst, only a few ounces of blood were lost, and by holding it until the ligature was placed, first above and then below the wound, all was secure.

I mentioned the apprehension that I had

lest the blood should come from the vein, and I will tell you why. You know that when a great vein is wounded above the valve, it is equal to a wound of the heart itself. You are aware, as veins contract in size, the blood must necessarily flow more rapidly through these contracted tubes—that it flows very languidly in the extremities, because their united calibre is so much greater than the veins near the heart. But if a vein which carries the whole blood to the heart be not larger in diameter than the aorta, it is clear, without much demonstration, that the blood must pass as rapidly through the vein as through the aorta, in order that the circulation may continue; and if the vein be wounded, there will be a great discharge of blood from it, because it will come directly and unimpeded, the wound being above the valve. I shall relate a circumstance that occurred under the eye of the late Mr. Alcock. As he was walking through the Horse Guards, a lad, in the act of climbing over the railings in the park, fell: he had his knee upon the horizontal part of the railing; his knee slipped, and the upright spike ran into his groin, under Poupart's ligament, and into the external iliac vein. Of course there were immediate, though unavailing, attempts to assist him, as in all cases of this sort; every one being desirous of rendering aid, a crowd jostled around him, but nothing was done; and with malediction on his lips, the lad expired. Mr. Alcock, a very excellent surgeon, and forward in his profession at that day, forced himself into the midst of the crowd, but too late to be of service: the lad died as if the heart itself had been wounded.

I must here break off abruptly: I have no more to say respecting this case, because it is in progress; but I am very sorry to state that symptoms, unconnected with the aneurism, have taken place, which, I am afraid, will hereafter lead us to make more particular remarks upon it.

Note. 12th January.—After some threatening symptoms of peritoneal inflammation, this man has reaped all the advantage of his resolution, and is perfectly recovered.

MIDDLESEX HOSPITAL.

(CASE ABOVE ALLUDED TO BY SIR C. BELL.)

Inguinal Aneurism—Ligature of the External Iliac—Rupture of the Vessel during the Operation—Cure.

WILLIAM KNEE, 36 years of age, was admitted December the 12th, with an aneu-

atism at the top of the left thigh, close to Poupart's ligament. Its size was that of a turkey's egg. A small swelling was first observed in this situation about eight months ago, whilst he was at Florence; and he supposes it to have been occasioned by his leg and thigh having been stretched backwards, as he was getting out of a boat six weeks previously. Being a gentleman's coachman, he continued to drive as usual; but latterly the swelling became more painful, especially when handled, and slowly increased in size. He was sent to England to be operated on; and having brought a letter from the surgeon under whose care he was, to Mr. Arnott, he was received into the hospital about three weeks after his arrival.

He had not suffered pain from the journey. He walks lame—*i. e.* he lifts the whole of the left lower extremity forwards without flexing the thigh. He states that this limb becomes cold if not in motion, or near the fire; in other respects he is in good—in florid health. The tongue is clean, and the evacuations from the bowels are natural in appearance. His pulse is quiet; the action of the heart and lungs regular; but some of the stethoscopists assert that the aorta is heard over a larger space than is natural. Having been domesticated five days in the hospital, the operation was performed on the 17th of December.

An incision was made nearly perpendicular to Poupart's ligament, the lower extremity commencing a little above it, and just over the outside of the artery. The external, and the outer part of the internal oblique muscles were divided with the knife simply; but the internal fibres of the latter muscle conjoined with those of the transversalis, were divided partly upon a director, partly on the finger carried under them. The peritoneum being then displaced, the artery was readily found; felt, but not seen. The point of a silver knife was now used to divide the fascia a little on each side of it, and an attempt was made to carry the needle under the vessel, from the inside outwards; this not being easily accomplished, it was carried beneath it from without inwards; but when the ligature was laid hold of by the dressing forceps (for it was too deep to be seen) it was found that the threads, three in number, of which it was composed, had got entangled, so that it could not be drawn round the artery. Another needle and ligature was then called for; but instead, Weiss's aneurism needle was handed to the operator. In passing this, a thicker instrument, round the vessel, more force was required; and as its point was pushed up on the inner side of the artery, the wound suddenly filled with blood, which was,

however, directly stopped by the operator, who, with admirable presence of mind, seized the artery with his finger and thumb, and completely commanded the hæmorrhage, observing at the same time, "the artery has given way; there is a small ossified part where I can feel the aperture. I must apply a ligature above and below it." This was done; Mr. Arnott retaining his hold of the vessel with one hand, and carrying the common aneurism needle under it with the other, first above the pinch of the finger and thumb, and then below. Where the *upper* ligature was applied, Mr. Arnott stated that the coats of the vessel felt quite healthy: the *lower* one was placed just below the patch of ossification, which was represented to be of a small size on the inner side of the vessel. Previous to tightening the latter ligature, the pressure being slightly remitted, the blood flowed freely (of course from the lower end), shewing that the anastomosing circulation was already in full operation, but pulsation in the aneurism had now ceased, and never returned.

Two hours after the operation the patient complained of the leg (on which a worsted stocking had been drawn) feeling cold. In the evening and the next morning it was warm, apparently more so than the other. Towards midnight he complained of pain shooting from the groin towards the chest, and, as the pulse was rising, sixteen ounces of blood were taken from the arm. On the following day there was slight traumatic fever, and in the evening, as he felt pain in the abdomen, thirty leeches were applied; an aperient draught not having operated, two oily injections were given, which brought away sufficient evacuations. On the evening of the 19th, and on the morning of the 20th, he complained so much of twisting pain round the navel, attended with hiccup and tension of the abdomen, that the house-surgeon took twenty ounces of blood from his arm, which was buffed, but not cupped; leeches were afterwards applied, and calomel, in two grain doses, was given every two hours.

On the 21st, the symptoms being removed, the calomel was stopped, and all medicine discontinued. From this time the case proceeded favourably. At night on the 26th—*i. e.* on the sixteenth day from their application—the ligatures came away. On the 28th, he was ordered a chop and a couple of ounces of wine. The wound is now (January the 12th) almost healed, and the aneurism considerably diminished in size.

GUY'S HOSPITAL.

Lithotomy.

IF any mode of operating on any part of the body has reached perfection, it is that of lithotomy in the hands of Mr. Key. The rapidity and certainty with which he seizes the stone, cannot be excelled. The patient, who was operated upon on Tuesday, so as to lead to these remarks, was a man of the middle age, of a dark swarthy complexion, of middle stature, and by no means corpulent. Mr. Key, as is his usual custom (as soon as the patient's hands and feet were bound together), passed the straight staff into the bladder, to satisfy himself of the presence of the stone: this part of the operation is not the least worthy of notice; for the extreme ease and rapidity with which it is done must strike the most superficial observer. The staff was held by Mr. Morgan; and from the first incision to the removal of the stone, only *forty-five seconds elapsed*. The second incision momentarily followed the first; the knife then lateralized and carried into the bladder, the fore-finger of the left hand was then introduced into the wound, the stone felt, and the forceps were then passed along the finger as a guide. The stone was immediately seized, and found to be the size of a small walnut. It was formed of an external brittle coat, of a light colour, and probably was one of the phosphates; whilst within it was much darker, and appeared to resemble the lithic acid, being of a reddish brown colour. At the moment that it was passing the external wound the crust broke in halves, one of which fell on the floor; the other was retained in the forceps, with the darker central portion. The patient was immediately removed to bed, but appeared entirely indifferent to the operation.

Amputation.—The inferior extremity of a child was then removed by Mr. Bransby Cooper, for extensive ulcerative disease of the knee-joint, with ankylosis, the leg being at an acute angle with the thigh. Mr. Cooper practised the flap operation; it was well performed, and was completed in rather less than two minutes.

ST. GEORGE'S HOSPITAL.

Ligature of the Femoral Artery.

THIS operation was performed on Wednesday, by Mr. Hawkins, in a case of necrosis and abscess of the thigh, with sloughing and hæmorrhage, threatening fatal consequences. The patient was bet-

ter next day, having rallied considerably. The history is very interesting, and we shall give the details when the case is complete.

Tubercle Operation.—A nose was manufactured on Thursday, by Mr. Keate, in the neatest possible style. We shall give details of this case also on a future occasion.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Mr. Key on Ulceration of the Joints.

THE paper (which we mentioned was recently read) is the continuation of one published in the last volume of the *Medico-Chirurgical Transactions*, on the subject of ulceration of the cartilage of joints. In the former part of his paper Mr. Key intends to establish the pathological fact, that the absorption of the cartilage covering the articular ends of bones, is effected by means of a vascular membrane, and not through the agency of its own vessels. For the circumstances under which this membrane is developed, the reader is referred to the volume just quoted. The present observations are on the primary ulceration of cartilage.

The author commences by drawing a distinction between the process of ulceration and that of absorption. He observes, that ulceration has been erroneously regarded as an act of absorption; and that proofs are altogether wanting to establish these processes as being identical. He considers ulceration under all circumstances, whether occurring in soft parts or in the less organized structures, as bones and cartilage, as a process of disintegration, or degeneration of tissue; and that the absorbents are not concerned in the process.

According to his view of the subject, ulceration is analogous to the softening of tubercular deposits in the different tissues of the body, or to the softening of the fibrine in the canals of arteries under inflammation, or to a similar process in the texture of the brain. A change similar to this takes place in the structures that are undergoing the ulcerative process; they are not absorbed, but break down and form a puriform mass, in which the *debris* of the original structure can sometimes be detected. Several examples are adduced to illustrate this process.

There are many circumstances irreconcilable with the opinion that the parts removed by ulceration are absorbed into the system. In the formation of chancre, which is a form of ulceration, the parts contaminated by the poison, under this

view of the process, are always taken into the system, and must therefore uniformly contaminate the whole mass of the circulating fluid. Such must be the consequence attending a chancre, if ulceration is an act of absorption,—an absurdity that almost carries with it its own refutation. The action of iodine is another instance that shews, *ex absurdo*, that this process is not an absorbent action. Iodine frequently produces absorption of a node on the tibia, and at the same time checks and heals a cachectic ulcer on the same leg in the vicinity of the node: in this instance the same remedy quickens the action of the absorbents in removing the swelling of the bone, and also checks the action of the absorbents, by healing the ulcer—two opposite actions of one remedy. He instances the decay of a tooth as a familiar act of ulceration, in which the part that is destroyed by the process can be observed in its several stages; and that it is a living action, and not a mere chemical decomposition of the tooth, is proved by the fact that dead teeth do not continue to decay. The distinction between ulceration and absorption may be observed in the spine under the pressure of an aneurism, and under scrofulous disease. In the former, which exhibits the simple effects of absorption, the bone, which is more highly organized than the intervertebral substance, is often extensively eroded, while the less organized fibro-cartilaginous structure is frequently unchanged, absorption requiring a certain extent of organization. In scrofulous ulceration, on the contrary, the intervertebral substance is often extensively destroyed, while the bone is much less affected, ulceration being an act of disintegration, and therefore not depending on a high degree of organization.

Having devoted a large part of his paper to the subject of ulceration, and endeavoured to prove that it is in all respects different from progressive absorption, the author proceeds to apply his doctrine of ulceration to the diseases of joints. He draws a line of distinction between absorption of cartilage, which is a healthy action, and ulceration of cartilage, which is a destructive process.

He observes, that primary ulceration of cartilage, as far as he has seen, is a much less frequent form of disease than Sir B. Brodie describes it; and that he has found, in the earliest stage of joint disease, signs of synovial inflammation, and, more or less, traces of a newly-formed membrane, when the disease has proceeded so far as to destroy the cartilage. He considers the absorption of the cartilage by means of a membrane, as a process set up by nature to prevent ulceration, which is a destructive process, and must sooner or later end

in suppuration and the disorganization of the joint. Joints are often examined in which (as in the knee) one side has been deprived of its cartilage by means of the membrane, and the other side has gone on to ulceration and suppuration.

The primary ulceration of the cartilage is most frequently met with as a consequence of a wound of a joint, which is often followed by acute inflammation, and a breaking down of the cartilage, which may be sometimes seen in flakes separating from the bone. In this process nothing like absorption is going on: there is often no development of a membrane; and the action is evidently one of disintegration.

This view of ulceration explains the circumstance of suppuration not taking place during some of the most protracted forms of joint disease. Nature endeavours to remove the cartilage by absorption, and succeeds when means are used to keep down inflammation; but if inflammation takes place, and the general health be impaired, the absorbing action ceases, and a process of ulceration ensues, which causes suppuration and ulceration for the removal of the *debris*.

In the observations which the author makes upon joints, it is his intention to describe two modes by which the cartilage of joints is removed under disease, which may be briefly summed up thus:—In ordinary chronic inflammation, either in the synovial membrane or in the bone, the cartilage is uniformly removed by means of a highly organized membrane, developed for the purpose of absorbing the cartilage, which, from its low degree of organization, is incapable of effecting this process. In acute inflammation, on the contrary, this absorbing process is either altogether wanting, or is superseded by a process of ulceration under which the cartilage softens down, and the *debris* is carried off by the process of suppuration.

The limits of this abstract do not allow the author's proofs and illustrations to be stated at length; but we have given, we presume, enough to shew the nature of his views, and the manner in which he supports them.

NEW PREPARATION OF THE ACETUM OPII SEDATIVUM.

To the Editor of the Medical Gazette.

SIR,

HAVING had the honour of presenting a paper to the Medico-Chirurgical Society, which was read at their last meeting, Jan.

13, 1835, entitled, "On the Preparation of the Acetum Opii Sedativum, and its Use, as a Sedative, in the Treatment of Mania Melancholia and Puerperal Mania, with Remarks," I will extract, with your permission, that portion of the paper which refers to the preparation, &c.; and I shall feel honoured by its insertion in your valuable journal, in order that the profession may have the opportunity of preparing and giving it a trial; it being considered as highly deserving of the same, by so eminent authorities as Drs. Elliotson and Paris*. To Dr. E. I am indebted for its name.—I am, sir,

Your obedient servant,

J. H. HORNE,
Surgeon, &c.

5, Gerrard-Street, Soho,
Jan. 14, 1835.

Fermulary.—I take three times the quantity of the best opium, reduced to fine powder, that is ordered by the London Pharmacopœia for two pints of tincture; add to the opium two pints of dilute acetic acid; after they have digested a few hours, add to them six or eight pints of rectified spirits of wine; macerate about seven days, then carefully filter, in order to separate the insoluble parts of the opium. Introduce the liquor into a retort, accurately closed, and distill off the spirit. The product in the retort, after the spirit has all passed over, is the required *acetum opii sedativum*.

If the distillation be carefully conducted, the result will always prove of one uniform strength—1 ℥ equivalent to iij℥. tincturæ opii, and free from spirit, and will keep unchangeable for an indefinite time. The *acetum opii sedativum* will be found the same, or very similar, to Mr. Battley's liq. opii sedativus (except in the strength, which latter falls short, according to the opinion of our most able experimentalists, as nearly j. to ij. instead of j. to iij.); a preparation too well known to require describing, except in regard to its mode of formation, which the preparer, in spite of his ranking as a scientific druggist, has hitherto kept a profound secret: should this slight effort of mine be the means of eliciting that secret, my object, in part, will be attained.

* In commendation of the process and preparation, I am proud to add Dr. Paris's valuable testimony:—

"SIR,—I do not see any objection to the process you have suggested, for obtaining an acetic solution of the active matter of opium: the product is certainly highly distinguished by its narcotic odour and flavour. I think it merits a trial, for we cannot be too well provided with a variety of forms of so important a medicine.

"Yours, &c.

"J. A. PARIS.

"To Mr. Horne, Jan. 7, 1835."

The rationale of the process may be briefly stated as follows. The acetic acid unites with the morphia of the opium, and forms an acetate of morphia, which is held in solution by the diluted acid; the remaining ingredients of the opium, acted on by the rectified spirits of wine, are extracted, and detained by the acid, after the spirit has been distilled over. I shall be happy to give a full description, if required by any of your numerous correspondents, should the subject be considered of sufficient interest to be allowed to excite inquiry in your useful and scientific journal.

EFFECTS OF LIGHTNING—RUSSIAN TREATMENT.

THE *Medical Gazette* of St. Petersburg gives an account of the successful treatment of a soldier who was struck by lightning. Two pounds of blood having been taken from his arm, he was buried up to the neck in earth. Although he was perfectly cold before, he came to himself in about five minutes. He was then carried to the hospital, where only tea and gentle aperients were administered to him. On the following day he was able to walk, and to answer all the questions put to him by the Grand Duke Michael and Sir J. Wylië, who visited the hospital. He is now quite recovered.—*Times*.

MR. PHILLIPS'S PRIZE ESSAY.

From the report of the proceedings of the Institute of France, we learn that of fifty-seven memoirs forwarded by the competitors for the Monthyon legacy, the commission had decided that that of B. Phillips, Esq. of Wimpole-Street, was entitled to the first place.

The subject of his essay was "A Mode of Curing Aneurismal Tumors without Ligature or the Knife;" by passing through the sac, one, two, or more threads of silk.

Supported as this invention is by the sanction of the Institute, we hope soon to be enabled to record its successful adoption in practice.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CERTIFICATES JAN. 15, 1835.

Patrick Benson, Roscommon, Ireland.
George Cooper, London.
Charles Collambell, London.
Montgomery Robertson, Scotland.
Henry Shaw, Exeter.

POSTERIOR DECUSSATION IN THE MEDULLA OBLONGATA.

[Communicated by MR. MAYO.]

19, George-Street, Hanover Square,
Jan. 15, 1835.

DEAR SIR,

I HAVE this day, in the presence of Mr. Kiernan, carefully looked at the specimens, sent by Sir Charles Bell for exhibition, in the museum of the College, in proof of the existence of a posterior decussation in the medulla oblongata, and to which the attention of physiologists has been called by a letter from Sir Charles to you, in the GAZETTE of last week.

The specimens which were shewn me were four in number: two in separate closed bottles; two together in one bottle, with a glass stopper, to admit, I suppose, of their being taken out and examined. Of these four specimens, the two in the closed bottles, and one of those in the open bottle, display nothing satisfactorily. They exhibit an *adhesion* only of medullary fasciculi, but nothing like *crossing*, or *decussation*. The appearances in them are such as may be produced at any part of the posterior fissure of the cord, by *favoured* in the process of separation some membranous adhesions, and *dividing* others.

The fourth specimen, however, displays on the posterior aspect of the medulla oblongata a strong and distinct decussation. This specimen I very carefully examined, taking it from the bottle, and identifying all the parts; when I distinctly saw two things in it, which any body else may see: first, that this *unquestionable decussation* is *not* in the same place with the *indistinct appearances* in the other specimens; secondly, that the decussation here really displayed is *only* a posterior view of the decussation of the anterior pyramids. The depth to which the crossing fibres of the anterior pyramids thus penetrate, has been shewn in figures, some years ago, in my plates of the brain, and recently in my pathological lecture in the last number but one of the MEDICAL GAZETTE.—I am, my dear sir,

Yours very truly,

HERBERT MAYO.

To Mr. Clift,
Curator of the Hunterian Museum.

LITERARY INTELLIGENCE.

In the press, A Practical Compendium of the Diseases of the Skin; including a particular consideration of those the most inveterate and intractable of these diseases, and of those characterized as syphilitic. —By Jonathan Green, M.D., M.R.C.S., &c. &c.

In the press, and nearly ready, the third edition, with important additions, of the Pathology and Diagnosis of Diseases of the Chest. Illustrated chiefly by a rational exposition of their physical signs. By Charles J. B. Williams, M.D.

Preparing for speedy publication, 4to. with numerous coloured plates, A Treatise on the Formation, Constituents, and Character of the Urinary Calculus. By John Green Crosse, Esq., Surgeon to the Norfolk and Norwich Hospital; being the Essay for which the Jacksonian Prize for 1833 was awarded by the Royal College of Surgeons in London.

NEW MEDICAL WORKS.

Tables and Diagrams illustrative of Chemistry and Pharmacy. By John Murray, M.D.

Records of General Science. No. 1. January 1835. A new monthly periodical, edited by Dr. R. D. Thomson.

Explanation of the Anatomical Atlas of Dr. Weber. Part VI.; being the accompanying letter-press to Weber's Plates, translated into English. Part VII. is in preparation. Schloss.

DISEASES OF THE CHEST,

In the course of which the Practice of

PERCUSSION AND AUSCULTATION IS FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE XVII.

DISEASES OF THE PARENCHYMA- TOUS STRUCTURE OF THE LUNGS.

ADVENTITIOUS DEPOSITS—*continued.*

I HAVE thus, gentlemen, concluded the description of the tubercular adventitious deposit, and have directed much of your attention to that subject, in consequence of its great importance. We now proceed to the other species of accidental formations which occur in the lungs: they will occupy much less of our time, because of their greater rarity, of their signs being scarcely known, and their mode of treatment being very imperfectly understood.

You will recollect I divided the adventitious deposits into two classes—the one of inorganic, the other of organic substances. Tubercles, and the formation I am next to describe, are included in the first class; the second, or organic, contains cysts, hydatids, medullary sarcoma, and melanosis. As these deposits occur but rarely in the lungs, I shall be brief in my description of them.

Cartilaginous and Osseous Adventitious Deposits.

Cartilage.—We have already spoken of the cartilaginous nature of the tubercular cicatrix, of the semi-cartilaginous structure

of the lining of fistulous tubercular excavations, and of the formation of cysts of a similar character, occasionally enveloping tubercular matter. There are also found cysts of an analogous structure occasionally investing the adventitious deposits, which we shall presently describe; and finally, portions of cartilage, of irregular forms and of moderate volume, are sometimes seen in the lung, presenting here and there points of ossification.

Osseous deposit.—Accidental ossific deposits never present the same physical appearances, or proportion of chemical elements, as ordinary bone: no fibrous or cellular texture is seen within them, and the quantity of earthy matter is always greater in these formations than in healthy bone. The gelatine in them is sometimes so slight, that these concretions are like small stones, from which they have been called *calculous* or *tophaceous*; sometimes even there appears to be no admixture whatever of gelatine, so that the deposit is like half-dried chalk or mortar: hence Laennec has denominated the first kind *imperfect ossification*—the second, *cretaceous concretion*.

Imperfect ossifications are found encysted or non-encysted. The first rarely occur in the lungs; they vary in size, from a pin's head to a nut, and adhere strongly to their cysts. The cysts are of a semi-cartilaginous structure.

The non-encysted, of which these are specimens [presenting them] are very irregular in their forms: their surfaces are uneven and rough; their centres white and opaque, of a calculous appearance; and they are easily reducible into powder by a hammer; their external parts are of a yellowish colour, are slightly transparent, as if horny, and are broken down with difficulty.

These ossifications are occasionally found in the pulmonary tissue, or in the midst of a cartilaginous mass, as of a tubercular cicatrix; they are found also in

tubercles, particularly those developed in the bronchial glands. When a mass of tubercles containing these petrous substances soften, the concretion will remain free in the excavation until a bronchial orifice of sufficient size opens into the cavity to admit of its expectoration.

Cretaceous concretions are of much more common occurrence. [Several specimens were shewn.] They present the appearance of chalk slightly wetted, or they are mixed with so much fluid as to render them like mortar more or less thick. In the latter case they are always encysted; in the former most frequently, but not always. When this matter is pressed between the fingers, it appears to consist of an impalpable powder; but frequently it contains small fragments of a firmer texture, giving the sensation of a mixture of small grains of sand with chalk more or less wetted.

Their cysts are usually cartilaginous; they are spheroid, or irregular in form. Laennec saw one shaped like a pyramid of four sides. The rounded cysts are sometimes themselves imperfectly ossified, and present the characters of the external surface of the stony concretions previously described—that is, they are very hard, and slightly transparent, like horn. Occasionally several concentric cysts are seen enveloping each other, either of a bony or cartilaginous structure; they are usually separated by layers of cretaceous matter.

A half liquid cretaceous substance is often found in the centres of tubercles, and particularly in those contained in the bronchial glands. This matter may easily be distinguished from the tubercle by its opacity and whiteness; and if it be dried, it becomes still whiter, and acquires more cohesion.

Laennec observes, that these concretions are never larger than an almond: you perceive, however, one on the table larger than a walnut. This matter is often met with infiltrating the portion of a lung around a tubercular cicatrix.

Causes.—Cullen and others have attributed these formations to the inhalation of certain powders; and they state that starch-makers, lapidaries, stone-masons, coachmen, &c., are most subject to them. A very simple and convincing answer may be given to this opinion—which is, that then the chemical composition of these concretions should be as various as the different kinds of powders which persons in these occupations inhale; but their chemical nature is always the same; they are always composed of *phosphate of lime*. Were any other proof of the incorrectness of this notion necessary, it might be inferred that these powders would remain and accumulate in the bronchial tubes; this, however,

never occurs: the dust we inhale daily becomes entangled with the tracheal and bronchial mucus, and is expectorated.

Laennec believed that in the greater number of cases these ossific substances were the result of nature's efforts, who, in cicatrizing pulmonary excavations, has deposited in too great quantity the calcareous phosphate necessary to the formation of the accidental cartilages which constitute pulmonary fistulae and cicatrices.

This explanation is insufficient, as he himself partly admits, inasmuch as cretaceous matter may exist in the centre of a tubercle before it has softened; and it may be found also disseminated in various parts of a lung otherwise healthy, in neither of which cases has there been a semblance of previous cartilaginous formation; nor is the phosphate of lime necessary to the accidental deposit of cartilage, although it be frequently superadded to it.

The occasional expectoration of cretaceous matters is the only sign we possess of the probable presence of a still greater quantity in the lungs.

Cysts.

By a cyst is meant an accidental membrane forming a sac without an opening, usually round, but sometimes irregular in form, and containing a matter more or less liquid, secreted by the membrane forming the cyst.

The cysts containing liquid matters vary as to the nature of the membrane or membranes which compose them: thus, they may be formed of a mere serous membrane, like the pleura or peritonæum; they are then thin and transparent, appearing like a vesicle sometimes not larger than a pin's head; at others of the size of a walnut. These are called *serous cysts*. I have never met with them in the lungs, but generally in the kidney [presenting preparations of them.] Occasionally the cyst is formed of a thin membrane analogous to a mucous membrane; these are often imperfectly surrounded by a layer of fibrous matter, or condensed cellular tissue, uniting them to the neighbouring parts: they may be called *mucous cysts*.

Sometimes the cysts containing liquid matters are formed of fibrous and condensed cellular tissue, enveloped more or less extensively by a cartilaginous layer, which is itself ossified at many points. The internal surface of these cysts is unequal, rough, and lined here and there by a semi-concrete albuminous or fibrinous substance. These are called *composed cysts*.

These cysts are the rarest of all the accidental deposits in the lungs of man; the serous forms are not infrequent in those of oxen and sheep. Laennec met with but a single instance of a composed cyst in the

human lung, and that probably had contained an hydatid; it was situated in the right inferior lobe, large as an apple, and of very irregular form. Its parietes were from two to four lines thick, lined internally by a fibrinous or albuminous substance of a whitish yellow colour, and similar in appearance to the middle coat of an artery; its external surface was of a perfectly fibrous texture, like to that of a tendon; here and there it had somewhat the structure of cartilage, in which there were many osseous points placed in various directions, some of which penetrated naked into the cyst, others plunged into the pulmonary tissue, which was, however, protected by a thick fibrous layer covering the projecting spiculae of bone. The cyst contained a liquid yellowish matter.

We have no specific signs of the presence of these accidental formations.

There are also cysts containing solid matters: I have described two species enveloping tubercular and cretaceous deposits; I shall speak of the rest in describing the substances they enclose.

Hydatids, or Acephalocysts.

These worms have long been confounded with cysts; they consist of a simple bladder of an ovoid or spheroid form, soft, and of the appearance of half-boiled white of egg; their parietes are usually uniform, although sometimes of unequal thickness; they are diaphanous, or semi-transparent; they are colourless, or of a milky tint, or slightly red, yellow, green, or gray.

The cavity of the hydatid always contains a fluid, which is usually limpid, but sometimes a little yellow or red. Frequently small hydatids are attached, like buds, to its internal parietes; these buds may be seen of various sizes, from a pin's head to a completely formed hydatid. When they have arrived at the latter state, they fall off. A single hydatid may contain a considerable number of others in various degrees of development. This mother hydatid, as it has been called, sometimes acquires an enormous size. I have seen them of a capacity equal to three gallons.

[A fine specimen of an hydatid which had been only an hour extracted from the human liver was shewn, in which the smaller hydatids, some attached, and others separated from the mother hydatid, were extremely distinct.]

Rudolphi has denied that the hydatid is an animal, from the extreme simplicity of its organization; Laennec asserts that they are organized beings; Baron Percy, and my friend Mr. Langstaff, the latter of whom has paid great attention to the subject, declare that they have seen their contractions.

Hydatids are always contained in cysts, by which they are separated from the surrounding parts. The cysts are usually fibrous, although cartilaginous and osseous matters often enter into their composition. Their internal surface is commonly unequal and rough; most frequently it is lined by an opaque, semi-concreted, yellowish albuminous matter.

A single cyst may contain a number of hydatids; they are then found floating in a fluid, either limpid or troubled, yellow or red. If it contain but one hydatid, it completely fills its cavity.

The natural cure of this hydatid takes place from its spontaneous destruction; it then bursts, its fluid escapes into its cyst and becomes absorbed, and the cyst itself, no longer subjected to distention by the increase of the hydatid, gradually contracts, its capacity diminishes, and it is probably ultimately obliterated by the adhesion of its parietes to each other.

Hydatids may develop in many of the organs; and although they are rarely seen in the lungs, yet authors have occasionally described them situated there.

The signs of the presence of hydatids in the lungs are extremely obscure; they would be the same when arrived at a considerable volume as those of effusion into the chest; and it might be impossible to distinguish the two diseases. Hydatids have been expectorated; in that case there would be no difficulty; and the previous absence of the respiratory murmur, and the dulness on percussion, would indicate their original situation. The result of the treatment of this disease is as uncertain as its signs: Laennec imagined, that since sheep, who are so frequently affected by certain species of these worms, producing in them the *rot*, are cured by salt pasturages, that salt might be used with advantage in these cases by man.

Medullary Sarcoma.

This deposit has received a variety of names, as spongoid inflammation, fungus hæmatodes, soft cancer, cerebriform cancer, fungoid disease, encephaloide, cephaloma.

Medullary sarcoma was first particularly described by Burns, of Glasgow, in 1800; since which period several have given their views of the disease, as Abernethy, Monro, Hey, Sir Astley Cooper, Mr. Wardrop, Laennec, Cruveilhier, Andral, and Dr. Carswell. The last author, to whom the medical public is also so much indebted for his splendid plates on morbid anatomy, has, I fear, generalized incorrectly, in including in the same genus the hard and almost inorganic scirrhus with the soft and highly organized medullary sarcoma. I have carefully examined the different

authors upon this subject, and find that the description given by Laennec accords best with what I have seen, and what I shall this evening shew you.

From the resemblance which this deposit has to the cerebral substance, Laennec has denominated it *encephaloïde*. He describes it as existing under three forms:—1, encysted; 2, non-encysted; 3, infiltrated into the tissue of the organs.

In whatever mode this matter is primarily deposited, when it is fully developed it is homogeneous, and very similar to the substance of the brain; it is here and there slightly tinted with a rose colour. Cut in fine slices it has a slight semi-transparency, but is opaque in the mass. Its consistence is similar to that of brain, but is less supple, and breaks more easily. When the deposit has acquired a certain volume, trunks of blood-vessels run along its fissures, and from thence penetrate in ramifications into its substance. The coats of these vessels are thin, and often break; clots of coagulated blood are then extravasated into the medullary mass, presenting a striking analogy with the appearances found in the brain of persons destroyed by sanguineous apoplexy: these extravasations are sometimes so great as to destroy nearly the whole of the adventitious mass, a few portions of its peculiar substance being only left. When this occurrence happens near the surface, and the skin inflames and ruptures, a bleeding fungoid tumor appears, to which the name of *fungus hamatodes* has been applied. This state has been confounded with tumors formed by accidental erectile productions bursting through the skin.

The mass now softens, and soon arrives at the consistence of a thick paste, and then of thick pus, still preserving its white or rosy tint. When, however, it contains extravasated blood, it becomes of a blackish red colour; the blood soon decomposes, its fibrine concretes and combines with the medullary matter, while the serous part is absorbed. These mixed matters are yet, however, of a deep black red, and present the appearance of a slightly dried and friable paste. Usually some portions of the cerebriform substance still remain, by which the nature of the original disease may be detected. Frequently, too, masses of medullary sarcoma may be found at the same time in different parts of the body, in various stages of destruction.

We now proceed to describe the three varieties in which the deposit is seen.

Variety 1st: Encysted.—The encysted medullary sarcoma varies in size from that of a nut to a middle-sized apple.

The parietes of the cyst have a tolerably uniform thickness, of about half a line; their colour is, grayish white, or milky,

and they are more or less transparent, according to their thickness; they are of a cartilaginous texture, although of greater softness, and less brittleness, than cartilage in general.

The cerebriform matter adheres but slightly to the cyst; it is separated into lobules by a delicate and fine cellular tissue, analogous to the pia mater. A number of vessels ramify upon this membrane, and penetrate into the interior of the mass. The coats of these vessels are very thin, easily break, and the effusions of blood I have already spoken of occur. Sometimes the trunks of these vessels, while placed in the fissures separating the lobules, break, and the blood accumulates beneath the cellular membrane, and forms a clot between the membrane and the medullary mass.

It is in this early state that these tumors present the lobular form: the lobes are principally seen upon the surface, and then are very similar to the convolutions of the brain. To detect them, the cyst must first be dissected off.

At this period the medullary mass is firm: if cut in fine slices, it is slightly semi-transparent; its colour is pearly gray, or yellowish. If the tumor be cut into, it appears to consist of a much greater number of lobules than its external form would indicate; these smaller lobules are closely applied to each other, leaving no intervals; their separation from each other is only expressed by red lines of injected cellular tissue. These lines rarely intersect each other, but are arranged in irregular curves.

As the tumor softens, it presents the greatest analogy to the cerebral substance; its texture is now homogeneous; there are no traces of the internal lobules, although the external are perfectly distinct; the vessels on the surface are much larger, and it is at this period that their rupture takes place.

Finally, the tumor becomes still softer; it is now like the brain, in a very humid and pulsatious state. Laennec continues to observe that he never saw the encysted or non-encysted cerebriform tumor soften much more, or its matter to be absorbed or evacuated, so as to leave an excavation.

This variety is commonly found in the lungs, liver, and mediastinum.

Variety 2d: Non-encysted.—The medullary deposits often appear in this form; their size is extremely variable, existing as a mere point to the volume of a full-sized fetal head. Their forms are spheroidal, ovoid, flattened, or altogether irregular. Their external surface is divided into lobes, although less regularly than in the encysted species. A cellular membrane invests them, and if they be situated where that tissue is abundant, it is very distinct; if

placed in the interior of the organs of the body, the cellular envelope is then scarcely apparent.

The non-encysted masses present, at first, a greater degree of semi-transparency than afterwards; they are almost colourless, or of a slight blue tinge; they are firm, and divided into many lobules; they have somewhat the aspect of fat, but do not grease the scalpel; sometimes they appear rather humid than fatty. After this period, the substance of the tumor becomes opaque and whiter; most of the lines separating the internal lobules disappear; the larger external lobes preserve their primitive texture a longer time, so that they may still be firm, while the other parts of the same tumor may be completely softened.

These tumors may be developed in all the organs of the body, but they are particularly found where the cellular tissue is lax and abundant.

Variety 3d: Infiltration.—Laennec never saw this variety exist in the lungs. It consists in the molecular deposit of medullary matter into the tissue of an organ; at first the points of its formation are small, and irregularly disseminated; these points gradually enlarge, fresh ones accumulate between them, until at last the parenchymatous structure composing the viscus is more or less transformed into a medullary mass. The colour of this mass varies according to the colour of the organ in which the infiltration occurs; thus in the liver, where it is frequently seen, it is white, or of a whitish-yellow tint. The texture of the affected organ is at first somewhat firm, but it finally degenerates into a soft and pappy substance.

There are no specific symptoms by which this disease can be determined to exist in the lungs.

Melanosis.

This very peculiar accidental deposit has been successively described by Laennec, Breschet, Langstaff, Cullen, Carswell, and Fawcington.

In its first state, or, as Laennec calls it, the state of *crudity*, the melanotic deposit has the consistence of a lymphatic gland; its tissue is homogeneous, its colour deep black: as it softens, there may be pressed from it a ruddy thin liquid, mixed with grains, sometimes firm, sometimes friable; finally, these grains, and the whole mass of the tumor, break down, and are converted into a kind of black "bouillie."

Melanosis may exist in three forms: 1st, encysted; 2dly, non-encysted; 3dly, infiltrated into the substance of an organ.

Variety 1st: Encysted.—The cysts are generally round; they vary in size, from that of a nut to a walnut; their thickness is

equal, and generally of about half a line, and they appear to be formed of cellular substance alone. They adhere by a fine cellular tissue to the organ in which they are developed, and may be easily separated from it by dissection. The internal surface of the cyst is smooth, but the melanotic matter adheres closely to it; the means by which this union is effected is a fine cellular structure, which disappears as the mass softens.

This variety has been principally found in the liver and the lung.

Variety 2d: Non-encysted.—This has been seen in almost all the organs of the body.

The volume of the non-encysted masses varies from the size of a millet-seed to that of an egg, or they may even become larger. Their form is irregular; they adhere strongly to the parts in which they are contained, although they are sometimes united to them by a delicate cellular tissue which permits them to be detached. In the latter case they are generally of a rounded form.

Variety 3d: Infiltrated.—Sometimes the melanotic matter is deposited in points between the integral molecules of an organ. The appearance of the matter, then, varies according to the colour of the organ in which they are placed, and according to the state of crudity or softening of the melanotic deposit.

In the first instance, the organ is dotted here and there with small black spots, arranged irregularly or in striated forms; as these spots enlarge, they unite to constitute masses of various size and figure. The natural structure of the viscus in which they are placed gradually diminishes, and at last disappears entirely, leaving a perfectly black substance in its place. It is at this period that the adventitious deposit usually commences to soften; if it even should occur before, the natural substance of the organ begins to soften also, and in both cases is destroyed.

Too little is yet known of the special signs of this disease, to enable us to distinguish it when in the lungs.

Black pulmonary matter.—The lungs and bronchial glands are often tinted with a black colour; this is called the black pulmonary matter, and may easily be mistaken for melanosis; and, indeed, is often very difficult to distinguish from it. Laennec has established the following differences:—

Softened melanotic matter tinges the fingers of a black colour, which is easily washed off; but black pulmonary matter, if allowed to dry previously, will remain for many days, even with frequent washings. Black bronchial glands, according to Fourcroy, contain a large quantity of hydrogen and carbon, which are not found

in melanosis; the latter being composed almost entirely of albumen and a peculiar black colouring matter.

Melanosis is evidently a deleterious formation; black pulmonary matter is not: the first produces malignant symptoms; the second is innocuous.

The black pulmonary matter effects no alteration in the structure of the lung, except its colour. When the melanotic matter is deposited in a slight degree, it may produce no other change also. Laennec then gives us the following rules by which we may distinguish them:—

We ought not to admit the existence of melanosis in the lungs, except we meet with masses of the organ is as dense and hard as that of the liver; but when this density has a doughy character, and the hardness is caused by osseous or cartilaginous points, the colour should be considered as produced by black pulmonary matter.

We ought not to admit that the lung is infiltrated with melanotic matter, until the tissue of the organ is as dense and hard as that of the liver; but when this density has a doughy character, and the hardness is caused by osseous or cartilaginous points, the colour should be considered as produced by black pulmonary matter.

I have now, gentlemen, concluded the diseases of the parenchymatous substances of the lungs, and shall proceed to those of the third section, or diseases of the pleura.

[This lecture was illustrated by preparations and drawings shewing the different adventitious deposits in their various stages.]

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

BY HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Continued from page 560.]

Excitement may be the result of Mechanical Impulse, of Vascular Congestion or Irritation, of Inflammation, of Structural Disease, or sometimes of mere Functional Disorder.

HAVING noticed the symptoms and consequences of excitement of a nerve upon the one hand, and of defective energy upon the other, I shall next proceed to consider the causes of each of these conditions, beginning with those of excitement; and from the bare enumeration of these, it must be obvious that they are somewhat numerous, inas-

much as there may be many causes and modifications of mechanical impulse, perhaps of congestion, certainly of inflammation and its consequences, and equally certainly of functional disorder.

That violent mechanical impressions upon the trunks of nerves, in any part of their course, will produce symptoms of excitement in the parts which they supply, has been known from a remote period, and is the foundation of a large proportion of the experiments of physiologists, who have pricked them with a needle, or the point of a scalpel, or pinched them with dissecting forceps, as the instruments most ready to their hands. These experiments have been most commonly made upon nerves of motion, the effects of which are obvious to the senses, as convulsive movements are the result. Upon this point the observation of Haller, and the simple and interesting experiment of Sir Charles Bell, confirmed by those of Magendie, upon the anterior roots of the spinal nerves, are conclusive. “*Deinde irritato nervo convulsio in musculo oritur qui ab eo ramos habet*.”—“On irritating the anterior roots of the nerve, at each touch of the forceps there was a corresponding motion of the muscles to which the nerve was distributed. Every touch of the probe or needle on the threads of this root was attended with a muscular motion as distinct as the motion produced by touching the keys of a harpsicord †.” Again: “on irritating the nerve of the fifth pair at its root,” the muscles of the jaw ached, and the jaw closed with a snap ‡;” and Mr. Shaw adds, “so as to nip an assistant’s finger severely §.”—“When the anterior roots singly, or the whole spinal nerve, was pinched by the forceps, or pricked by the scissors, an evident motion was produced on the muscles, not only perceptible to the eye, but when the third or fourth dorsal nerve was touched, the whole scapula moved in the hands of the assistant. . . . The motion given to the muscles was not the slight tremulous motion arising from the natural irritability still remaining in them, but it was *convulsive and spasmodic*, and followed each successive prick of the scissors ||.” “The slightest touch on the

§ *Ibid.* p. 63.

|| Note of Experiments performed by Mr. Shaw, by Mr. Cesar Hawkins.

portio dura, or respiratory nerve, convulsed the muscles of the face, whilst the animal gave no sign of pain*." Such are the evidences of the influence of sudden mechanical impressions upon motor nerves: they not only produce action, but action which, in the language of Mr. Caesar Hawkins, is "convulsive and spasmodic."—"Convulsio ositur." It is the same with nerves of sensation: the sensibility is augmented, and pain the consequence. If an ass be tied and thrown, and the "superior maxillary branch of the fifth nerve exposed, touching this nerve gives acute pain†." And again: "the cutting of the fifth nerve gave pain in a degree corresponding with our notions of the sensibility of nerves‡." With regard to the spinal nerves, strictly so called, the experiments of Magendie are the most decisive we possess: when he "pinched, stretched, or cut the posterior roots, or the nerves of sensibility, the animal exhibited signs of pain, but not to be compared, in intensity, with that produced by even a slight touch of the spinal marrow at their origin§." Lastly, from experiments upon nerves which minister both to sensibility and motion, these mechanical stimuli produce both convulsive movement and pain; for "when a nerve is pinched, or pricked, the muscles, which it supplies, contract with more or less violence, and at the same time the animal experiences suffering more or less severe||."

Pathological facts lead to the same conclusions. In the case of a late estimable physician, a spiculum of bone within the cranium, irritating (if we may judge from the effect) a nerve of sensation from its very origin, produced incurable *tic douloureux*, and ultimately serous effusion, which was probably the cause of death. In many instances, a similar cause operating upon the cerebrum has produced epileptic convulsions; and it is said that a sharp fragment at the end of the bone of a stump has, by coming occasionally in contact with the extremity of a nerve, occasioned the combination of violent neuralgia and muscular spasms—violent, uncontrollable, and painful jumpings of the stump.

It has been generally believed that stretching of nerves will produce a morbid development of nervous energy; and this stretching of the medullary filaments constitutes the very foundation and essence of the distinction, adopted by M. Portal, of the diseases of nerves into those of painful and convulsive stretching, and those which are characterized by the insensibility of compression; and he adduces, as illustrations, the opposite conditions of the nerves of the thighs, according as these are distended upon the one hand, or compressed upon the other, by the gravid uterus*. It forms also a most important element in the explanation offered by Mr. Swan, of the painful effects of a partial division of a nerve†, and constitutes the introduction of his chapter on "the compression of nerves;" from which, perhaps, it may be inferred that he considers distension and compression as similar or identical in their influence. "A nerve," he says, "may be extended some way without giving pain or uneasiness; as I have frequently observed in making experiments, when I have passed a probe under the sciatic nerve and drawn this from its situation, and as is shewn in cases of popliteal aneurism, when the swelling may attain some size before much pain is produced. But when a nerve is extended in any considerable degree, pain is excited; and if the extension be increased, the pain is increased in proportion, till at length the nerve begins to ulcerate; and if the pressure be not removed, it becomes almost destroyed by this process‡." From this statement of fact, upon unquestionable authority, I should be induced to draw the conclusion that distension alone is not sufficient to produce excitement of a nerve, the effects of which excitement are generally in proportion to the suddenness with which the cause is applied, excepting in cases wherein inflammation is the result of this peculiar mode of mechanical violence. Then the inflammation which precedes the ulceration, adverted to by Mr. Shaw, is the cause of the suffering induced; but previously to this, paralysis, in its various degrees, is infinitely more common.

This view of the subject derives much support from the observations of Bichat

† On Diseases of Nerves, p. 111.

‡ Ibid. p. 155.

and Bourdon upon the same point. The former contents himself with alleging, in general terms, that sudden distension more completely *interrupts* ("interrompt,") sensation and movement than that which is produced slowly*; the latter alludes to the occurrence of *paralytic* asphyxia, from the tiraillement of the recurrent nerve produced by aneurism of the arch of the aorta, at that part around which this important nervewind, before it proceeds to its destination†.

The experiments of M. Descot upon this point, appear to me to be inconclusive; or if they justify any particular inference, it would be that distension of the nerve itself is little painful unless carried to the extent of tearing it asunder, or, at all events, without separating some of its filaments by the violence. He distinctly states, that "they may be gradually elongated without any change of their texture, or considerable disturbance of their functions, as in cases of exophthalmia, when it occurs gradually."‡ But he alleges that the functions of the nerve suffer materially when the distension is more sudden, as is the case when the nerves are raised by a popliteal aneurism, as well as in some instances of acute exophthalmia. Cases, however, of neuralgia accompanying popliteal aneurism, admit of another and more satisfactory explanation, as will appear hereafter, from a consideration of some recorded examples of this kind; and as to the "*exophthalmie aiguë*," it is probable that in such instances the eye has been displaced by inflammation behind the globe, of which the nerves, in all probability, have also partaken. With regard to the experiments which M. Descot instituted with a view to the elucidation of this point, they were accompanied with so much violence to surrounding textures, as well as the tearing asunder of the whole nerve, that it is difficult to ascertain how much "*d'une violente douleur*" was to be ascribed to the injury of the nerve, and how much to the other mischief inflicted. The latter could not have been inconsiderable, seeing that the nerve, elevated by a blunt instrument, did not give way at the part where the injury was inflicted, but at a distance of five or six

inches below that point; and a case of extensive laceration of the arm, by a spinning machine, communicated by M. Beclard, would lead one to suppose that the pain was rather to be referred to the surrounding injury than to the nerve itself, as, notwithstanding that a large nerve was completely torn asunder, no immediate and severe ill consequences followed, and afterwards nothing but the loss of skin interrupted the progress of cicatrization. My friend, Mr. Phillips, of Wimpole Street, also, who is much conversant with experiments of this kind, and with the progress of experimental physiology amongst our continental neighbours, has assured me that in the course of his own experiments upon nerves, he has raised them from their natural position to the extent of from half to three quarters of an inch, with the handle of a dissecting-knife, and although they were nerves which ministered both to sensation and motion, neither suffering nor convulsive movement resulted from the injury inflicted. When the nerve was distended rapidly, a paralytic affection appeared to be the only consequence. This, however, gradually subsided, the nerve apparently becoming accustomed to the elongation of its filaments, and resuming its function, notwithstanding the continued operation of the distending cause.

Another mode of mechanical impulse is that occasioned by a blow upon the trunk of a nerve from any blunt substance, as in the trick common amongst schoolboys of striking "the funny bone" with a key. The ring and the little finger immediately start from their position with a convulsive movement, which is, moreover, attended with a severe and tingling pain. The cause, however, being only temporary, produces only a temporary effect, unless the mechanical violence has been so great as to occasion confusion of the nerve, in which case inflammation is apt to supervene, and to excite a new train of characteristic symptoms.

Other stimuli, if violent in character, or sudden in application, may also excite a nerve to excessive and abnormal exertion of its influence. So electricity and galvanism directed suddenly, and in their concentrated form (as from an electric or powerful galvanic battery), upon the trunk of a given nerve, will excite to involuntary movement the muscles which it supplies, even for some

* Anat. Gen. tom. i. p. 160.

† Principes de Physiologie Médicale, partie deuxième, p. 678.

‡ Des Affect. Loc. des Nerfs, p. 46.

time after the death of the animal; and they are amongst the most familiar remedies for defective energy. Concentrated acids have also, in the experiments of physiologists, been frequently applied to nerves exposed by dissection, and convulsive movement has been the result. "*Dum nervum quemcunque irritavimus sed chemico veneno minus, scalpello melius, continuo is musculus, quem nervus adit, contrahitur, et motu, ad quem factus est, defangitur, artumque suum aut flectit, aut extendit, aut alio quocunque modo emovat.**" Even cold may be enumerated amongst such chemical stimuli acting by direct application; for Haller expressly asserts, that touching a nerve with a cold sponge will occasion a convulsion†.

A nerve may be also morbidly excited, so as to produce what Bichat and others have denominated "an exaltation of function," by vascular congestion and irritation of the nerve itself, perhaps even of contiguous parts from which the nerve derives its arteries, upon the due action of which the ordinary performance of its function depends; as is proved by the negative evidence of exposure to severe cold, which benumbs the faculties, and deprives the sentient extremities of the fingers of their sensibility. This is also strikingly exemplified in the effect, upon some constitutions, of cold bathing, which driving the blood from the surface to the interior, leaves the nails blue like those of a corpse, and the fingers at once bloodless, powerless, and all but insensible. The converse is, perhaps, equally true. If blood, as in blushing or violent anger, be sent in superabundant quantity to a particular part, that part is red, and violently hot, and augmented secretion frequently results: the ordinary attributes of the nerve are increased; but this is rarely more than morally painful—there is no positive physical suffering; but if there be inflammation, the extremities of the nerves may partake of the inflammatory action, and pain will be the consequence. I believe this to constitute the great distinction between simple and phlegmonoid erysipelas. In the former the inflammation is exterior to the nervous expansion upon which the sensibility of the surface depends; there is little pain, therefore, although the mor-

bid increase of arterial action produces violent heat, as is found also in a disease somewhat analogous, scarlatina. But in phlegmonous erysipelas, and in whitlow, the inflammation extending to that cushion-like texture upon which the remote extremities of the nerves of sensation are expanded, pain, frequently very severe, is the result.

It has been frequently observed, and I believe with truth, that irritation of the trunk of a nerve will be followed by the same consequences as excitement of its extremity. Of this, no better illustrations can be offered than the experiments of physiologists upon the pneumogastric nerves. It is well known that any cause of irritation applied to the extremities of these nerves in the larynx, trachea, bronchi, or pulmonary cells, which all derive their nervous energy from the same source, will occasion violent cough; and Cruveilhier found that mechanical irritation of the trunk of the same nerve was productive of a similar effect—the occurrence of violent spasmodic cough.

Now since local determinations of blood to the surface are found to produce an excessive development of nervous energy, as is proved by its influence upon the capillaries in increasing heat, it is probable that congestion of the vessels of the neurilema of a given trunk, especially if accompanied with arterial excitement, may occasion similar results at the ultimate destination of that nerve. After all, however, it may be difficult to define with accuracy the line of demarcation between mere congestion with increased arterial activity upon the one hand, and actual inflammation upon the other, so closely do they approximate to each other; and what we ascribe to mere congestion and increased arterial action, may, in truth, be the result of inflammation in some part of the course of the nerve.

Analogy appears to lead to the belief that in nerves, as in the brain, vascular turgescence and irritation, short, however, of the occurrence of inflammation, though having a strong tendency to terminate in that pathological condition, may produce a morbid excess of nervous energy. Excessive arterial action within the cranium is said to produce such an irritable state of the nerves which minister to the organs of sense, as to render them acutely and painfully sensitive to their ordinary stimuli, this be-

* Haller, Elem. Phys. vol. iv. p. 322.

† "A nervo spongia frigida tacto convulsio."

ing the only evidence of their excited state, for it does not appear that they are subject to neuralgia: hence the intolerance of light and sound so characteristic of cerebral excitement. But since even in the most favourable of these cases, where the patient is cured by active remedies, the existence or non-existence of meningitis, in a greater or less degree, cannot be determined; since we generally find that mere arterial fullness, even to the extent of threatening or producing extravasation of blood, more frequently occasions torpor or local palsies than irritation; and lastly, since these symptoms of excitement of the organs of sense are so frequently the mere precursors of the more prominent and formidable phenomena characteristic of phrenitis, it is far from impossible that even in such cases, and at such early period of the malady, there may be some degree of membranous inflammation; perhaps even cerebritis itself. It has, indeed, been generally believed that mere meningitis, either within the cranium, or of the spinal cord, will occasion morbid excitement of the nerves which issue from the part affected, although the medullary substance may not be implicated in the inflammatory affection. Such a supposition is not altogether improbable, and, if true, then it is easy to comprehend that vascular congestion of the neurilema, which is but an extension of a membrane of the brain, and envelopes medullary filaments which are also alleged to be an emanation from, or a continuation of, the fibres of the brain (although it has been a mooted point among French physiologists whether the brain terminates in nerves, or the nerves terminate in brain), may also produce similar excitement in a nerve. The details of an operation performed upon a diseased nerve by Mr. John Hunter, in the presence of Sir E. Home, who records the case, seem much to countenance this opinion; for upon the division of the nerve, such were the size of the artery within its substance, and the extent of the bleeding, as to require a ligature. There was, however, embedded in the substance of the nerve, a large tumor, which at least justifies a suspicion that there may have been some previous inflammation, upon which, or upon the mere existence of the tumor, the symptoms may have depended. A less equivocal instance is that related by Bichat, in which it would

appear that mere venous congestion had occasioned the symptoms of excitement. "Je conserve," says this distinguished anatomist, "le nerf sciatique d'un sujet qui éprouvoit une douleur très vive dans tout son trajet, et qui présente, à la partie supérieure, une foule de petites dilatations variqueuses des veines qui le pénètrent." We can scarcely doubt the competency of Bichat to discriminate between tortuous arteries and varicose veins, and yet a most respectable living author has, through inadvertence, given at least an imperfect, if not an incorrect account of this case, leaving the impression that it was one rather of arterial fullness than of varix, in these terms:—"That there is an increased flow of blood *to the part* in these painful nervous affections is not only shewn by the redness and arterial action, but has been proved by an interesting dissection made by Bichat, of a case of painful affection of the sciatic nerve, where the vessels of the neurilema were evidently enlarged in size, and increased in number, so as to be quite tortuous." The difference in these two statements is obvious; and Bichat's more minute and accurate account justifies the argument, that since varicose veins can produce severe pain throughout the whole course of a nerve so large and important as the sciatic, arterial congestion without inflammation may produce similar effects.

The weight of testimony, then, is upon the whole in favour of the supposition that the state of the circulation in the vessels of the neurilema modifies the exercise of nervous influence; and it is probable that the functions of nerves may be influenced also by the state of the arterial circulation in surrounding parts. There is scarcely an instance of any important plexus or single nerve proceeding to its destination, without either surrounding, or crossing, or accompanying in its course, some large arterial trunk. This is well illustrated in the axillary, the aortic, the pulmonary, the cardiac, the celiac, and the uterine plexus. All the intercostal nerves pass over the corresponding arteries, and are elevated by each impulse of the arterial circulation, as was demonstrated to me by Mr. Swan, in the very simple experiment of blowing into the aorta of a minutely dissected trunk, when the intercostal arteries, distended by successive columns of air, in imitation of the natural circulation, raised sensibly by their

elevation the intercostal nerves; and to approach nearer to my own province, the par vagum in its course lies close to the carotid artery, and passes over and in contact with the subclavian upon the one side, and the arch of the aorta upon the other; whilst the two recurrents wind round the same large vessels before they proceed to the parts which they supply. This general law must be for some wise purpose; and it is hardly possible to resist the inference, that the ordinary offices of nerves are materially influenced by the movements of these contiguous arterial trunks; and if so, it is not irrational further to conclude that an excess of action in such vessels may produce an "exaltation of function" in the nerves which they so influence; but after all, probably this influence is but a modification of "mechanical impulse."

The ordinary impulse of arterial action, however, only promotes or assists the ordinary functions of contiguous nerves; its excess does but increase those attributes. The effects are not morbid or abnormal, the parts upon which the nerves are distributed being free from pain or muscular spasm, although there may be increase of heat and of secretion; excepting, indeed, in cases where the nerve is diseased; then the results are greatly modified,—any thing that can increase the momentum of blood under such circumstances often producing neuralgic attacks or convulsive movements, just as pressure with the finger, in a case communicated by Sir Charles Bell to Dr. Cooke, or the contraction of a muscle, as in Mr. Denmark's case, upon an inflamed nerve, will occasion similar effects.

But whatever may be said of the influence of vascular excitement of the nerve itself, or of contiguous parts, in producing an excessive development of nervous energy, there can be no doubt of the effects of inflammation of a nerve, whatsoever its producing cause, or in whatsoever part of the course of the nerve it may occur. I believe it to be a cause of much more frequent operation than is generally supposed.

I have already adverted to the difficulty which must occasionally exist in drawing the precise line of demarcation between simple vascular congestion upon the one hand, and actual inflammation upon the other. That the latter state, however, may and does not infrequently exist, we may safely infer from the

nature of the producing cause, the peculiarity of some of the symptoms, and the appearances on dissection; and where we can obtain this combination of evidence, the symptoms always assume the character of excitement, unless or until the nerve has been destroyed by the inflammation, or the latter has subsided or become subdued. Who, for instance, can doubt, when neuralgia or convulsive movement is produced in the finger by a prick from the thorn of a gooseberry-bush,—as in the case related by my friend Mr. Wardrop, or by an angular piece of porcelain embedded in the lip, as in that recorded by Mr. Jeffries, or from pouring an undiluted acid upon the sciatic nerve, or from transfixing with a needle the nerves of the fore-leg of a dog, as in the experiments of M. Bichat,—that these agents must have occasioned neuralgia by producing inflammation of the nerve, or at least of its enveloping and connecting membrane? for it has been questioned by some whether the medullary matter be subject to such diseased action. Without, however, entering minutely upon this question, which I shall have presently to consider, I shall content myself for the present with the assertion of my belief in the affirmative.

Symptoms of Inflammation.

Besides the ordinary and general symptoms of excitement, inflammation of a nerve commonly presents some which are peculiar. Amongst the most prominent of these are pain and tenderness in its course. In the case of neuralgic affection which I have related, the sciatic nerve in the progress of the malady became affected, and wherever it could be reached in its course, it was tender to the touch. In the instances of ischias nervosa, in the well-known dissertation of Cotugno*, as well as in those more recently described by M. Martinet†, there was tenderness in the nerve, in which dissection proved the existence of inflammation. In the interesting example recorded by Mr. Earle, "the course of suffering marked the nerve affected; the pain, with heat and fullness, established the existence of excitement; and the morbid sensibility, when touched, of the whole course of the ulnar nerve, proclaimed the existence of an

* Sandefort's Thesaurus.

† Rev. Med. 1824.

inflamed state of that nerve.*" The patient was cured by excision of a portion of the nerve, when its inflamed condition was manifested in the appearance of the excited portion; for "the neurilema covering the nerve appeared firmer and thicker than natural." It is not stated whether the interior structure of the nerve was examined.

Similar evidence presented itself during life in the case, communicated by Sir Charles Bell to Dr. Cooke, "of partial palsy, with great debility, preceded by inflammation of a nerve, accompanied with excruciating pain." The inflammation was in the ulnar and fibular nerves, and "the pain, which was of the most agonizing kind, had quite subdued a powerful frame. Observing that the pain was confined to certain parts of the hands and feet, and that a distinct class of muscles were become paralytic and shrunk, Mr. Bell's attention was directed to the corresponding nerves, and he found them *tender and acutely sensible* to the slightest touch."† The existence of inflammation was thus detected by the *peculiar symptoms*; anti-inflammatory remedies were employed, and the patient cured without an operation. These characteristic symptoms, however, cannot always be traced, for the inflammation may exist, although at too great a distance from the seat of the symptoms, or too remote from the surface, to be within reach.

Occasionally also, as in some of the instances recorded by Martinet, the nerve may be felt swollen, and hard, as well as exquisitely tender to the touch. In one case the cubital nerve swelled to a considerable size, equal to the little finger, and felt like a tense cord along the arm. It remained swelled, rigid, and painful, for four months. In a second case, also, the cubital nerve could be felt enlarged and tense, especially between the elbow and the arm-pit. In a third, the radial nerve was felt tense, and somewhat enlarged. In these nerves the enlargement may be traced during life, on account of their superficial situation; the sciatic, though enlarged to the size of the fore-finger, could not be traced, on account of its depth, but we may content ourselves in such cases with the excruciating pain produced by pressure

[To be continued.]

ON THE
MORTALITY OF THE MANUFACTURING DISTRICTS OF ENGLAND.

To the Editor of the Medical Gazette.

SIR,

IN a recent number of the Medical Gazette, you have done no more than justice to M. Villermé, in your praise of his intrepid industry and his sagacity in examining the three volumes of our British Population Abstract; and you have also favoured your readers with some of the valuable results of his investigation.

I perceive that you reserve for another opportunity the observations of M. Villermé, as to the influence of our manufactures on mortality; a discussion strictly belonging to medical statistics, and one in which I cannot but think that M. Villermé has been led to pre-judge the question by the declamation which has been lavished on that subject in England; whereby he has been convinced of the extreme misery of the manufacturing population.

If you are not alarmed at a few arithmetical details, I will endeavour to prove to your readers that this supposed misery is confined to the greater mortality of infants; much of which disappears upon considering the inevitable effect of rapidly increasing population. Before I proceed to this examination, I hope you will permit me to soften any preconceived opinion, by alleging the acknowledged fact of immigration into the manufacturing counties.—(See M. Villermé, § 10.) What the amount and effect of such immigration may be, I will endeavour to shew in the sequel of this letter. At present, I only beg your readers to remember that migration indicates the comparative *prosperity*, not the comparative *misery*, of the region towards which it directs its course.

As the basis of my remarks, I must refer to some of the results of the Population Abstract; and I propose to advert especially to *Lancashire*, as compared with the general results of England and Wales. The marriage registry may be deemed unexceptionable, as far as the total of 1,052,095 marriages in ten years, 1821-1830; of which years, throughout this discussion, I must be understood to speak. It is needless to advert to the unregistered

* Med-Chir. Tr. vol. vii.

† Cooke on Palsy, p. 98.

marriages of Jews and Quakers, or of the Scottish border, because it suffices (for the purpose of comparison) to presume that Lancashire shares not unequally in the defect thus produced.

The registry of burials is known to be defective, as were also, in some degree, the estimates of the amount of such defect obtained from the clergy; some of whom, from various causes, pleaded inability to furnish such estimate: but it will be seen by those who investigate the subject, that the number of deaths in the ten years did not differ materially from 2,657,797 (see Pop. Preface, p. 45), and the increase of population having been 1,978,312, the births must have exceeded the deaths by that number; supposing always that immigration from Ireland and Scotland, and emigration to North America and the Colonies, balance each other. Thus the births appear to have been 4,636,000; which number, divided by 1,052,000, gives 441 births to 100 registered marriages; from which result, deducting illegitimates at 5 per cent. and irregular marriages at 1½ per cent., the average number of children will be reduced to 416 from 104 actual marriages in England and Wales.

The ages of 3,938,496 individuals buried in 18 years (1813-1830), are known; and of them 1,044,526 died under two years of age*—that is, 26 per cent. or one-fourth part. The ages of 359,438 individuals buried in Lancashire during the same period, are also known,

and of them 121,103 died under two years of age*,—that is, 31 per cent. or one-third part.

The registered burials in England and Wales, averaged at 246,290 from 1820 to 1830; deduct *one-fourth* part for the infants who died under two years of age, and the remaining burials (184,718) are as one in 75 of 13,897,187, the population of England and Wales in the year 1831. In like manner the registered burials in Lancashire, averaged at 26,047; deduct *one-third* part for the infants who died under two years of age, and the remaining burials (17,365) are as one in 77 of 1,336,854, the population of Lancashire in 1831;—and the different proportion of mortality (except of infants, as above) is in favour of Lancashire. The unregistered burials would add one-twentieth to the above number of burials in England and Wales—one twenty-fifth part in Lancashire; an immaterial difference, not worth mention, except to shew that it has not been neglected in this investigation.

Here the discussion might close, were it certain that the births in Lancashire are really as four to three in comparison with those in England and Wales; a question which, I think, may be elucidated by further recourse to the Population Abstract.

For this purpose the proportion of marriages in the year 1830, to the population in 1831, must be considered:—

	Marriages.	Population 1831.	Proportion.
In England and Wales †	107,719	13,897,187	1 in 129.
In Lancashire §	12,075	1,336,854	1 in 111.

But the illegitimate children born in Lancashire exceed the proportion born in England and Wales as one-thirteenth to one-nineteenth part||, a proportion which assigns an excess of 959 illegitimates annually to Lancashire. The births in England and Wales have already been stated at 4,636,000 in the ten years—say 463,600 annually, and in the proportion of 441 to 100 registered marriages; and marriages equivalent to the above 959 illegitimates (in fact, 217 marriages) are to be super-added to the above number of marriages

in Lancashire; and the comparison will stand thus ¶:—

Lancashire Marriages.	Popul. 1831.	Proport.
12,075 + 217 = 12,292	1,336,854	1 in 109

so that the proportion of children born in Lancashire must be 129 to 109—*i. e.* as 100 to 84 or 85, in comparison with the proportion born in England and Wales; and in that proportion the deaths of infants in Lancashire would exceed the similar deaths in England and Wales, were the mortality of infants in both cases equal.

* Population Abstract, vol. iii. p. 487.
† Vol. iii. p. 486.
‡ Vol. iii. p. 490.

* Vol. iii. p. 186.
§ Vol. iii. p. 156. Vol. i. p. 304.
¶ Vol. iii. p. 156.

But the actual deaths of such infants in Lancashire are as 34 to 26 per cent., or 100 to 88 or 89; and the excess in Lancashire of 4 per cent. (say 88-84, or 89-85) remains to be accounted for by the crowded habitation of the families of workmen in the vicinity of the factories—an excess which would be incredibly small, were there not many adults in Lancashire who have spent the dangerous years of infancy elsewhere. These are the immigrants from Ireland, and from the agricultural counties; and the annual accretion of these admits of estimate, or approximation, in the following manner:—

The population of Lancashire having nearly doubled itself within thirty years*, the increase may be assumed at 2.6 per cent. per annum. The marriages in Lancashire (with the addition already stated on account of the excess of illegitimates) averaged at 11,464 from 1820 to 1830†. Multiply this number by 4.41, and the births in Lancashire must have been annually 50,556.

At the same time the increase of population was at the rate of 28,400 annually, which number deducted from the births (50,556—28,400=22,156) admits of no more than 22,156 deaths annually. But the actual number of deaths (allowing for unregistered and unnoticed deaths) must have averaged at nearly 28,000 per annum‡; so that the immigration may be taken at 5,844 annually (28,000—22,156=5,844), and must have augmented the proportion of the deaths of adults in Lancashire, but not in such manner as to be susceptible of exact calculation; because (as M. Villermé says, in his note on *§ x.*) the ages of immigrants cannot be ascertained.

For the sake of approximation, it may be allowable to assume that few or none of these are so young as to be under two years of age; and if the existing immigrants are 170,000 (a conjectural estimate, which cannot be explained in this letter), their deaths at 1 in 77 will be 2000 per annum; which number being expunged in considering the mortality of natives of Lancashire, the deaths of infants under two years of age amount

to 37 per cent. instead of 34 per cent.; and the disadvantage of infant life becomes 7 per cent. instead of 4 per cent., as before stated, without reference to immigration, which cannot be unnoticed in fair discussion.

But the mortality of infants implies not the misery of their parents, being, indeed, but the effect of dense population, and incidental to all large towns, where the incipient functions of infant life encounter the unwholesome atmosphere of a small apartment inhabited by the father, mother, and family. But these infants have not been employed in manufacture; and I am not aware that extraordinary mortality can be *proved* to fall on individuals so employed.

Thus I cannot but suspect that the misery imputed to manufacturing population has no other foundation than that kind of benevolent prejudice which cannot be dispelled unless by arithmetic and tiresome deductions, little suited to the impatience of our contemporaries, who are daily becoming more repugnant to laborious investigation; and I must appeal to the candour and perseverance of M. Villermé, who will experience no difficulty in clearing his mind from prejudice, when he pursues the foregoing details, founded on the results of the Population Abstract, with which he is perfectly familiar.

Your obedient servant,

J. RICKMAN.

January, 1835.

CASE IN WHICH LITHOTRITY WAS UNSUCCESSFULLY ATTEMPTED.

To the Editor of the Medical Gazette.

SIR,

FULLY impressed with the conviction that, for the right understanding and due appreciation of any new method of treatment, unsuccessful cases, and the causes of failure, should be made as well known as the more flattering cases of success, I send the enclosed account of an unfortunate stone case, in which lithotripsy was attempted, and of the cause of failure.

This case may appear the more interesting, taken in conjunction with one an account of which was detailed by Dr. Arrowsmith, in a late number of your journal.

From fear of intruding too far on

* In 1801, 672,731; in 1831, 1,336,753.

† Vol. iii. p. 356, marriages 11,247+2.7=11,464.

‡ Vol. iii. p. 356. The registered burials in Lancashire average at 28,947; add unregistered 653; and 1 or 5 per cent. for further defect, as in p. 45 of Pop. Preface, the total will be about 28,990.

your columns, I have not added any remarks, leaving the interesting points and practical deductions to be derived from this case, to the discrimination of your readers.—I am, sir,

Your obedient servant,

GEORGE BUCK.

Seamen's Hospital, Dreadnought,
Jan. 13, 1835.

George Patterson, *ætat.* 24, admitted September 24th, 1834. Complains of pain about the pubes and hypogastrium, and of difficulty in making water, which he is obliged to do very frequently. The pain is considerable when the bladder is full, and is not increased when it becomes emptied; with the last portion of urine there is generally, but not always, a purulent admixture. The flow of urine is occasionally interrupted suddenly, and it is always passed in a very small stream; it becomes tinged with blood after long retention.

He states that he has been affected in this way for about twelve days, but that he has been occasionally subject to the same complaint for the last eighteen months. But a very confused account, however, of either his feelings, or the history of his complaint, can be obtained from him.

On examination, it was found that there was a urethral fistula about the middle of the perineum on the right side of the raphe; the length of time that this had existed could not be learnt. There was also a close stricture at the commencement of the membranous portion of the urethra; the orifice was also much contracted. With the elastic gum bougie that was passed through the stricture, a calculus could be felt, which gave the sensation at first of being lodged in the neck of the bladder or commencement of the urethra, and was consequently judged to be of small size.

A silver catheter was then passed, by which eight ounces of *clear* urine were drawn off, and latterly about two drams of purulent matter. By the catheter the calculus was not felt; neither did the moderate search for it appear to cause much irritation of the bladder.

These points being ascertained, and there being no marked signs of disease elsewhere,—although his general appearance was such as to lead to the supposition of that being the case,—there appeared to be no reasonable objection to the performance of either lithotomy or lithotritry; the only obstacle, especially to the latter, being the presence of the stricture and fistula in the urethra.

Under these circumstances lithotomy was proposed, but to this the man reso-

lutely refused to submit; the nature of the only alternative was then explained to him, and he consented readily to undergo the trial. In the course of about a month or five weeks the stricture and urethra were so far dilated as to admit one of the largest sized elastic bougies, but the fistula did not close. His urine and other symptoms remained the same, and his health appeared slightly to mend.

At this time, Mr. Weiss not having brought the lithotrite to the admirable perfection to which it is now arrived, and being desirous of having the advantage of the latest improvements, I did not immediately proceed to attempt the operation, attention being paid to the improvement of the general health, &c. For the last fortnight before the operation, nothing was done in the way of dilatation, the passage being already quite large enough for the instrument I was to use; and I hoped that by leaving the parts at rest the fistula might have closed, but this, unfortunately, did not happen: the leaving of an elastic catheter in the urethra excited more irritation than could be borne.

On the 13th of November, things being in a favourable state, I attempted the operation with Weiss's screw lithotrite and the usual instruments, but failed in being able either to inject a sufficient quantity of fluid into the bladder, or to make it retain the little that was injected, principally from the very powerful contractile efforts of the bladder, by which the fluid was forcibly ejected, both through the fistula and along the urethra by the side of the catheter, the size of which was probably hardly large enough for the purpose. Another probable obstacle also to the retention of fluid in the bladder appeared on post-mortem examination.

Under these circumstances, although the lithotrite passed readily into the bladder, it would have been of course useless, and even dangerous, to make any attempt to seize the stone. I determined, therefore, to await the closure of the fistula before making another trial.

The man, who endured much pain from the injection of the bladder, appeared to suffer nothing more than he had usually done a few hours after the operation.

For fourteen days his symptoms remained as before. At this time considerably more purulent discharge came away, mixed with his urine, but without anyropy mucus; and the stone frequently afforded great obstruction to the flow of urine, and he consequently required occasionally the aid of a catheter, with which, however, never more than four or five ounces were drawn off; and he had the sensation always remaining as if the bladder were full

to bursting, although manifestly quite emptied.

On the afternoon of the 1st December he was suddenly seized with a severe rigor, from which he imperfectly rallied in the evening, complaining of severe pain beneath the edge of the ribs on the right side, which was increased by pressure and motion; this was temporarily relieved by leeches, fomentations, calomel and opium, &c.; but the rigors recurred in the night, he became collapsed, and died early the following morning.

On examination *post mortem*, there were found in the right side of the chest signs of recent acute pleurisy over a small extent of surface, as deposition of fibrine on the surfaces of the membrane, and effusion of sero-purulent fluid into the cavity.

The urinary organs, *in situ*, were next examined. The right kidney was a little larger than natural, and resembled a bladder full of pus, which had escaped also into the surrounding cellular tissue, especially on the inner side. The right ureter, to within an inch of the bladder, was enormously dilated and distended by fluid. The left kidney was also larger than natural, of a pale colour, and flabby. The ureter on this side was also considerably enlarged; becoming contracted, however, before entering the coats of the bladder. This viscus, containing a little fluid, was large, and through its thickened parietes a calculus could be felt: laid open, its neck appeared wide, but perfectly healthy; there was superficial ulceration on the anterior and posterior walls about the middle, where it had been contracted on a smooth calculus, of a circular flattened form, one inch and a half long, one inch wide, and hardly half an inch thick, composed of concentric layers of lithic acid.

The openings of the ureters were plainly visible, like two small round ulcers. Opening the right ureter, its upper half was found divided into four or five sacculi, by circular contractions or strictures of the mucous coat. Some of these contractions were perfect rings, others included only a portion of the circumference of the tube. The situation of these bands could not be perceived on the external surface, and they were formed by a thickening of, or deposition into, the submucous cellular tissue. At the point where this ureter became contracted before entering the bladder, a small calculus was lodged, of a conical form, exactly fitted to the calibre of the canal, and acting evidently as a valve. The right kidney was dilated to a mere bag, subdivided into nine or ten cells, hardly a vestige of the glandular structure remaining. This bag and the ureter were distended with thin purulent urine, which

had become diffused to a circumscribed extent in the surrounding cellular tissue, through a small irregular opening in the capsule of the kidney, situated in that part which rests on the diaphragm; and in several other points the bag appeared on the point of giving way. The emulgent vein and artery were of the natural size.

The left kidney when cut open appeared of a paler colour than usual, and the glandular part thinner, the pelvis being dilated and lined by a very vascular mucous coat. The dilated and thickened ureter on this side did not present any of the circular contractions.

Before laying open the bladder and ureters, water or air injected into the former were found to pass readily into the latter, the valvular structure of their vesical openings appearing to be completely destroyed.

ON THE CHANGES PRODUCED IN THE COMPOSITION OF THE BLOOD BY REPEATED BLEEDINGS.

By THOMAS ANDREWS, Esq.

THE object of the following experiments is to determine with precision the changes which are produced in the composition of the blood by repeated abstractions of large quantities of it from the general circulation. In the human subject, opportunities seldom occur of procuring proper specimens for examination, although the operation of venesection is so frequently performed; as in those cases where it requires to be repeated at short intervals the blood is generally in a morbid state. Instead of waiting for such casual occasions, I directed my attention to those animals in which the composition of the blood is nearly the same as in man, conceiving that similar results would in either case be produced. I selected the blood of calves for the purpose of experiment; and as it is the practice of butchers in this country to bleed these animals several times before they are slaughtered, I availed myself of this circumstance to procure suitable portions of blood. The animal is bled from a large orifice in the jugular vein, till symptoms of syncope appear, and the operation is in general repeated at intervals of twenty-four hours. It is once fed between each operation upon a mixture of meal and

water, but this is often omitted before the last bleeding.

The appearance of the blood becomes greatly altered by the successive abstractions; the crassamentum is at first very large, and a portion of the red globules are unattached to it, but it progressively diminishes in bulk, while its consistency increases, till upon the fourth bleeding it appears a small contracted ball immersed in a large quantity of serum, adhering to the stopper of the vessel in which it is contained, and presenting on its external surface an exact cast of the interior of the vessel.

The following analyses were per-

formed by the same method that I formerly employed in a set of experiments on the blood of cholera patients, which were published in the Philosophical Magazine for September 1832. They are nearly all a mean of two separate analyses, which seldom differed from each other more than 0·5 per cent.

A calf was bled four times; between the first and second bleedings a week elapsed, but the rest took place at intervals of twenty-four hours, and the animal was fed between each operation. The composition of the serum and blood at each bleeding is exhibited in the following tables:

SERUM.

	FIRST.	SECOND.	THIRD.	FOURTH.
Water	92·19	93·96	93·81	94·18
Albumen and Salts.....	7·82	6·04	6·19	5·82
	100·00	100·00	100·00	100·00

BLOOD.

	FIRST.	SECOND.	THIRD.	FOURTH.
Water	81·36	85·49	87·41	89·25
Albumen and Salts.....	6·89	5·50	5·77	5·52
Red Globules and Fibrin	11·75	9·01	6·82	5·23
	100·00	100·00	100·00	100·00

The serum had at the third bleeding a specific gravity of 1·020, and at the fourth, of 1·017. At the third bleeding, the specific gravity of the blood itself was 1·031.

The next calf whose blood was examined was nine weeks old. I did not

procure any blood from the first bleeding. The third bleeding was twenty-four hours after the second, and during that period the animal was once fed; twelve hours afterwards it was bled a fourth time, but it received no more food:

SERUM.

	SECOND.	THIRD.	FOURTH.
Water	93·32	94·39	94·59
Albumen and Salts	6·68	5·61	5·41
	100·00	100·00	100·00

BLOOD.

	SECOND.	THIRD.	FOURTH.
Water	82.05	89.14	88.92
Albumen and Salts	5.85	5.29	5.06
Red Globules and Fibrin	12.10	5.57	6.04
	100.00	100.00	100.00

The albumen and salts, it is evident, decrease at each bleeding; the diminution is, however, very variable, and even after the fourth time does not amount to one per cent. and a half. In the globules, the same diminution takes place, but to such a degree that they are at least reduced to less than one-half their original quantity. To this principle a remarkable exception occurs in the composition of the blood taken at the last bleeding of the second calf, where the globules are slightly increased above the preceding analysis; but it will be

observed that the animal received no food during the intervening period, from which the blood might obtain a fresh supply of serum, while the tendency of the different excretions of the animal was to drain from the circulating mass its aqueous part, and thus to increase the apparent quantity of the globules. This explanation is confirmed by the following analysis.

A calf, three weeks old, was bled twice before it was killed; twelve hours elapsed between the two bleedings, during which time it obtained no food:—

SERUM.

	FIRST.	SECOND.
Water	92.48	93.35
Albumen and Salts	7.52	6.65
	100.00	100.00

BLOOD.

	FIRST.	SECOND.
Water	82.48	83.47
Albumen and Salts.....	6.70	5.95
Globules	10.82	10.58
	100.00	100.00

The globules have here, it is true, diminished at the second bleeding, but so slightly, that we may attribute this circumstance to the unassimilated chyle which must have been present in the system. In the former case, the animal had been exhausted by previous depletions, and hence possessed no store from which the blood could derive even a small portion of serum, as in the latter instance*.

PREMATURE DEVELOPMENT OF THE BRAIN.

To the Editor of the Medical Gazette.

SIR,
IN August last, Mrs. Wilson, of Ernest-Street, Cumberland Market, brought to me her little boy, just two years old, with an account, that since he was six months old his head had been gradually increasing in size, till it

* Records of General Science.

had become so large as by its weight to prevent the child's continuing long in an upright posture. The head was obviously remarkably large for an infant, but I neglected at that time to measure it. He appeared active and lively, though thinner than children at that age usually are when in health. He had never had any fit or convulsions, but occasionally seemed uneasy, when he relieved himself by laying his head upon a chair. His pupils contracted naturally. He had never squinted, nor was he subject to drowsiness or startings during sleep. His appetite was good, and all the animal functions were properly formed. Under these circumstances, I requested my friend Mr. Mayo to see him, who, although we both considered it a case of hydrocephalus, agreed with me that it was not advisable, in the absence of symptoms, to risk deranging the digestive organs by active medicines. I did not see the child again, but a few days since I received a message from its father, stating that it had died of inflammation in the chest, and that I was at liberty to examine the head. In order to secure the full advantages of this permission, I obtained the assistance of Mr. Mayo, who is necessarily more familiar with the pathology of the brain than myself.

The head, of which I have a cast, measured, from ear to ear, over the vertex, 12 inches; from the superciliary ridges to the occipital, 13 inches; and in circumference, 21 inches. The anterior fontanelle, which was quite flat, measured across its opposite angles $2\frac{1}{4}$ inches by $1\frac{1}{2}$; the posterior fontanelle was completely closed, as was the frontal suture.

There was no absorption of bone at any part; on the contrary, it was becoming thicker, a section of the parietal bone at the centre of ossification measuring .38 of an inch. The dura mater adhered more firmly than I ever before saw it, even in infants, for it was only by great violence that the bones could be separately detached, after the skull-cap had been sawn around, and the membrane of the fontanelle dissected out. Upon raising the dura mater, a layer of false membrane, a tenth of an inch in thickness, and of the size of a crown piece, was found adherent to it at its upper and anterior part; the false

membrane adhered less firmly to the arachnoid. Under the arachnoid some gelatinous effusion had taken place to the same extent. Except at this part, there was no effusion on the surface of the brain. The convolutions were perfectly distinct, and retained their rounded shape. All the ventricles were found empty, and not dilated. The surfaces of the medullary matter exposed by different sections presented very unusual vascularity.

It appeared to us that the enlargement of the cerebellum was less in proportion than that of the cerebrum; while that of the latter was greatest above the level of the lateral ventricles. While, however, the brain as a whole, might, when removed from the body, have been taken for that of an adult, the nerves arising from its base, and the medulla oblongata, were in size those of a child. The whole of the fluid that escaped during the examination, including blood, amounted to only two ounces and a half. The brain was afterwards weighed, and found to be within half an ounce of three pounds avoirdupois.

The above description, it will be obvious, differs essentially from all those which have been recorded under the name of hypertrophy of the brain. In these the brain is said to have exhibited signs of *great compression*, arising from the rapid growth of the medullary matter, giving it a bulk too great for the bony case containing it; the convolutions are therefore *flattened*, their lines of separation rendered indistinct, and the cerebral mass is firm, and remarkably *destitute of blood*. The disease has, I believe, in these cases been confined to the cerebrum. Should it be objected that this instance occurred in a child, where the skull readily yielded, and that the difference in the appearances may thus be accounted for, we have still to explain the thickening of the bones, and the want of prominence in the fontanelle,—circumstances the reverse of which are met with where the skull yields to pressure from within. I have always understood that the symptoms of hypertrophy of the brain indicate not *mere* enlargement, but the existence of such a morbid action as would be quite inconsistent with the state of health the child enjoyed. Epilepsy is, I believe, the common effect. It has been suggested to me that there might, in the

first instance, have been an effusion of fluid; that that fluid might have been absorbed, and the brain have grown so as to fill up the cavity,—a supposition arising, I presume, from a fact I had almost forgotten to mention—viz. that there had been no increase in the size of the head since I first saw it. Now this hypothesis supposes either a high degree of elasticity in brain, or such a new growth of particular parts, as would have completely altered the relative proportions of the whole. Surely, too, some symptoms would have marked the change from diseased to healthy action in so important an organ as this.

The only way in which I can reconcile the appearances after death with the state of the child during life, is by regarding this as an instance simply of *premature development*, analogous to what occasionally takes place in other organs—the genitals, for example; and the growth having ceased of late, I see no reason to doubt that, had he remained free from disease, the rest of the body would gradually have gained ground (if I may so express it) on the head, and the disproportion have been ultimately remedied. It is true that there were no remarkable evidences of previous intellect; but knowing so little as we do of the connexion between mind and organization, I consider this but a feeble objection to the view I have taken, especially as I believe that, in the other instances I have alluded to, it is rarely if ever found that the premature growth of the organ is accompanied by a corresponding development of its functions.

I have been induced to relate this case, not merely by its rarity, nor by any wish to enter upon a physiological discussion, but in the hope that it may be received as an useful caution not hastily to subject a child to a course of mercury, or other powerful medicine, and thereby ruin its health, merely because it has a large head—a practice I have more than once seen carried to a very mischievous extent.—I am, sir,

Your obedient servant,

JOHN SWEATMAN,

Surgeon to Queen Charlotte's Lying-in Hospital.

Berners-Street, Jan. 20, 1835.

MEDICAL GAZETTE.

publicum sit, dicendi periculum non recuso.”

CICERO.

FACTS AND INFERENCES FROM THE POPULATION RETURNS.

In a late number we called attention to M. Villermé's paper, in the *Annales d'Hygiène*: we only, however, noticed that part of the learned writer's observations which related to the movement of the population, and the probable duration of life in this country. His remarks on the comparative mortality of the agricultural and manufacturing districts we reserved; and we are glad now we did so, as we have had the opportunity of reconsidering them, under correction of Mr. Rickman's emendatory statements, given in a preceding page.

There can be no doubt but that it was the intention of M. Villermé to be perfectly impartial, and that he draws his inferences in a spirit of fairness not always met with in foreign reviewers of our statistics; yet there unquestionably is in his reasoning (at least on the subject to which we now more particularly advert) a sort of bias, which can in no other way be accounted for than by supposing it to result from preconceived opinion. Exact a science as statistics would seem to be, and fixed and stubborn as the data on which it is founded, it is curious how differently its facts may be viewed by different persons, and how opposite the deductions which may be gathered by opposite parties. Even the simple circumstance of the increase of population, whether it should be considered as a sign of prosperity in a state, or the reverse, is far from being agreed upon by our Malthuses and our Godwins. Jean Jacques Rousseau maintained the po-

pular opinion, that it was the surest sign of the stability and success of a nation, that its people should go on to increase and multiply. More recent philosophers admit the truth of the position, but in a greatly qualified manner. Sir Francis D'Ivernois, of Geneva, even holds that the criterion of the civilization and happiness of a people, consists in the births and deaths being kept in a steady state of *non-increment*: a decrease in the births, indeed, under certain circumstances, not being according to him prejudicial to the healthy subsistence of a community. This looks like paradox; but it is a new view of human society, and, as such, acceptable to many speculators, who, as well as their opponents, profess to found their sentiments on exact and incontrovertible details.

The facts brought forward by M. Villermé, and from which he deduces inferences favourable to the popular notion of the superior mortality of the manufacturing districts, are interesting and cleverly selected. He quotes Mr. Rickman's remarks on the extraordinary difference of the *probable life* in the north and west districts of Yorkshire. "In the north riding of the county of York," says Mr. R. in his Preface to the Abstracts, "one half are not dead until the age of 38; whereas, in the west riding of the same county, one half are dead at 18 years of age: an incredible disparity in adjoining districts, were it not known that the population of the north riding increases slowly, that of the west riding rapidly." The west riding, besides, is densely peopled, and a manufacturing district; the north being agricultural, and of a comparatively thin population. But what is chiefly deserving of attention, and in some degree noticed by M. Villermé himself, is, that the mortality in this densely thronged west riding is owing to the great number of the deaths of *infants*—a cause, as Mr. Rickman says, "so powerful, that in Lancashire, where the

population increases even more rapidly, one half of the individuals born have not attained the age of 12 years; one half of the males being dead at 7, and one half of the females between 16 and 17 years of age. Such, indeed, on infant life," continues the same author, "is the effect of the crowded residence in the immediate vicinity of the several factories, that, in Lancashire, 36 per cent. of male infants, and 31 per cent. of female infants, die before they are two years old. A rapid increase of population infers the birth and existence of a large proportion of infants, and therefore a large proportion of short-lived persons; thereby accelerating, *pro ratâ*, the time or age at which one half of the population collectively are dead."

If the reader refers to the letter given at p. 588, he will see how Mr. Rickman expands the passage just quoted, and he will be convinced how necessary some such development of its meaning was, when he is informed that the mortality of Lancashire, mentioned in the above quotation, is adduced, by M. Villermé, as a *proof* of the sufferings of the *manufacturing* people in that county, establishing fully all that had been related to him concerning the deep distress of the said operatives*. After which, he (M. V.) proceeds to remind us that Lancashire is that part of England which abounds most with manufactories—that it contains Liverpool and Manchester—that its population is excessive for its extent, and the working portion of the inhabitants so numerous as to reduce the price of labour to a ruinous degree, in consequence of the great competition that exists among them for employment. "It is not surprising," says M. Villermé, "when we consider these facts, that while the mean life has been found to be 33 years

* La rapide mortalité observée dans le Lancashire . . . prouve la souffrance des habitants, ou d'une grande partie d'entre eux, beaucoup mieux que tout ce qu'on raconte de leur *profonde misère*.

for all England and Wales, and even 40 in the north riding of Yorkshire, in Lancashire it should be no more than 25 years. I am the more solicitous in calling attention to these facts," he continues, "on account of their importance. In the *actual state* of Great Britain, be it observed, it is in the thickest of her population—it is where her industry is most conspicuous, in the great source of her commerce, and in her most populous towns—that her new-born children have the least chance of life—her infants the least probability of becoming adults: whilst, on the other hand, it is in her most thinly-peopled districts, and where there is little or no manufacture carried on, that life has the longest prospect, and new-born babes in especial have the best chance of surviving." We can very well understand how the contemplation of these facts must be interesting and perhaps consolatory to foreigners; but such persons ought first to assure themselves that they are not indulging in day-dreams. M. Villermé would even seem to avoid bestowing a thought on what might serve to remove his misapprehension. He quotes Mr. Rickman, who distinctly attributes the great decrement of the mean life in Lancashire to the great increase of population in that county, implying, of course, that such increase is eminently destructive of infant life; but the French commentator *merely* quotes the remark, and passes on.

One great fallacy which consciously or unconsciously is adopted by all those who advocate the *humane* side, as they consider it, of the factory question, is to estimate the mortality by decennial periods, wholly forgetting to attach the importance which it deserves to the first biennial period of life in the manufacturing, or rather the densely-peopled, districts. Thus the infant mortality, or that of the great number of infants cut off before their second year, is reckoned by these advocates as belonging to all

children who die under ten: framing in this way for themselves an argument which tells strongly enough in showing the destructive influences supposed to operate in the early labour in which the children used not long since to be occupied—many of them previous to their tenth year. But the charitable purpose of such argumentation being answered, it is full time to set the matter on its right footing; and before proceeding to calculate the mortality of the ages employed in factory labour, we should at least deduct that of the infants under two years who are born in the populous manufacturing towns. Mr. Rickman, in a letter to which we have much pleasure in again referring, has proved this to a demonstration. He has very satisfactorily shown that the greater mortality in certain counties (particularly Lancashire), depends more upon the inconveniences to infant life attending a dense population, than upon any supposed deleterious influence of the *manufactures* carried on in those counties. He has also proved that adult life in the districts alluded to is more secure than elsewhere. To the medical inquirer the cause of all this cannot be obscure. On the one hand, the absence of those cares and comforts best suited for infant life—perhaps too the neglect of which those parents are guilty who already have many children—without difficulty solve the problem of premature mortality. On the other hand, the *miseries* of the adult operatives have been greatly exaggerated: they by no means all live in densely-crowded habitations, as it has been asserted; while it must not be forgotten that they enjoy a considerable immunity from exposure to cold, earn an amount of wages amply sufficient for their subsistence,—nay, are better fed and clothed, perhaps, than any similar class of adults in the agricultural communities. But our French statistical friends, having caught up the echo of a benevolent party here,—having also perused,

no doubt with a romantic interest, the able speech of Mr. Sadler; but above all, consoling their national spirit in the contemplation of the high price which England pays for her superiority in manufactures,—have suffered themselves to be led away even in their sober arithmetic to an extent not readily to have been anticipated. What M. Villermé says, finally, on the subject, runs in this fashion: “The premature destruction of that class which constitutes the manufacturing portion of the population, the short tenure of their lives, or rather those of their children (on whom the mortality chiefly falls), warrant us in considering their lot as very wretched indeed; and yet, in spite of this dreadful evidence of their distresses, there are people who hold that the operatives of England are much better off than those of France! But how can such a position be reconciled with all that has been written on the subject, and above all, with Mr. Sadler’s speech, delivered in the House of Commons on the 16th of March, 1832*, subsequent to the labours of the committee of inquiry? This speech, or rather the report of the committee, has become famous throughout Europe, and certainly presents a picture of the most disastrous misery as attendant upon the English operative and his children employed in the factories.”

We will not offer Mr. Rickman, or the reader, so bad a compliment as to analyse the letter in which the error of M. Villermé regarding the mortality of our densely peopled districts is confuted; let it suffice for us to state, that it is clearly made out in that document—1. That a third part of the infants born in Lancashire die before their second year, while a fourth part is the proportion for all England and Wales; and 2. That deducting

these infants, the mortality of those who die above the age of two years in Lancashire is only $\frac{1}{7}$ th of the population; while for England and Wales generally it is $\frac{1}{3}$ th. Both these important positions we consider as proved, by an accumulation of evidence.

In M. Villermé’s paper, however, always excepting what has been just pointed out as ill founded, there is abundance of excellent matter, from which we are desirous of making an extract or two more.

In comparing the mortality at different ages in England, Belgium, and France, M. Villermé, availing himself of the labours of M. Quetelet, together with the materials afforded by our Parliamentary Abstracts, and Duillard’s statement of the French law of mortality, constructs a valuable table of the *probable life* in these respective countries, of which the following is a specimen:—

Ages.	In England.	In Belgium.	In France.
	Years.	Years.	Years.
At Birth	26 $\frac{1}{2}$	24	20·4
1 yr.	39 $\frac{1}{2}$	41	36·9
2	44	47 $\frac{1}{2}$	42·7
3	46	48 $\frac{1}{2}$	44·5
4	46 $\frac{1}{2}$	49	45·7
5	47	49 $\frac{1}{2}$	45·5
6	47	49	45·4
7	46 $\frac{1}{2}$	49	44·8
8	46	48 $\frac{1}{2}$	44·2
9	45 $\frac{1}{2}$	47 $\frac{1}{2}$	43·5
10	45	47	42·7
15	42	41	39·1
20	39	40 $\frac{1}{2}$	35·7
25	36 $\frac{1}{2}$	37 $\frac{1}{2}$	32·5
30	34	34	29·4
35	31	31	26·2
40	27	27	23·1
45	24	23	19·9
50	20 $\frac{1}{2}$	19 $\frac{1}{2}$	16·8
55	17	16	13·9
60	14	13	11·1
65	11	10	8·7
70	8	7 $\frac{1}{2}$	6·6
75	6	5	4·8
80	4 $\frac{1}{2}$	4	3·5
85	3	3	2·8
90	1 $\frac{1}{2}$	2 $\frac{1}{2}$	3·0

* This speech is given at full length in the *Annales d’Hygiène*, as a separate article, or by way of supplement to M. Villermé’s paper.

This is a remarkable table; the coincidences, especially in the columns belonging to England and Belgium, are peculiarly striking, and must appear the more so, when we consider that the results have been gathered from such very distinct and independent sources. In the years belonging to infancy and boyhood, however, there are certain discrepancies which cannot escape notice; the probable life, for example, of infants just born, would seem to be above two years longer in England than in Belgium; but after that epoch up to manhood, the respective periods are apparently rather the reverse; that is to say, there might be an even wager laid, that persons at those ages would live one, two, or three years longer in Belgium than in England. From 30 to 40 the chances of life are as nearly as possible the same in both countries; and subsequently to the 45th year they seem to be rather in favour of our countrymen, though, perhaps, the *maximum* does not exceed one year.

M. Quetelet's column has been calculated on 387,168 deaths occurring in Belgium during five years, from 1827 to 1831 inclusive. It is very satisfactory to have such a voucher for the probable accuracy of the British column; we only regret that our registers of births are in so defective a state,—for to this circumstance alone can we attribute the discrepancy which attaches to the earlier years. Of the birth of infants who die previous to baptism in this country, no note is taken; in Belgium, on the contrary, the act of birth is registered with the same precision as it is in France.

Here we conclude, but not without once more expressing the satisfaction we have derived from the perusal of so able an analysis of our voluminous population documents. M. Villermé has given himself a new claim to the gratitude of continental statistical inquirers,

by this his most recent performance; and we have no doubt that, availing themselves of his valuable guidance, they will now be able to become better acquainted with our national resources, and more competent to explore the rich mine of information afforded them in the records of the British decennial census.

ANATOMY.

WE understand that a report has been made to the Home Office by those members of the Council of the College of Surgeons who undertook to inquire into the causes of the late scarcity in the supply of subjects for anatomical purposes. The report is said to be highly favourable to the Inspector, and to recommend that matters should remain much on the same footing as heretofore; any direct or official interference with the parish authorities being thought likely to do harm. It would appear that the chief difficulties have originated in the actual decrease of deaths during the last three months of 1834, and the mutual jealousies of each other among the teachers.

EXTRAORDINARY OPERATION.

THE following appeared in the official journal of the *Valetudinarium*, on Saturday last; the very day we published the "Advertisement Extraordinary," offering a bonus for rare and striking cases: "Mr. Liston this day removed a *warty excrescence from the lower lip* of a middle-aged man! The lip being held by the left hand, kept on a stretch by an assistant, a bistoury was passed through it," &c. &c. Wonderful, really! As this is the first *great* operation which has been "done," of course a clinical lecture on the subject may be expected in the next number of the *L. U. Journal*.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, Jan. 13, 1835.

Horne's New Preparation of Opium.

THE first meeting for the present year was held at the house of the President, where

we understand that yet another meeting may take place before adjourning to Berners-Street.

After the usual preliminary business, a paper was read by J. H. Horne, Esq. surgeon, of Gerrard Street—"On the Preparation of the *Acetum Opii Sedativum*, and its Uses as a Sedative in the Treatment of Mania, Melancholia, and Puerperal Mania."

The author commenced his paper by an account of the *acetum opii sedativum*; a preparation of opium which he has been in the habit of using for the last four years, in lieu of laudanum. It is made by distilling a mixture of powdered opium, dilute acetic acid, and spirits of wine, after macerating for seven days, and straining, as long as any alcohol passes over: the resulting liquor is the *acetum opii sedativum* of the author, and is three times the strength of laudanum*. After explaining the process just glanced at, the author argued that the dis-favour into which opium has generally fallen in lunacy, has arisen from prescribers having overlooked the stimulant effect of small doses of that drug, and given it in quantities insufficient to secure the sedative effect that liberal doses generally produce. He then detailed several cases in confirmation of the utility of the acetic laudanum above described.

His first case was that of a lady, whose sensitive and vascular systems he found in a state of great disturbance. Her tongue was coated, her skin parched, and she had other symptoms of high febrile excitement. Her mind was much affected; the predominant feelings and emotions melancholic. He commenced the treatment by a small bleeding, followed by cold lotions to the head, and a dose of his acetic laudanum, equal to 90 drops of the official tincture. The blood was slightly buffed. The sedative was repeated at intervals, gradually lengthened from four to six hours, during the first three days of treatment, and digitalis was used to depress the pulse. On the third day, at length quiet sleep was procured. The opiate was repeated thereafter nightly, for two months, and sometimes in the day-time, when indicated by returning irritability, &c., and in doses varying from ten to twenty drops of the acetic solution; and the patient recovered perfectly.

His second agrees in all important points of symptoms, treatment, and result, with the one just described.

The third case was that of a female of 50, afflicted with mania melancholia, as

the author seemed to think, from exclusive study of religious books; but more probably from domestic misfortunes, to which he alluded as sources of inconvenience to himself in his treatment. In this case, also, similar treatment to that employed in the two former was completely successful.

The author related a fourth case, of a young girl recently delivered of an illegitimate child, and who, from her parents having threatened to throw her upon the world on account of her misconduct, became the victim of puerperal mania. The author found her in a state of high febrile excitement, and in great dejection of spirits. In this case he prescribed the official tincture in preference to the acetic, as more stimulant, and therefore more proper for a subject familiar with ardent spirits. He ordered a mixture containing laudanum, in doses equivalent to 20 or 25 drops, every second hour; under which plan, with little other medicine, she was convalescent in a fortnight.

The author concluded his paper with some general observations, inculcating the propriety of small bleedings as preliminaries to the sedative medication; and the importance of early distinguishing the true nature of the excitement, as erethismal and not inflammatory, for which latter he thinks it liable to be mistaken.

Before adjourning, the President announced that at the next meeting, which will take place, we believe, on Tuesday the 27th of this month, a paper will be read by Dr. Bright, of Guy's Hospital.

REMARKABLE CASE OF SUICIDE BY THE INHALATION OF CARBONIC ACID GAS.

THE following case, by M. Gerard de Gray, was read at a late meeting of the *Paris Société de Médecine*.

A young man, 23 years of age, of a fair complexion, tall, and rather robust, having spent in the capital all the finances allowed him by his parents, returned home to recruit his purse, as he hoped, through the indulgence of a fond mother; but failing in his object, he resolved to put an end to himself. He made no secret of his design, and on the 16th of August last carried it into execution. His bed-room was about nine feet square, and little more than six in height. On every aperture in it by which the air might possibly have admittance, he pasted paper; and about five in the afternoon lighted a brasier of coals,

* See Mr. Horne's account of the mode of preparation in our last No. p. 575.

which he set on the floor close by his bed. After this, he left the apartment for a while, carefully closing it after him, and told several persons of his intention to destroy himself. At six he said to an old lady, "My brasier is now ready—I go to die." On the following morning, the family having become alarmed, the door of the chamber was forced open, in presence of the *Maire*. An insupportable vapour issued from the place, and the body of the unfortunate youth was found stretched across the bed.

The official examination of the body took place on the 19th, sixty-six hours probably after death. Nothing had been disturbed since the first visit: the corpse lay as it was originally found, the clothes on, and a handkerchief tied round the head. The face and hands seemed swollen, and violet-coloured; and the mouth was soiled with matter ejected from the stomach. The arms were partially flexed across the trunk. On a closer view of the face, it was observed to be dreadfully tumefied and livid; in some places black, with greenish wheals intermixed. The eye-lids were closed and greatly swollen. Alimentary matter, half digested, was issuing from the mouth and nostrils as the body was turned over a little.

The chest, on being stripped, was found bluish, and the lower garments were observed to be stained with urinary and faecal discharges. The whole body seemed at this time to be one-fourth, perhaps one-third, larger than its proper dimensions. The limbs were not stiff.

On the floor the brasier still occupied its place already mentioned; it was of considerable capacity, and seemed to have been lighted with paper. Near the body were placed two volumes of an old *Encyclopædia*; one of them, at the foot of the bed, open at the article *Estasy*—the other, near the right hand, displayed the article *Death*. On the latter volume were a pencil and a bit of paper, with the words *Je meurs avec calme et bonheur* clearly written, with the date annexed; but beneath that there appeared, in characters very difficult to be read, the following words: *Au moment de l'agonie j'aurais voulu m'être procuré une sensation agréable*. It would seem that the deceased, immediately on writing this scrawl, had fallen into the position in which he was found. The attitude did not betoken any struggle at the last moment; yet it seems probable, from the signs of sickness of the stomach, and the mention of agony in the last phrase, that life did not become extinct without some painful sensations.

Abdomen.—The division of the integuments was attended with the extrication

of abundant putrid gas. The parenchymatous viscera contained in the cavity were gorged with blood; but they were otherwise sound. The intestines filled with gas; no faecal matter. The mucous membrane in its whole length of a deep rose colour, uniform, except at the small curvature of the stomach, where it was more intense. The mass of alimentary matter in the stomach seemed to consist of cabbage, potatoes, and milk, in a half digested condition. There was no reason to suspect the presence of any poisonous substance among the contents.

Thorax.—The lungs, on being cut into, yielded a great quantity of black blood; the right lung adhering to the pleura-costalis by numerous bands of firm lymph, showing the existence of pleurisy at a former period; the left lung also in some degree adherent, but chiefly posteriorly. The heart collapsed and contracted: its four cavities completely empty. In the pulmonary artery and veins there was a little blood, of a thickish consistence; a larger quantity was found in the hepatic artery and veins. But with regard to the vacuity of the heart, the author thinks it must have resulted from the development of gas, expelling the blood before it.

The head was not examined, the circumstances of the case leaving no doubt of the perpetration of deliberate suicide.

Some deep incisions being made in different parts of the surface of the body, it appeared that the violet-coloured infiltration of the skin and cellular tissue was of the same character every where, whether in the dependent parts or elsewhere. The effect of the pressure of the clothes in different places was to leave pale indentations. There were phlyctenæ or vesicles filled with a dark red serosity in several situations, especially at the base of the chest, where this formation was favoured by the compression of the waistband of the trowsers, which was very tight.

Had this *post-mortem* been made at an early period, it might have served as a model of the effects produced by asphyxia from charcoal fumes—the cause of death being beyond all doubt and question. But after sixty-six hours, putrefaction had already given rise to marked changes; not, however, to such an extent as to conceal organic lesions, had any such existed.

A note, it should be added, was found in the pocket of the deceased, stating the reasons which led to this deliberate act of self-murder.—*Gazette des Hôpitaux*.

ST. GEORGE'S HOSPITAL.

Case of violent Hysteria (?) in a Man, successfully treated.

HENRY INGRAM, æt. 22, labourer, admitted March 19th, under the care of Dr. Macleod. Is seized every two or three minutes with shaking, which at first resembles the rigors of a fever, but increases gradually, till the whole body becomes violently convulsed. The paroxysm begins sometimes by gentle motion in the lower extremities, which are soon thrown into strong convulsive action; the hands are then clasped together, or the arms crossed, and thrust rapidly and violently up and down. The head is moved forcibly—sometimes from side to side, at others up and down, as in the action of nodding, but with inconceivable rapidity; and not unfrequently is made to perform rapid rotatory motion on the shoulders. The muscles about the throat are at the same time thrown into strong spasmodic action, inarticulate sounds are uttered, and the face becomes first red, and then nearly purple.

At other times the first indication of an approaching fit is a gurgling in the throat, accompanied by what seem to be repeated attempts to swallow, and by spasmodic action of the anterior muscles of the neck. In a few seconds the paroxysm becomes general and perfect. The whole anterior part of the neck is considerably and permanently enlarged, giving the idea of a diffuse bronchocele, and during a paroxysm it undergoes a still further augmentation of size.

The patient retains entire consciousness during the severest paroxysm, and as soon as he can articulate, answers questions in a precise and intelligent manner. His general aspect, however, indicates some degree of imbecility.

The attempt to make any muscular exertion, or the application of the finger to the throat, occasions him to gasp, and even excites a paroxysm, if persisted in.

He states that about fifteen months ago he was seized, after exposure to cold, with pain in the chest, attended with cough, tremor of the limbs, and an uncontrollable shaking of the head. After the lapse of about a month, all these symptoms subsided, excepting an occasional paroxysm of shaking of the head. Three weeks ago, after a similar exposure, all his former maladies suddenly returned, the fits of shaking becoming immediately more frequent and violent, and his condition getting daily worse up to the present time.

He states, likewise, that at the onset of the complaint he experienced great giddiness, accompanied by a disposition to step

backwards, to counteract a supposed tendency to fall in that direction.

On making him attempt to walk, the muscles of both lower extremities are seen to be affected with a sort of tonic spasm, being drawn into hard knots, so that he is unable to advance the shortest distance without assistance.

His bowels are habitually costive.

Twelve ounces of blood were taken from the back of the neck by cupping, a blister was applied, and the bowels acted upon by purgative medicine. The fits continuing without interruption, at intervals scarcely ever extending to an hour, he was ordered, the next afternoon,

Acet. Morphiae, gr. j.; Oxymel, ʒj.;
Mist. Camph. ʒviij. Fiat haustus statim et hora somni sumendus.

The object of which was stated to be chiefly with a view of ascertaining whether the disease was in any degree simulated; as it was supposed that, if sent to sleep by the morphia, he would not wake at the proper time to have his fits.

22d.—Soon after taking the second dose of morphia he fell asleep, and remained tranquil for about an hour, continuing to sleep for periods of that length during the whole night, but being awake by fits in the intervals. This morning the paroxysms are as severe and frequent as ever; usually beginning by the patient forcibly springing off the bed, and projecting himself to the head of it. He was ordered a grain of acetate of morphia this afternoon, and to be repeated twice at periods of four hours, unless previously asleep.

22d.—Took three grains of the acetate of morphia in all, yesterday afternoon and evening. More tranquil last night; slept for two or three successive hours, when he was observed to become slightly convulsed, and awoke in a paroxysm. This occurred several times. It was observed this morning that longer intervals are interposed between the attacks. There is now, during the paroxysm, more of gasping and exertion about the throat, with much moaning. Complaints of pain, which he compares to cramp, just below the short ribs on either side, and there is, in the paroxysms of to-day, much more of rotatory motion of the whole body.

24th.—A friend having visited him yesterday, his presence greatly excited the patient; the fits became more severe, and sleep was almost entirely prevented during the night by their constant recurrence, notwithstanding the morphia. He willingly attempts any muscular effort which he is desired to make during a paroxysm, with the double effect, first, of arresting the convulsions for a moment,

and, secondly, of aggravating their violence, when, at length, they overcome the resistance of the will.

He was taken out of bed, placed in an empty bath, and a couple of pailsful of cold water were poured over his head and body. This immediately produced a violent paroxysm, which, however, soon subsided; and he was decidedly more tranquil during the afternoon, though with a good deal of tremor.

25th.—The douche was repeated several times. In the intervals he had several fits, but the repetition of the bath was followed by the decided effect of subduing the convulsions, and he remained afterwards for some hours free from an attack, but still with violent trembling. Towards evening the paroxysms again became urgent, and he passed a very restless night. The morphia was omitted; the cold dash and the purgatives continued, and he had

R Argent. Nitrat. gr. ss. ter die.

30th.—The violence and frequency of the fits have been materially diminished since the last report. Complains much of flatulency, and of something rising to his throat, impeding respiration, which is like to choke him. Bowels confined. He now had

Compound Galbanum Pill, gr. iv.; Nitrate of Silver, gr. iv. every six hours; Senna and Salts each morning, and the cold dash daily.

April 7th.—The nitrate of silver has been progressively increased to gr. ij. every six hours. The fits are diminishing in violence and frequency.

10th.—But one fit to-day.

15th.—The last three attacks have come on on alternate days.

R Liq. Arsenical. ℥x.; Sp. Lavend. ʒss.; Aquæ, ʒviij. ss. M. t. d. s. Haust. Sennæ, p. r. n.

19th.—A fit yesterday; none on the two preceding days. Complains of pain in the upper part of the chest, at the left side, attended with cough and a free expectoration of muens, tinged with blood. Pulse 72, soft.

Omit. Liq. Arsenical. Appl. Hirud. xij. parti lateris dolenti. Habeat misturam Cetacci pro tussi.

29th.—Has had a slight fit daily since last report. The pain in the chest, and cough, relieved; expectoration still streaked with blood; can now walk pretty well with the assistance of a stick.

Yesterday he felt as if something had burst in his throat, after which he brought up a quantity of what he calls blood and matter, but threw it away. He now suffered chiefly from weakness and a cough, and a

little bloody expectoration; for which appropriate remedies were prescribed.

He left the hospital on the 16th of May, to all appearance perfectly cured.

On the 12th of last November he again applied for relief, his complaint having returned, though not to the same extent as before; yet so violent were the convulsions, that it required two men to hold him, in order to prevent him from injuring himself; and the paroxysms excited the astonishment of those who had not seen him on the former occasion.

He stated, that after having been dismissed from the hospital in May, he returned to his usual occupation of farmer's labourer, and continued perfectly well until about six weeks ago, when he became again attacked with his old symptoms. The only cause that he could assign for the return of his complaint was having eaten to excess two or three days previously; and it was ascertained from his friends that he was in the habit of indulging his appetite very freely whenever he had it in his power to do so; that he was affected, in short, with something like bulimia.

His bowels having been previously opened by medicine, he was ordered to be eipped on the neck to ʒxiv. and to have the cold douche as before.

R Pil. Aloes Comp. gr. x. omni nocte.

Under this treatment he rapidly lost his complaint; and on the 10th December left the hospital, once more cured.

REMARKS.—The anomalous symptoms which characterized the case, considered collectively, render it difficult to decide under what particular appellation it should be described. I think, however, I do not greatly err in regarding it as a specimen of that rare affection, hysteria in a man. There are three circumstances connected with the case, the consideration of which assists materially in leading to a clear comprehension of it. The first is the giddiness and disposition to step backwards, to prevent a supposed tendency to fall in that direction, experienced at the on-set of the complaint; the second is the degree of imbecility in the look and manner of the patient, noticed on his first admission into the hospital, but more particularly marked on his second admission; and the third is the enormous appetite with which he was afflicted, and the habitual constipation of his bowels.

The disposition to retrograde motion is a morbid perception, that leads directly to the supposition of a diseased condition of the brain. The convulsions, of themselves, are characteristic of no particular affection; but the hideous distortion of the face

during the attack, the occasional violent protrusion of the tongue, and the discharge of frothy saliva, would seem to shew the existence of something more than hysteria; while the particular expression of countenance, and the imbecility of mind,—both of which increased with the duration of the disorder,—are physical and mental impressions that attacks of epilepsy are perfectly well known to produce. On the other hand, the circumstance of the patient remaining conscious during the paroxysms, seems incompatible with our ideas of that disease.

The occurrence of hysteria in men, of which there are recorded numerous unequivocal examples, has completely exploded the old notion of the uterus being the only organ the disordered condition of which is adequate to the production of the complaint. Among other causes of hysteria, gastro-intestinal irritation has of recent years been adduced as one. The large quantity of food which Ingram was in the habit of pouring into his stomach, and the habitual delay in the intestines of their contents, would soon induce irritation in the alimentary canal; this would not, in ninety-nine cases out of a hundred, have consisted in hysterical paroxysm, but the individual in question happened to possess some peculiar nervous susceptibility and constitutional disposition*, which required only the exciting cause to develop that disease. The closer affinity of the case to hysteria than epilepsy is farther indicated by the following circumstances:—The sensation of a globus in the throat, the retention of his mental faculties during a paroxysm, the partial command over himself which he could exercise over a fit, and the absence of drowsiness after the fit was over.

The treatment (after unloading the vessels of the head), was adopted with the view of guarding against imposition, the character of the convulsions being so unusual as to excite general curiosity in the hospital. Some who saw them only once, and were unable to explain their nature, got over the difficulty by asserting that they were feigned; but those who saw most of the case came to a different conclusion. The fits, as has been already remarked, came on at least every half hour when he was first admitted, and this continued equally night and day. Persons were employed to watch him constantly; and it was observed that if he dropt to sleep, he was always awake by a fit in less than half an hour. He was then brought under the influence of morphia in

very large doses; but still, though he slept for longer periods, he either was awake by the supervention of fits, or had slighter ones as he slept.

The remedy from which he unquestionably derived most benefit was the cold dash, which was very effectually applied, and which the poor man, after the first time, was very anxious to have repeated, from the relief it afforded. On the occasion of his first admission, indeed, it was combined with other powerful agents; but the second time nothing was done for him except keeping his bowels open, and the daily use of the cold dash. In detailing a case of this nature, no adequate idea can easily be given of the violence of the convulsions, which constituted the great peculiarities of the case. I may mention, however, that no ordinary instance of epilepsy made even an approach to it.

A PUPIL.

RESEARCHES ON THE BLOOD.

By L. GMELIN & F. TIEDEMANN.

OBSERVERS have differed with regard to the presence of carbonic acid in the blood.

Vogel found that under the receiver of an air-pump, lime water was acted on by the disengaged carbonic acid.

Scudamore obtained in the same way, by means of barytes water, a precipitate of carbonate of barytes, equivalent to $\frac{1}{3}$ or $\frac{1}{2}$ cubic inch of carbonic acid gas, from six ounces of blood.

Brande procured from one ounce of arterial or venous blood 2 cubic inches of carbonic acid.

On the other hand, Darwin could detect no such acid; and Dr. Davy asserts that it is neither extracted during the spontaneous coagulation of the blood, nor by the air-pump, nor by coagulating the serum by heat, and that serum absorbs carbonic acid in greater quantity than pure water, which would not be the case if it was charged with carbonic acid.

Gmelin and Tiedemann examined with great care the blood of a dog taken from the femoral vein and artery, and placed in different tubes under the receiver of an air-pump. The result was that neither carbonic acid nor any other permanent gas was extricated. To ascertain the accuracy of Davy's statement with respect to the absorbing power of blood being greater than that of water, carbonic acid was allowed to stand over arterial blood for five days, when it was ascertained that 100 measures of blood absorb 120 of carbonic acid. The coagulum appeared

* It has since been ascertained that Ingram has a sister subject to "fits."

blackish-red, and the liquid portion was extremely clear.

Since blood contains no free carbonic acid, it was necessary to ascertain whether any existed in it in a combined state. Vinegar was added to each of the kinds of blood which had been collected, as in the former experiments, with every precaution to ensure accuracy, and was placed under a receiver. A quantity of carbonic acid escaped from both, more abundantly from the venous than the arterial. The arterial blood mixed with vinegar, as well as the venous blood, left over mercury for three weeks, was converted into a blackish brown mass, without being separated into serum and coagulum. About the same period, without a knowledge of the Heidelberg experiments, Ed. Ch. F. Stromeyer obtained the same results.

How do these facts agree with the present theories of respiration?

Lavoisier conceived that without coming in contact with the respired air, a liquid consisting principally of carbon and hydrogen is absorbed through the pulmonary membranes into the bronchi, and is converted into carbonic acid and water through the oxygen of the inspired air. As this theory does not render it necessary to suppose free carbonic acid in the blood, it is not at variance with the observations of Gmelin and Tiedemann, but the passage of gases into moist animal membrane, and also the immediate contact between air and blood, cannot be well doubted of. Davy inferred from his results that air passes through the moist coats of the pulmonary vessels, and is taken up by the serum, the oxygen partly forming with the carbon of the crur carbonic acid, and partly combining with the crur. When he found that after the inspiration of hydrogen some carbonic acid was expired, though much smaller in quantity than after the inspiration of air, he concluded that venous blood contains some free carbonic acid. According to the observations already given, it appears that the arterial and venous blood contain no free acid, but carbonic acid combined with alkali. And if we suppose acetic acid to be formed in respiration, (for we find it in the blood and in most organic liquids which are exposed to the influence of air in combination with alkalies), then must the venous blood contain more alkaline carbonate than the arterial, when by the formation of acetic acid a portion of the alkaline carbonates will be converted into acetates.

By means of a barytes solution in an exhausted receiver, they estimated that 10,000 parts of arterial blood contain 8.3 of combined carbonic acid, and 10,000 parts of venous blood 12.3 of acid in the

same state, being in the proportion of 2 to 3.

They sum up their views of respiration in a few propositions:—

1. That in the pulmonary cells inspired air is absorbed into the moist membranous vessels, and is thus brought in contact with the blood.

2. The azote of the air is not sensibly absorbed by blood, but almost the whole of it remains in the cells. On the contrary, as oxygen is taken up by the blood abundantly, it flows out of the cells into the vessels in proportion to its absorption, and the mixture of gas remaining in the lungs must therefore contain more azote and less oxygen than the air.

3. The oxygen taken up by the blood combines partly with carbon and hydrogen, and forms carbonic acid and water, and partly unites with the solid organic compounds contained in the blood. From these proceed acetic or lactic acid, which combines with a portion of carbonate of soda contained in the blood, and drives its carbonic acid into the cells.

4. The acetate of soda loses, in its course through the different secreting organs, its acetic acid, combines again with carbonic acid, after undergoing many decompositions in its passage with the mass of blood through the body, and enters into the lungs on its return as carbonate of soda.

Is urea contained in the blood after the extirpation of the kidneys?

The authors directed their attention to this point, which it is well known has been decided in the affirmative by Prevost and Dumas, (*Ann. de Chim.* xxiii.)

On the 14th January, 1832, the right kidney of a dog was removed, and in fourteen days the wound healed.

The left kidney was cut out on the 11th February, and on the 13th the animal died. The substances taken from its body which were subjected to examination, were—1. The liquid vomited; 2. The blood collected from the great vessels, amounting to 2 ounces; 3. The bile; 4. The contents of the small intestines. All these substances were dried separately on the water-bath, and digested with hot water. The filtered liquid was precipitated by acetate of lead, and the lead removed by carbonate of ammonia. The fluid was evaporated to dryness, and treated with absolute spirits. The residue, after evaporation, was dissolved in a little water, and evaporated with nitric acid in a glass tube. The solution from the blood produced, with a drop of nitric acid, a yellowish, white crystallized precipitate, which was collected on a filter, washed with cold water, and dried. A portion of it heated in a pla-

tinum spoon left a trace of carbon; another part, heated with potash, disengaged no ammonia. A third portion was heated with water and carbonate of barytes. The mixture was digested with absolute spirits, and filtered. This liquid, which was not precipitated by sulphuric acid, gave by spontaneous evaporation, long colourless needles, weighing 2 milligrammes. They were soluble in water and spirits; were dissipated by heat, and precipitated by nitric and tartaric acids; they consisted therefore of urea.

From the vomited matter urea was procured, but in such small quantity as with difficulty to be appreciated. A brownish floccy precipitate was obtained from the bile, not completely resembling urea. No precipitate could be detected in the contents of the small intestines, or from the fæces.

Thus the result of the German chemist's researches is, that urea can be formed without the aid of the kidneys. The French chemists, Vauquelin and Segalas, found no urea in the blood of a dog forty-eight hours after the extirpation of the kidneys; a circumstance which is probably to be ascribed to the short period which elapsed between the operation and the experiment.

Nourea, or sugar of milk, in healthy blood.

Ten pounds of fresh blood from the cow, evaporated to dryness in the water-bath, were digested with hot water, and again evaporated. The residue was taken up by water, and precipitated by acetate of lead. The filtered liquid was precipitated by carbonate of ammonia, and evaporated to dryness, and the residue digested with absolute spirits. The latter process was repeated, when, by evaporation, a combination of soda, with a fatty acid, remained.

In the solution of the residue, nitric and oxalic acid occasioned no precipitate of urea, but they separated the fat acid (acid of oil?). It should be observed, that by this process they had previously ascertained $\frac{3}{500}$ of urea, and $\frac{1}{100}$ sugar of milk, to be appreciable. It appears, therefore, that cow's blood contains neither urea nor sugar of milk, or at least in extremely minute quantity.—*Poggendorff's Annalen, and Records of General Science.*

NOTE ON KREOSOTE.

By A. BUCHNER, OF MUNICH.

ACCORDING to M. Reichenbach, of Blansko, kreosote ought to be prepared from the tarry matter of the beech tree, by dissolving it three times in caustic potass, and

setting it free each time by sulphuric acid. M. Buchner has procured it of the same purity from the tar of the pine, and has found that it is not necessary to repeat the operation so often, if the following precautions be adopted:—

1. At the first distillation of the tar, which is carried on in an alembic, the distilled liquor must be carefully removed several times, and the recipients changed. At first eupione comes over, which swims on the water; but as soon as a little of the oil sinks to the bottom, it is formed in a great part of kreosote, and the distillation is to be continued until the residue is of the consistence of black pitch.

2. The oil, which is heavier than water, is to be agitated with a little concentrated sulphuric acid, to separate the ammonia, and favour decolouration.

3. It is then to be mixed with its volume of water, and distilled in small retorts.

4. The distilled liquid which is formed at the bottom of the water, consisting in a great measure of kreosote, is to be dissolved in hot caustic potass of the specific gravity of 1.120, after which it is to be left for some time to settle at a slow heat. If there be any eupione, it will float on the surface of the liquor, and must be carefully removed.

5. After the cooling of the alkaline solution, a slight excess of sulphuric acid is to be added, which will set free the kreosote.

6. The kreosote separated from the sulphate of potass is to be distilled anew, in small retorts, taking care, as in the first distillation, to reject several times what comes over. The distillation advances slowly at first, and is attended with violent agitation, in consequence of the presence of water. Thus, the first portion which comes over consists only of water and a small quantity of eupione, which must be rejected. The residuum is a brown mass.

7. If the kreosote thus obtained be distilled two or three times without any addition, it will be found sufficiently pure for medicinal purposes.

Kreosote ought to be colourless, and possessed of great refrangibility of blue and yellow, of the specific gravity 1.037 at 20 C. (68° F.); and its alcoholic solution, when mixed with water of barytes, does not become brown in the air. It boils at 203 C. (397.4 F.), and distils without any alteration. It possesses a very peculiar odour, which is something like a mixture of the odour of smoked meat and castor. In its general properties it resembles essential oils.—*Edinburgh Med. and Surg. Journal.*

TREATMENT OF CANCEROUS AFFECTIONS.

PASTE OF CHLORURET OF ZINC.

M. CANCOIN has submitted to the Académie de Médecine a phagedenic paste of his invention. The dangerous accidents arising from the use of the arsenical paste, induced M. Cancoin to seek for some better kind of escharotic. Chloruret of antimony seemed difficult to manage, there being no limits ascertained relative to its action: on large surfaces it produces severe pains, vomiting, and purging. In the year 1824 it occurred to him to try the anhydrous chloruret of zinc,—a substance not without its inconveniences; for it attracts moisture from the atmosphere, and neither is it limited in its action. M. Cancoin, however, has composed a paste which possesses all the properties of the chemical substance, keeps perfectly, is elastic, and not deliquescent. It requires to be made up in exact proportions, otherwise it is dangerous. Its action may be varied at will, from half a line to two lines. Like caoutchouc in its consistency, it is, in its ordinary form, only applicable to plane surfaces; for concave or convex surfaces it must be thickened or thinned in the centre. There are three kinds, varying in strength, and made up in the following proportions. 1. The most active: chloruret of zinc, 1 part; farina, 2 parts. 2. Less active: chloruret, 1 part; farina, 3 parts. 3. The least active: chloruret, 1 part; farina, 4 parts. Very little water is added in the composition. By the addition of one-third chloruret of antimony to two-thirds of the chloruret of zinc, together with the proper proportion of farina, a soft wax is formed, well adapted for uneven surfaces.

This paste has now, it is said, been employed successfully for ten years, in all sorts of cancerous cases where the constitution has not become radically tainted. MM. Sanson and Amussat are appointed by the Academy to report on its true value. —*Gaz. des Hôp.*

In a more recent sitting of the Académie, M. Velpeau has exposed certain quackeries connected with this arsenical paste. The inventor lays great stress on the employment of the chloruret of zinc—a very dear article; while M. Velpeau has produced an identical paste with the very cheap hydrochloruret. The addition of the chloruret of antimony is said to be perfectly superfluous; and it seems that the paste, at the best, has no action even on the skin, if the epidermis be sound and uninjured.—*Ibid.*

A PORTUGUESE BULLETIN.

THE young Queen of Portugal has lately been indisposed, when the following curious bulletin was issued, containing one word for her majesty and two for the doctor:—"Her majesty's health continues to improve gradually. I have only to assert, that my lips never utter any thing but the truth—the clear plain truth.

ON THE

DISEASES OF THE CHEST,

In the course of which the Practice of

PERCUSSION AND AUSCULTATION

IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE XVIII.

ON DISEASES OF THE LUNGS.

SECTION III.—DISEASES OF THE PLEURA.

THE pleura, you are aware, gentlemen, is a fine serous membrane investing the lungs, and reflected over the diaphragm and the inner surfaces of the ribs. It secretes a fluid, for the purpose of lubricating the parts, and allowing their free play upon each other. Almost all the diseases of this membrane have for their results an alteration in the quantity and quality of this fluid. We shall consider the diseases of the pleura in the following order:—

Pleuritis.

Hydrothorax.

Pneumothorax.

Pneumothorax, with effusion of fluid.

Adventitious deposits.

PLEURITIS.

By *Pleuritis* or *Pleurisy*, we mean an inflammation of the pleura. Laennec has given several minute divisions of this disease, which I think unnecessary, as they all may be included in the three following forms, which I shall successively describe:

- Pleurisy, { 1st. Acute.
2d. Chronic or latent.
3d. Gangrenous.

1st. *Acute Pleurisy.*

We shall proceed in our usual order, by first describing the morbid anatomy of the parts affected.

Morbid Anatomy.—The inflamed pleura presents in the first instance a red colour: after a short time, probably only a few hours, an effusion takes place from its surface, varying exceedingly in its quantity: to this effusion succeeds a deposition of coagulable lymph, which forms pseudo-membranes covering the inflamed parts: these false membranes finally unite, become organized, and converted into cellular membrane, or fibro-cartilage. We shall consider these conditions, as indicating different stages of the disease, in precisely the order described: viz.

1st. Redness.

2d. Effusion of fluid.

3d. Formation of false membrane.

4th. Conversion of false membrane into Cellular membrane.
Fibro-cartilage.

First Stage.—Redness.—In the first stage of pleurisy, the inflamed membrane is of a red colour, sometimes appearing uniform and diffused in its tint, at others in spots of various sizes. This last appearance is probably a post-mortem result, for there is every reason to suppose that the redness is uniform in the living subject, and that the absence of colour between these spots or stains arises from the partial transudation of the blood through the vessels after death. Thus we see that in persons dying of erysipelas on the surface of the skin, the blood transudes the vessels of the inflamed parts, and the skin returns almost to its natural colour, leaving a few spots only here and there. Guersent injected stimulant liquids into the serous membranes of living animals, and found that the redness produced by their inflam-

mation was uniform, and not maculated. The red colour penetrates through the membrane.

Besides this diffused colouration, vessels are seen ramifying in an arborescent form, in the same manner as upon the conjunctiva, when that membrane is inflamed. The extent of the redness varies considerably; it may occur only in a small point, it may occupy the whole of the pleura on one side of the chest, but it very seldom affects both sides at the same time.

Some authors have thought that the pleura becomes thickened during this stage, but a careful examination will shew that it is not.

Second Stage.—Effusion.—It is very probable that at the commencement of the red stage, the pleura presents a dry surface, or nearly so, because we have then no signs of effusion; the secretion commences in a few hours.

The effusion consists of a citrine, straw, or yellow-coloured fluid; it is sometimes slightly reddened, from the admixture of a little blood, small clots of which may be occasionally seen floating in the liquid. When this accidental coloration takes place, Lacunæ has called the disease *Hæmorrhagic Pleurisy*. The fluid is at first limpid, and inodorous, and varies in quantity from an ounce or two to seven or eight pints.

It may readily be conceived that this effusion of fluid must produce certain mechanical effects upon the parts within which it is contained. It is of the highest importance that we should be well acquainted with these effects, as they afford the most valuable signs to direct us in the diagnosis and treatment of this stage of the disease.

The pleura bounds the cavity containing the effused secretion; that membrane invests the lungs and pericardium, covers the upper surface of the diaphragm and the inner surface of the ribs and intercostal muscles. The effect of the accumulated fluid must be to compress these parts, and increase their distance from each other. Let us examine these results.

As the fluid is secreted, although a portion of it gravitates to the lower part of the pleuritic cavity, a considerable quantity spreads over the whole surface of the lung, and compresses it, and in proportion to its accumulation, so the lung becomes diminished in size, until at last it is reduced to so small a volume that it is not larger than the hand: the pressure of the fluid upon the organ is directed from without to within, from before backwards, and from below upwards: the lung is flattened against the vertebral column, and in consequence of its compression becomes

denser and less crepitant than usual; it contains but little air, its blood-vessels are flattened and empty, and the bronchi are contracted: the pulmonary tissue is, however, perfectly distinguishable, and if air be forced down the trachea, the viscus may be completely inflated, and restored to its original size.

Old adhesions modify the form and situation of the lung when compressed. If these adhesions have existed between the upper lobe and its corresponding costal pleura, the organ can only be pressed from below upwards, and it then occupies the superior part of the plenritic cavity, while the fluid is accumulated beneath it. If old adhesions have formed between the lower surface of the organ and the diaphragm, the reverse takes place; the pressure of the fluid is from above downwards; the lung occupies the lower part of the chest; and the fluid is placed above it; finally, when there are adhesions between the outer surface of the lungs and the costal pleura, the pressure is directed from within outwards, the organ is flattened against the ribs, and the fluid collects nearer to the median line of the chest.

If the previous adhesions are so situated as to isolate the effusion in a diminished space, the disease has been called *partial or circumscribed pleurisy*.

The heart becomes also displaced, if the fluid be considerable in quantity: thus, if the effusion be situated on the left side of the chest, that organ is pressed towards the right; and its beatings can no longer be felt or heard in his natural position. If the accumulation be in the right side, the heart is pressed still farther to the left.

The pressure of the fluid upon the diaphragm forces it to descend, but that effect is inconsiderable on the right side, in consequence of the support which the liver affords to this muscle. In extreme cases, the compression may be sufficient to force the edge of the liver below the margins of the cartilages of the false ribs, but I have rarely seen it. If the left side of the diaphragm be compressed, the stomach is pushed before it, and a diffused and irregular swelling becomes very distinct below the cartilages of the false ribs on that side.

We must now consider the effect of the pressure of the fluid upon the intercostal muscles and ribs. The internal surfaces of these muscles are forced outwards, and are brought to a level with the external surfaces of the ribs, so that the intercostal spaces are altogether effaced, and the whole side of the chest is rendered perfectly smooth and even; nay, some have said that these spaces have been seen projecting outwards: I have often sought for, but

have never met with, this appearance. The pressure of the fluid forces the ribs directly outwards, by which the whole of the affected side becomes enlarged; and sometimes to a considerable degree; so much so, that in measuring and comparing the two sides of the chest, I have seen a difference of two inches. This difference of size affords us a most important sign of the disease.

Third Stage.—*Formation of False Membranes.*—The effused fluid, which in the first instance was transparent and of a straw colour, now changes its characters, although the precise time at which it does so has not been discovered, and probably varies in different individuals. Small particles of white and opaque albumen, like curds of milk, are now seen floating in the secretion; these particles enlarge, unite, and form masses of various sizes up to that of an egg; sometimes they present the appearance of fresh mesenteric fat. The colour of the fluid itself also changes; it becomes milky; the floating albuminous matter breaks down into small fragments, and mixes with it, so as to give the whole the appearance of flower diffused in water; finally the comminution of the albumen becomes still more complete, and the whole effusion then presents a puriform character.

As these changes take place, the albuminous matter gradually precipitates and adheres to the surface of the pleura, forming a false membrane upon it, to an extent of surface proportionate to the extent of the inflammation. This false membrane is at first of the consistence of thick pus, or the curds of milk, then of boiled white of egg, or of the inflammatory crust of the blood; and, finally, it acquires the cohesion of the elastic coat of an artery. Its colour is whitish yellow, and according to its thickness it varies from semi-transparency to opacity. Its thickness, at the period of its primary formation, is inconsiderable, but gradually increases, so that it has been seen to measure two or three lines: its surface is occasionally smooth, although more frequently irregular. It would seem that after the membrane had been formed, fresh albuminous matter had been deposited upon it in irregular and intersecting lines, giving its reticulated appearance; these lines are often so numerous, and cross each other so often, that the points of intersection become so close and elevated as to appear like granulations, and the surface has been mistaken for an ulcer.

The relative proportions of false membrane and of fluid vary exceedingly; in some instances the effusion is considerable, and the false membranes are but thin, and slightly extended; in other cases, the membrane exists alone, and there is

scarcely any serous exudation; the last case being considered as a variety, under the name of *dry pleurisy*. It may be established as a general rule, that the greater the power of absorption, the less is the quantity of serum. Thus in individuals of firm fibre, or in children the activity of whose functions is great, there is very often but little serum, compared to the false membrane, while in the aged, and in those of lymphatic temperaments, the latter is often inconsiderable.

It may also be observed here, that, generally in proportion to the limpid and transparent state of the effused fluid, the false membranes are thin, but as the serum becomes turbid, and similar to pus, they gradually grow thicker, and of greater density and firmness.

Conversion of False Membranes into Cellular Tissue, or Fibro-Cartilage.

Cellular Tissue.—The effusion being accomplished, and the false membrane formed, nature endeavours to effect a cure by absorbing the thinner matter. In proportion to the activity of the absorption the fluid gradually diminishes, and the compressed lung expands. The degree, however, to which that organ can dilate, not only depends upon the diminution of the fluid, but also upon the thickness and density of the false membrane which has formed upon it, and by which it is bound down to its abnormal situation. If the false membrane be very thin, the lung can freely dilate until it arrives at or very near the costal pleura; in that case, bands of albuminous matter cross through the remaining fluid, nearly at right angles from the false membrane lining the costal pleura to that which covers the pulmonary pleura: these bands are at first of a yellowish white colour, and opaque, sometimes round, sometimes irregularly angular, and frimbriated at their edges; they vary in thickness, not only as compared to each other, but in the different parts of their own extent; thus they may be thickest at their costal or pulmonary extremities, or at their centres: they are in the beginning very soft, so that you may pass the finger between the two pleura, and rupture a series of them with the greatest facility. These bands gradually increase in number, encroaching constantly upon the space previously occupied by the effusion.

These bands, and the pseudo-membranes to which they are attached at their extremities, gradually become organized: an irregular streak of blood, arising apparently from the healthy pleura, which is spotted with red at the corresponding point, penetrates the band, and soon assumes a cylindrical form of a certain dia-

meter, and ultimately becomes a vessel. If the rudimental vessel be examined at this period, it is very red, soft, and formed of blood scarcely coagulated. In cutting into it, a round, white, and fibrinous mould may be extracted, formed of con-creted fibrine, whose centre is perforated to form a small canal: this fibrinous mould, in becoming thinner, appears to form the parietes of the new vessel.

The false membranes and their bands now become thinner and more transparent, their consistence is yet softer than cellular tissue, and they appear as if injected with fine injection; finally they become perfectly thin and transparent, and lose their vascularity; their firmness is increased, and they cannot be distinguished by their structure from the cellular tissue of any other part of the body. They are subject also to the same physiological and pathological laws as the cellular and serous membranes; like them they secrete and absorb, and may become the seat of inflammation.

Fibro-cartilage.—But when the false membrane is thick and firm, the lung is not only bound down by it, but the function of absorption is very imperfectly carried on through its inorganic texture. The circumstances necessary to the cure of this disease are then extremely unfavourable.

If the patient die in this state, and you examine his chest, you will find the lung reduced to a very small volume, and covered by a thick, yellow, and opaque false membrane. The cavity of the pleura is filled with a turbid fluid, often as if mixed with flour, often also of a completely puriform appearance, constituting that form of pleuritic effusion called *empyema*. Similar bands to these I have already described pass at right angles from one false membrane to another, the only difference being that they are much longer, in consequence of the greater distance now between the pleura pulmonalis and costalis.

It occasionally happens, however, that the absorption of the fluid is effected to a certain degree, and that the false membrane enveloping the compressed lung is not so thick as to prevent its expansion, although it may be sufficiently so as not to allow it to extend to the costal pleura: in that case nature makes an extraordinary and beautiful effort to effect the contact of the opposed false membranes, by forcing the whole of the diseased side of the chest inwards upon the lung, by which that side becomes contracted. Laennec was the first to discover this singular phenomenon.

Let us now suppose that the thick and apposed false membranes have by this means become in contact; what is their mode of union?

They adhere, and if a transverse section be then made, it will be seen that they form a single solid membrane composed of three layers, the two external being the original membranes now appearing white and opaque, fibrous or cartilaginous, or of a mixed character, and sometimes even partly osseous, as this preparation evidently shews, [shewing it]. A third and intermediate layer is the means of union; it is semi-transparent, and, as Laennec expresses, perfectly similar to the most transparent parts of the intervertebral cartilages.

The *fibro-cartilaginous* membrane thus formed, varies in thickness from two lines to half an inch, but it gradually diminishes as the time advances from its original formation.

Laennec supposed that this species of membrane could only be formed from hæmorrhagic pleurisy, or at least that the presence of blood was necessary in the effused fluid. This opinion is hypothetical, and unsupported by facts.

It is, gentlemen, when the fibro-cartilaginous membrane is completely formed, that the contraction of the chest becomes the greatest. You perceive in this east, that the shoulder of the affected side has become depressed; that the inferior angle of the scapula is an inch and a half lower than the opposite; that the intercostal spaces are diminished, and that the last rib approaches closely to the crista of the ileum. The sternum and dorsal vertebræ have deviated from the median line, so that the former bone is inclined over to the right or healthy side, and the spine is curved, the convexity being directed to the same side also: finally, the transverse diameter is so diminished, that the circumference of the diseased half of the chest is less by two inches than that of the healthy.

2. Chronic Pleurisy.

We now proceed to the consideration of the morbid anatomy of Chronic Pleurisy.

Pleurisy may be said to be chronic when the signs of the red stage have passed, and those of effusion have continued for some time: at least, if the fluid be not rapidly absorbed, the false membranes soon form, and then the progress of the disease is usually tedious and prolonged. It sometimes occurs that all the signs of the red stage are absent from the commencement, and the disease assumes a chronic form in its origin.

The morbid anatomy of chronic pleurisy is nearly the same as that which I have described of the acute, the only anatomical difference being that the effused fluid is never seen in the limpid or transparent state.

Laennec, however, thought that when the disease commenced in the chronic form, that there were some differences in the red coloration, and in the appearance of the effusion and false membranes. He observes that the pleura is more highly reddened, that the effused serum is more abundant and less limpid, and has the odour of garlick or gangrene; that there is a much larger quantity of small albuminous flocculi floating in it, so that they give the fluid the aspect of its mixture with coarse flour. He states also that the false membranes have not the same cohesion; that they are friable, and easily broken by pressure with the fingers, and that they sometimes appear to be formed only of very thick pus; that there is but a slight tendency to the conversion of the pseudo-membrane into cellular tissue, and that it is in this case the dilatation of the chest is greatest, and the compression of the lung most complete.

But, gentlemen, although these varieties in the appearance of the effused fluid and false membranes do exist, yet they are not necessarily depended upon, the disease having commenced in the chronic form, as Laennec supposed. I have had many opportunities of observing pleurisy in all its stages, and I can state with certainty that I have seen the appearances just described frequently consequent to the acute form of the disease also.

It sometimes happens that an abscess forms in the parietes of the chest, in consequence of the internal effusion, and it bursts externally: this constitutes the *empyema of necessity* of the ancient writers. I have seen seven instances of these ruptures, and most of them have occurred at the anterior superior part of the chest.

3. Gangrenous Pleurisy.

Morbid Anatomy.—This is a very rare disease, and is usually but slight in extent, although in the specimen I present you, it involves nearly the whole of the pulmonary pleura. This state is almost always consequent to gangrene of the lung, or to chronic pleurisy.

This affection appears in the form of round or irregular stains upon the surface of the lung, which are of a brown or black colour, and horribly foetid; the parts are soft, and easily broken down by the fingers: sometimes the gangrene scarcely extends deeper than the pleura; at others, the subserous tissue is infiltrated with a greenish or blackish serosity of a gangrenous odour.

The irritation of the gangrenous affection always causes a general inflammation of the pleura: abundant serous effusion then takes place, followed by false membranes, all presenting a dirty green or dark

colour, of the same smell I have already described. Gangrenous eschars have been known to form upon the pleura pulmonalis and costalis, which, when they fall, have occasioned a communication between the cavity containing the fluid, and the bronchial tubes, allowing a free expectoration of the secreted matter; or the intercostal spaces may be penetrated, and a copious discharge take place from the orifice—constituting another cause of *empyema of necessity*.

Such, gentlemen, is a general account of the morbid anatomy of the different stages of pleurisy. You have seen that the pleura is at first reddened; that it then throws out a serous fluid, from which an albuminous matter is formed, which becomes converted into cellular tissue, or fibro-cartilage. You have seen, also, variations in the degree of redness of the pleura, in the qualities of the serous secretion, and in the nature of the albuminous and pseudo-membranous deposits.

When the disease commences with pain in the side, and fever, symptoms denoting the red stage, it is denominated *acute pleurisy*; it may already be called *chronic pleurisy*, when the fluid has accumulated, and the albuminous matter has commenced to form; and this state may occur without the previous signs of the *acute*. Finally, a gangrenous state of the pleura occasionally, though fortunately rarely, takes place.

Laennec, in speaking of the products of inflammation of the pleura, states that the secretions are of two kinds: the one fluid, the serum; the other solid, the false membrane. I doubt exceedingly that the false membrane is a secretion; I believe it rather to be a deposit from the serum, from the following reasons:—

It must be admitted that the function of secretion (with a single exception) takes place by means of the orifices of the capillary extremities of the arteries; but these orifices are so small that they are beyond microscopic powers to discover. We infer their existence by reasoning, but cannot prove it by demonstration. Is it not almost impossible to conceive that such minute orifices can permit the passage of a solid material? Is it not more likely that they deposit fluids, charged with the specific nutritive matter which the organs in which their vessels ramify require? Do we not see that the phosphate of lime itself is not arranged in amorphous forms in the bones, but in the crystalline? And are not all our notions of crystallization associated with those of previous solution? If, then, the orifices of the capillary vessels are too small to allow the *materia* of nutrition to permeate them, except

in solution, so must they also be too small to carry an adventitious solid, to be deposited upon the surface of an inflamed serous membrane, except by the solution of that matter also.

But without adverting to arguments derived from the general theory of nutrition, we may adduce others which apply more specifically to the case in question.

It is evident that the first result of the inflammation of a serous membrane is a limpid and transparent secretion, and that the adventitious membrane is the second; the latter never precedes the former. It is a principle in philosophy, that when two or more events succeed each other, *always* in the same order, that the first must be the cause of the second, the second of the third, and so on. I believe the solid deposit is effected in the following manner:—The serous effusion is charged with albuminous matter; nature soon commences to absorb the fluid; the thinnest parts of it are the soonest taken up, leaving the thicker matter, or albumen, floating in the remaining mass: this albumen becomes attached to the surrounding inflamed parts, covers them in the form of a thin and soft layer at first, which gradually becomes thicker from successive deposits. Irregular lines of albumen, like those floating in the fluid, are also attached to the false membrane thus formed, and give it a reticular appearance. The lowest part of the pleuritic cavity is covered most thickly, because of the gravitation and entanglement of the albuminous matter, until at last the pseudo-membrane is completely deposited, from separation, and not secretion.

If this be not the mode, why is the false membrane always the thickest at the lower part of the inflamed pleura? Are we to be satisfied with the gratuitous assumption that there the inflammation is always of the greatest intensity?

Why is it, too, that we find the relative quantities of serum and false membrane always proportionate to the activity of the absorbing function? Thus in weak and lymphatic individuals, the serum is great in quantity, and there is scarcely any solid albumen formed; absorption is here inactive, the serum remains, and no separation takes place. In children, in whom all the functions relative to their organization are extremely energetic, it often happens that all the serum is absorbed, and false membranes alone remain. From these circumstances, permit me to say, at least, that if I have not proved my own, I doubt Laennec's explanation.

ON THE FUNCTIONS OF SOME PARTS OF THE BRAIN,

AND ON
THE RELATIONS BETWEEN THE BRAIN, AND
NERVES OF MOTION AND SENSATION.

By SIR CHARLES BELL, F.R.S.

[From the Philosophical Transactions.]

THE difficulties which attend the investigation of the structure and functions of the brain are shewn by the ineffective labours of two thousand years; and the first endeavour of the author is to remove the idea of presumption that attaches to the very title of this paper. Perhaps the enumeration of some of the sources of error which have retarded discovery, may be the best introduction and apology.

The first impediment to success is in the nature of the inquiry, since extraordinary and contradictory results must be expected from experimenting on an organ so fine as that must be which ministers to sensibility and motion, and which is subject to change on every impression conveyed through the senses. This remarkable susceptibility is exemplified in what we often witness; extraordinary results, such as violent convulsions and excruciating pain, from causes which appear quite inadequate. For example: the presence of a minute spicula of bone which has penetrated to the brain, will at one time be attended with no consequence at all; at another it will occasion a deep coma, or loss both of sensibility and motion. Nay, symptoms apparently as formidable will be produced by slight irritation on remote nerves. Seeing these contradictory effects, is it reasonable to expect constant and satisfactory results from experiments in which deep wounds are inflicted on the brain of animals, or portions of it torn away?

Other circumstances evince the slight varieties in the causes which produce the most extraordinary effects. Water in the brain, which has free access to all the cavities of the brain, and which to all appearance both presses equally, and if it irritate must irritate equally, will have the effect of rendering one side of the body paralytic, and of convulsing the other with incessant motion.

Another source of error, especially to the experimenter on the brain, is the disturbance of its circulation; for the brain depends more directly than any other organ on the condition of the circulation within it. We may see this in the provisions for the free and equable supply of the blood within the head, as well as for its unim-

peded exit. Now by raising the skull, a necessary preliminary to most experiments on the substance of the brain, there is an immediate disturbance of the circulation, which of itself may be attended with insensibility or convulsions.

The most frequent source of error, perhaps, is the obscurity which hangs over the whole subject; for although the brain be divided naturally into distinct masses, not one of these grand divisions has yet been distinguished by its function. There is not even an opinion as to their relative importance. Hence it has followed that the experimenter has not known what to seek, or how to plan his experiment; and hence have been derived the weakest fancies that have ever obscured any science. Another difficulty meets the inquirer at every step, if he be not critically guarded. Whole masses of the brain may be destroyed by disease, or actually removed with impunity; that is to say, without any immediate influence on the mind, or on the power of motion or of sensibility; yet the very slightest general impression on the brain will in the instant deprive the individual both of sense and motion.

It will not be denied that the most unequivocal proof of the little success which has attended the efforts made to improve this part of physiology, is the failure of all attempts to explain the phenomena which attend injury of the brain; it is neither said why, in disease of the brain, sensation and motion should be lost together, nor why one faculty should be sometimes imperfect, and the other entire. There is no satisfactory reason given for the most common occurrence in practice, the loss of motion and sensation on the side of the body opposite to that side of the brain which has received the injury; nor has the condition of the face, as associated with that of the body, been accounted for. When circumstances so remarkable present themselves daily, consequent upon action or disease affecting the brain, without our teachers succeeding in offering a satisfactory reason for them, it is obvious that we are in a state of profound ignorance of the most interesting functions of the animal body, notwithstanding the innumerable experiments which have been made upon the brains of animals.

These are probably the reasons why ingenious men have failed to make us acquainted with the distinct functions of the divisions of the brain, and countenance us in advancing to the inquiry in a manner altogether different. If the real intricacy of the brain, and the disappointments met with, have inclined many to consider it as an inextricable labyrinth, we may well doubt whether the thread which is to lead us through has been properly selected.

This term is not altogether metaphorical, since it is our design to follow the course of the natural filaments discernible in the nervous matter of the brain. The investigation into the substance of the brain must be made in a manner different from common dissection; there is a new element to conquer. Every part of the brain is closely united and pent up within the skull, for the protection of its delicate substance. This compactness of structure guards the brain against impulse from within, as well as from external injury; but whether the whole of this structure be essential and of primary importance, or whether some part may not perform the merely accessory office of packing and joining together the more delicate parts, and so securing the finer filaments which run through it, is even up to the present time matter of conjecture. However, it is to the filamentous and striated texture that we attach importance, as leading in the right path, and as marking the relations which exist between the parts of the brain, and the connexions of these with the nerves distributed over the body. The advantage with which we now enter on this inquiry is obvious; for instead of seeking, by injuring the substance of the brain, to discover the effects on remote parts of the nervous system, we commence the inquiry with a knowledge of that system.

It being now universally allowed that nerves have distinct functions, and not a common quality, and that the sensitive and motor roots of the nerves spring from different sources, it must appear a very natural mode of inquiry to follow these nerves into the brain, and to observe the tracts of nervous matter from which they take their origin. It is surely an easy, as well as a natural proceeding, to follow these tracts, and to mark the portions of the brain to which they ultimately tend; finally, to inquire what is the effect of the diseases of these parts, what the accompanying symptoms, and to compare the symptoms with the anatomical details.

On this plan I now propose to demonstrate that sensibility and motion belong to the cerebrum,—that two columns descend from each hemisphere,—that one of these, the anterior, gives origin to the anterior roots of the spinal nerves, and is dedicated to voluntary motion,—and that the other (which from its internal position is less known) gives origin to the posterior roots of the spinal nerves, and to the sensitive root of the fifth nerve, and is the column for sensation.

Further, I propose to shew that the columns of motion which come from different sides of the cerebrum join and decussate in the medulla oblongata,—that the columns of sensation also join and de-

decussate in the medulla oblongata. Finally, that these anterior and posterior columns bear in every circumstance a very close resemblance to one another,—that is to say, the sensorial expansions of both are widely extended in the hemispheres: they pass through similar bodies towards the base of the brain, and both concentrate and decussate in the same manner; thus agreeing in every respect, except in the nervous filaments to which they give origin.

Of the striated Septa in the Medulla Oblongata and Pons Varolii.

We can have no hesitation in giving superior importance to those tracts of striated matter which descend from the brain to the spinal marrow, since they are obviously the lines of communication between the organ of the mind and the frame of the body. But these longitudinal tracts are separated by certain plates of fibrous matter, which go directly transverse, are very regular, very easily demonstrated, and although no doubt important in themselves, are particularly useful to us in our present view, as establishing the natural distinctions, or boundaries, between the columns which, descending from the encephalon, constitute the medulla oblongata and the spinal marrow.

I shall first name parts that are familiar, as being noticed in systematic works, and proceed to others which I conceive have been overlooked. Of the former class are the superficial transverse fibres of the pons, or *nodus cerebri*, which passing across, terminate in the *crura cerebelli*. When this part of the *pons varolii* is raised, and with it the longitudinal striated matter which passes from the *crus cerebri*, and is prolonged to the *corpus pyramidale*, a very distinct layer or septum of transverse fibres is seen crossing from the one hemisphere of the cerebellum to the other. This septum is best seen from behind, when the tracts which descend from the cerebrum, and from the *corpora quadrigemina*, are taken away, for then its appearance much resembles the plates now to be described.

As to those septa which I conceive have hitherto been neglected, the most remarkable is that which forms a plane in the median line, resting with its edge upon the last-named transverse septum, and extending its fibres directly backwards, so as to form a striated leaf, separating the two great longitudinal tracts which pass between the medulla oblongata and the *thalami nervorum opticorum*.

If we separate the *corpus restiforme* (meaning by that term the mass which passes between the cerebellum and the medulla oblongata,) from the *corpus olivare*, we shall find a layer of delicate fibres

which constitute a pellicle much resembling the fibrous layer which might be peeled from the bark of the birch tree; and this is a septum.

Another septum of the same kind intervenes between the two anterior *corpora pyramidalia*. So accurately are the extreme anterior fibres of this septum attached to the *corpora pyramidalia*, that if we separate these bodies, the fibres will alternately adhere to the right and left column, so as to present an appearance as if there was an actual commissure between them; and authors have mistaken this, describing that, which truly is a septum of separation, as a bond of union. And so on the back part of the medulla oblongata, when we push aside the restiform bodies, or those columns which have sometimes been called the posterior pyramidal bodies, and open the central slit, we have the same appearance of minute commissures, which, however, is only the separation of the fibres of the plate, or septum; and these fibres, instead of running in a direction to be a lateral bond of union, or commissure, run from before backwards, and intervene between the longitudinal columns.

These layers not only distinguish in a natural way the columns which are descending from the cerebrum to form the spinal marrow, but they are necessary as leading us to the true points of union between the longitudinal columns, where their fibres actually decussate, and where these septa are deficient to permit the union.

The *Pons Varolii*, or *nodus cerebri*, is undoubtedly an intricate part of the brain; but until this intricacy be explained, we can have no hope of making a correct arrangement of the course of the filaments in the brain, and which pass through this body. We shall therefore take it as a key to the composition of the brain.

The pons has, with seeming correctness, been considered as the commissure of the cerebellum. In this its capacity of joining opposite parts we have to notice its two transverse laminæ of fibres above alluded to, one superficial and the other deep seated. We observe also an oblique lateral process which passes from the cerebellum to the *crus cerebri*. These septa intersect and distinguish the grand fasciculi or tracts of nervous matter, which, coming down from the cerebrum, seem to flow under the bridge, and converge in the medulla oblongata*.

* The terms *pons* and *nodus* are sufficiently intelligible and harmless, as implying no theory: I retain the old names unless the new ones be countenanced by the just eminence of the authors who have invented them. This is the proper check against the multiplication of terms in

We commence our investigation with parts that are familiar. We trace the corpora pyramidalia of the medulla oblongata upwards from the point of their decussation towards the brain. They enter the pons by two distinct arches. The superficial layer of transverse fibres stretching from the crura cerebelli is over them, and the deeper septum is under them. On raising the superficial layer of the pons, we see the fibres of the corpora pyramidalia passing quite through to the crus cerebri; and now in one view we see a great portion of the grand tract which furnishes the nerves of motion.

Let us divide these tracts by a transverse incision where the corpora pyramidalia enter the pons, and lift them up. We keep close to the deeper transverse septum, which we shall find as distinct and smooth as a floor, and now directed by this septum we distinguish the portion of fibrous matter which is anterior to it; and if we follow this up into the crus cerebri, we shall come upon the corpus nigrum, and find that the crus is not a simple texture of filaments, but that it is compound, and that we are lifting that anterior division of it which belongs to motion, and which we shall find spreads over the tract of nervous matter which comes up behind the deeper-seated septum.

We may complete our view of this motor tract by making sections of the cerebrum, and pursuing the diverging fibres, first into the corpus striatum, and thence, as they proceed onwards, spreading into the hemisphere of the cerebrum and diverging to the cineritious convolutions.

Thus we have already found that the crus cerebri is not simple, but consists of parts easily and naturally divided. Returning, then, to the pons, as furnishing us with the means of making the natural distinctions of these tracts, we take the deep septum or posterior set of transverse fibres again as our guide, and trace

The posterior Tract.

To obtain a distinct view of the whole extent of the posterior tract, we require to have the parts carefully prepared*. It will be very convenient to have the crura, pons, and medulla oblongata, detached from the great masses of the cerebrum and

cerebellum, so that they may lie before us. We should first mark out and trace the columns of the spinal marrow; observing the corpora restiformia as they come down from the cerebellum, we may split them at the posterior fissure, and fold them aside.

We now survey the extent of the fourth ventricle. On each side of the calamus scriptorius are two pyramidal columns*. To trace these upwards we must cut into the iter ad tertium ventriculum, by dividing the corpora quadrigemina, and then we can trace them up into the thalami nervorum opticorum. By a section we may trace them through that body, and then diverging into the hemispheres of the cerebrum.

Having followed these columns upwards, we next trace them downwards, and find that they join, intermingle, and decussate, and again separate, and proceed down the spinal marrow.

From no part of this column does any nerve of motion take its origin; its relations to the sensitive nerve will be seen on further dissection.

The corpus striatum and the thalamus lie very curiously together: the thalamus forms a nucleus, round which the corpus striatum bends, and when their respective layers of striæ make their exit beyond these bodies to form the great fan or solar-like expansion into the hemisphere of the cerebrum, their rays mingle together. A rude representation of these two tracts of the cerebrum, as we have traced them, may be made with the hands. If I place my wrists together, parallel, and closing one hand, embrace it with the other, I represent the two portions of one crus. The closed fist is the thalamus, and the other is the corpus striatum. If I then extend my fingers, interlacing their points, I represent the final distribution of the portions of the nervous matter which are dedicated to sensation and volition.

But before proceeding further, we must distinguish a certain portion of the great tract of fibrous matter that lies behind the septum of the pons, which does not belong to sensibility, but to a different order of parts. If we dissect round the corpus olivare, we find it easy to separate this body from the column of motion on the fore part, and the column of sensation behind. Following, then, the fibrous portion of matter which ascends from it, we find that it runs close upon the back of the septum

anatomy. In describing the course of the fibres, the expressions I employ are used in their anatomical sense, as implying the direction in which the hand and eye are following the line, and not in reference to the course in which I may suppose the energy to pass in the performance of their functions.

* It will be in vain for the anatomist to attempt demonstrating these facts in the recent brain; but he will find it easy if he take some old preparation of the brain, which has been for some years in spirits.

* In fact, all the columns which form the medulla oblongata converge downwards and are pyramidal. We have the anterior pyramidal bodies, the posterior pyramidal bodies or corpora restiformia, and those deeper columns whose form might authorize the term, as they are more especially counterparts of the true anterior pyramidal bodies.

of the pons, and that a part of it goes off to the corpora quadrigemina, whilst a part runs directly into the crus cerebri.

On tracing the column which descends from the corpus olivare, we find that it is very soon attached to the columns both of motion and of sensation, and becomes incorporated with them as it passes downwards.

We have now traced three great tracts or courses of fibres into the crus cerebri; an anterior one for motion, a posterior one for sensation, and a middle one, which for the present we may call the tract of the corpus olivare.

After these dissections, it is impossible for us to consider the medulla oblongata as the mere commencement of the spinal marrow: it has a peculiar structure and distinct functions; it is the body formed by the convergence of the great tracts of the cerebrum, where these tracts respectively meet and decussate; in it the tract of the corpus olivare is joined to those of motion and sensation.

Below the medulla oblongata the spinal marrow commences, or rather is prolonged from it, but it is constituted with a distinct arrangement of its columns. On each side it receives three columns from the cerebrum, besides those which come down from the cerebellum, under the name of corpora restiformia, to form its posterior part, and these columns enter into relations which do not exist above.

Decussation of the Posterior or Sensitive Part.

We have noticed a fact of more than ordinary importance, as reconciling the occurrence of symptoms with our knowledge of anatomy. Where the posterior tract, descending from the cerebrum, has reached the point of the medulla oblongata, just opposite to the decussation of the corpora pyramidalia on the fore part, we described a coalescence. We have already stated, that when we proceed to separate the columns on the sides of the slit called calamus scriptorius, we see small, neat, and regular filaments, as it were, interlacing and joining the two columns. But when we examine further, we perceive that these filaments belong to a plate of fibrous texture which passes in the central plane from before backwards. This striated septum stops or is interrupted by the union of the columns of sensation; and now attending to the fibres of these two columns, we find them to decussate with an interweaving as distinct as that of the corpora pyramidalia or anterior columns. After this union and decussation has taken place, we may trace the nervous matter downwards in the two lateral portions of the spinal marrow, covered by the columns, which are the most posterior of all, and

which descend from the cerebellum under the name of corpora restiformia.

Before tracing the origin of the sensitive roots of the spinal nerves, and that of the fifth nerve, in their relation to these tracts, we may review their course. We cannot fail to observe the remarkable correspondence in the structure and course of the two grand tracts or divisions of the crus cerebri, which descending, form so large a portion of the spinal marrow. Tracing them from the brain, we find both converging from the periphery of the hemisphere; both entering masses of cineritious matter, emerging alike, and approaching, but not absolutely joining; both contracting into narrow pyramidal columns; both having corresponding decussations, and only distinguishable at last by one of them giving origin to the motor nerves, and the other to the sensitive.

The origin of the posterior roots of the Spinal Nerves, and their relation to the decussation of the Posterior Column.

The brain being before us so as to present its posterior aspect, and the back part of the spinal marrow, we raise the cerebellum and tear the pia mater, so as to expose the fourth ventricle. We may divide the processes of the cerebellum and take that body away. Having the parts thus prepared, we attend more particularly to the posterior series of roots of nerves which run towards the uppermost spinal nerve.

If we trace the line where the posterior roots of the spinal nerves arise, we find that the posterior columns of the spinal marrow are behind these roots; and if we trace these posterior columns upwards, we see them diverging under the name of corpora restiformia to the cerebellum. We strike a level by following the posterior roots of the spinal nerves into the spinal marrow. In doing this we shall find it necessary to lift the posterior column, and then, being able to trace the roots of the nerves, we shall find them connected with a course of longitudinal filaments; and these, on further investigation, will be found to be continued from the point immediately below the decussation of the posterior column of sensation, which I have described above.

Thus it will be found that the posterior roots of the first, and consequently of all the spinal nerves, are derived from that posterior column which descended from the posterior division of the crus cerebri, and that they are thus placed in the same relation as the anterior roots with respect to the decussation of the prolonged medullary matter of the cerebrum.

The origin of the sensitive root of the Fifth Nerve, and its relation to the Spinal Marrow.

In former papers I have proved the fifth

nerve of the head, according to the arrangement of Willis, to be the nerve of sensation to the head and face, thus distinguishing it from the nine nerves of the encephalon, and from the appropriate nerves of the senses to the nose, and eye, and ear.

I gave my reasons, at the same time, for distinguishing it as the nerve of mastication, and showed, in short, that it had all the characteristics of a spinal nerve. It becomes now a subject of interest to observe in what respect it further resembles the spinal nerves, and to inquire how its relations with the brain are formed. It is a happiness in this inquiry, that although it be difficult to trace the motor roots of nerves, owing to the delicacy of their connexions with the brain, the sensitive root is followed with ease into the brain or spinal marrow.

We commence the dissection of the fifth nerve by distinguishing its grand divisions as they emerge from the side of the pons, separated by a transverse band of fibres.

Leaving, for the present, the scattered roots of the motor portion which pass between the transverse cords of the pons, we shall proceed to follow the other in a retrograde direction towards its origin. For this purpose, with a small and fine knife, we cut into the substance which surrounds the sensitive root, to the depth of a twelfth of an inch, and then lay aside the knife and take the curette, and perhaps the ivory handle of the knife*. With these we push aside the substance of the brain, in doing which there is no difficulty in distinguishing the smooth, flat, and ribbon-like white nerve. Continuing to press aside the matter of the pons, and, when separated, to cut it away, we find the nerve taking a course backwards and downwards into the medulla oblongata, making a considerable angle. Here we are interrupted by the crossing of the *portio mollis* of the seventh nerve. We observe in passing, that the *portio mollis* has two roots; that besides that usually described passing round the *processus ad cerebellum* to the anterior part of the fourth ventricle, it has a round root, which enters anteriorly to that process. But by attention and much neat dissection we may preserve these roots of the seventh nerve, and, recovering the tract of the fifth nerve below, trace it downwards. We are again interrupted by the origins of the eighth pair of nerves; and here, too, it will be found, on careful dissection, that this nerve does not correspond with the description in systematic

works. But to proceed with our proper subject. Some part of the root of the fifth may be seen to deviate in a direction towards the *calamus scriptorius*; but the main tract descends behind the *fasciculus* of the *corpus olivare*, by the side of the great *fasciculus* of fibres which we have already traced down from the cerebrum. Disregarding this association, and following still the root of the fifth nerve, we find it continued to the roots of the superior spinal nerves; and in tracing it thus far, we must conclude that its relations are with the spinal marrow rather than directly with the brain, and that it joins the posterior column below the decussation of that sensitive tract or column. It remains a proper subject of inquiry to determine how far the deviation of a part of the sensitive tract of this nerve corresponds with its complex function in being the source of taste as well as of common sensibility.

It has been observed by diligent anatomists from time to time, that the nerves of the encephalon come off in a direction ascending from the spinal marrow. There can be no doubt that the sensitive root of the fifth ascends, and that it has its origin in the spinal marrow rather than the brain. Without at present inquiring into the minute anatomy of the other nerves, we may draw very important conclusions from what is before us.

It is rather surprising, that from what was known of the anatomy of the brain, pathologists should have so agreed in their explanation of the phenomenon of injury of one side of the brain producing its effects on the opposite side of the body. Their opinion was founded on the decussation of the anterior columns, or pyramidal bodies, and those only; but great misconception must have prevailed as to the anatomy, when such an explanation could be satisfactory; and, at all events, it must have been believed that the posterior roots of the spinal nerves were the same, in function, with the anterior roots. When, however, it is understood that the anterior column of the medulla oblongata gives off only filaments of motion, the rationale of decussating fibres fails, or rather is imperfect; for in injury of the brain, both motion and sensation are lost on the opposite side of the body. We perceive how important it was, in order to understand this symptom, that the posterior or sensitive part of this column should be shown to descend from the cerebrum, and decussate at a point corresponding to that at which the decussation of the pyramidal bodies takes place.

I have observed, that the *corpus striatum* is the part in which most frequently rupture of the cerebral vessels occurs; and the

* If we order dissecting instruments, there is no end to the trouble in procuring them fine enough. The operating-case of the oculist, however, furnishes at once all that is necessary for delicate anatomy.

observations of authors correspond with this opinion. In such cases we can readily believe that the power of motion will be most injured; whilst such derangement in the hemisphere must, at the same time, more or less affect the sensibility.

Certain circumstances essential to the study of the pathology of the brain are explained through this part of anatomy; first, that motion and sensation should, in by far the greater number of cases, be lost together, in disease of the brain; because the sensorial extremities of both columns are in the hemisphere of the cerebrum; secondly, it is seen why it is that the sensibility, as well as the power of motion, is injured on the opposite side of the body when the hemisphere of the cerebrum is hurt or diseased, for both columns decussate; in the third place, the anatomy of the origin or root of the fifth nerve explains very satisfactorily why, in palsy, the privation of sensibility of the side of the face corresponds with that of the body.

My paper should perhaps have terminated here, with these demonstrable facts, but I am tempted to reach a little further.

Further examination of the relation between the Brain and Spinal Marrow.

Other questions will be suggested in reference to the symptoms of disease in the brain. When the side of the body is paralytic, how far are the nerves affected which appear to have their origin above the decussations? Does the ninth or lingual, or the portio dura of the seventh nerve, correspond with the spinal nerves? Do the third nerve and the muscles of the eye partake of the condition of the body?

As there is no decussation above the apparent origin of these nerves, and as the commissures of the brain do not serve to explain this phenomenon, we are directed in our inquiries to the spinal marrow.

The spinal marrow has much resemblance to the brain, in the composition of its cineritious and medullary matter, and in the union of its parts. In short, its structure declares it to be more than a nerve, that is, to possess properties independently of the brain. Another consideration presses upon us. Where are the many relations existing between the different parts of the frame, and necessary to their combined actions, established? There must be a relation between the four quarters of an animal. If the muscles of the arm or of the lower extremities are combined through the plexus of nerves in the axilla, and in the loins, what combines the muscles of the trunk, and more especially what joins the extremities together in sympathy? That these combined motions and relations are not established in the

brain, the phenomena exhibited on stimulating the nervous system of the decapitated animal sufficiently evince. They must therefore depend on an arrangement of fibres somewhere in the spinal marrow. Comparative anatomy countenances this idea, since the motions of the lower animals are concatenated independently of a brain, and independently of the anterior ganglion, which in some respects gives direction to the volition of these animals.

It comes next to be inquired what use there can be in a decussation, by which one side of the brain is made to serve the opposite side of the body. Ingenuity can offer no reason for such an arrangement; the object must surely be an interchange of fibres, and consequently a correspondence in the movements of the sides of the body and of the extremities. And on this subject it must be admitted, that although in nine out of ten cases the side of the body opposite to that which is diseased in the brain is affected with paralysis, it is not always so, and very often a certain debility is perceptible in the side which is least affected. Again, when a man is seized with paralysis, he is sometimes at the instant affected with pain in the other side. These irregularities tend to countenance the belief that the decussations of the sensitive and motor spinal columns are rather intended to effect combination and sympathy between every part of the frame, than that one half of the brain should belong to the opposite half of the body, for no apparent object, and without producing any harmony of action.

Such arguments induce me to believe that the brain does not operate directly on the frame of the body, but through the intervention of a system of nerves whose proper roots are in the spinal marrow, and that the decussation, or rather the arrangement of the fibres, takes place at the point where the columns descending from the brain join the spinal marrow, and consequently in effect above the origin of all the nerves, excepting those of the four senses. This supposition would furnish an explanation of the whole of one side of the body, limbs, face, and head, being similarly affected in paralysis. It would also explain the appearance, which all the nerves of motion and sensibility have, of coming in a direction upwards from the spinal marrow, rather than directly outwards from the brain, as the nerves of the proper organs of sense do.

In reflecting on the origins of the nerves of the encephalon, it appears that neither nerves of sense nor of motion arise from the cerebellum or its processes. It further appears that the restiform bodies or processes form no union or decussation similar

to those which we have described in the columns of motion and sensation which descend from the cerebrum.

Those descending processes of the cerebellum, however, form a large portion of the spinal marrow; and we must thence infer that the cerebellum operates through the system of the spinal marrow.

The symptoms attributed to disease of the cerebellum do not remove the obscurity which invests this part of anatomy. We know that sometimes the whole hemisphere of the cerebellum is destroyed by suppuration, without loss either of sense or of motion. Moreover, when symptoms do attend disease of the cerebellum, its juxtaposition to the medulla oblongata inclines us to suspect that the effects are produced through the latter body. The substance of the cerebellum is not of diameter sufficient to have a large clot of blood in it, or a large abscess, without blood or matter communicating with either the fourth ventricle, or bursting out upon the surface. The influence thus becomes general on the nervous system, and a confusion in the symptoms is the necessary result. We have no distinct and well-marked cases of disease in the substance of the cerebellum, such as we possess of disease of the cerebrum; and on the whole it does not appear to stand in direct relation to the motions of the frame, or to the common sensibility.

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Continued from page 588.]

Structural Changes consequent on Inflammation.

DISSECTIONS of nerves after operations, or after death, often verify the suspicions which the symptoms before these events had led the practitioner to entertain; and the appearances are said to vary according as the inflammation is confined to the neurilema, or extends to the medullary substance itself.

Amongst the results of inflammation of the neurilema may be mentioned the deposit of lymph, producing thickening and increased hardness of the nerve. This deposit of lymph amongst the fibres of a nerve has been particularly

noticed by Mr. Swan, as the consequence of its being included in a ligature, and as occurring in the chronic inflammation of the extremities of nerves in stumps, in which, "after a perpendicular section of the nerve and tumor, the nervous fibrils may be traced down to the tumor, and coagulable lymph seen to have been deposited between them." This enlargement and hardness from inflammation were very strongly marked in the nerves of three cases of ulcerated limb, described by Mr. Swan; and equally so in some of the cases of inflamed nerve related by M. Martinet. In one the cubital nerve swelled to a considerable size, equal to the little finger; in a second, the cubital nerve could be felt enlarged and tense, especially between the elbow and the arm-pit; in another, the sciatic nerves on both sides were enlarged to the size of the fore-finger, being also hard and resisting; in another, the right sciatic nerve was increased to double its natural size, through an extent of an inch and a half; and in all these cases not only was the pain excessively severe, but the nerves were exquisitely tender throughout their course.

These deposits of lymph, occasioning thickening and hardness, may take place either upon the surface, or in the interior of the nervous cord, or more commonly in both. In some instances, where it has been confined to the surface, it seems to have strangled the nerve by pressure, and impaired its function; and hence, probably, the explanation of those comparatively rare instances in which a nerve, apparently thickened by inflammation, has become enfeebled rather than excited; agreeably to an observation of Galen, that "a nerve, if rendered thicker and harder than usual, will prevent the transmission of nervous influence, just as the sun's rays are intercepted in their passage through air by mists, smoke, and clouds, and through water by mud and clay*."

When, however, these inflammatory deposits of lymph take place in the interstices of still existing medullary filaments, the symptoms are generally, if not universally, those of excitement;

* Quippe in aere nebula, et fumus, et nubes, in aqua lutum et limus, solis splendorem, quo minus per ea syncerus procedat impellimento sunt ac vetant. Ad eundem igitur modum et nervus, si crassiore habitu et duriore quam propria natura sit reductus, virtutis transitum prohibebit. — De Symp. Causis, lib. i. cap. 5.

but it may be questionable whether in such cases the medullary matter itself may not have partaken of the inflammation.

As in other textures of the body, so in nerves, permanent redness, observable even after death, is often the result of inflammation. In one instance related by Martinet, the left median nerve was of a *deep red colour, internally as well as externally*; in another, the sciatic nerves were penetrated by a multitude of small vessels, which gave a *red appearance to the nerves*; in another, the sciatic nerve, which was the seat of pain, was of a *red colour from the hip to the ham*; in another, the sciatic nerve was of a *violet colour*, and ecchymosed; in another, the sciatic nerve appeared of a *brown colour*, for the space of two inches, both externally and internally.

In neuritis, other inflammatory deposits besides lymph have been occasionally observed. In some of the dissections of inflamed nerve, the record of which, by M. Martinet, contains ample internal evidence of his accuracy and fidelity, serous infiltration was particularly noticed. In the case already alluded to, in which the sciatic nerve was as large as the fore-finger, each filament of these nerves was distinctly visible, and separated from each other by a sero-sanguineous infiltration. In one instance, blood itself had been effused between the fibrils, and could be squeezed out by pressure; and in two instances pus had been deposited between the filaments. Suppurative inflammation, indeed, is not so common as the other changes enumerated, but its existence is conclusively established by these two cases, in the very valuable memoir by M. Martinet, "*Sur l'Inflammation des Nerfs* *," corroborated as they are by a fatal instance, related by Sir Everard Home, of suppuration after an operation for the removal of a tumor from one of the nerves of the axillary plexus†. That such effusions are the consequences of inflammation, is almost self-evident. The effusion of lymph, in whatever organ or texture of the body it occurs, is universally considered as conclusive as to the existence of inflammation; the colour of the effused serum excludes the

idea of its being mere dropsy, and establishes its dependence upon increased arterial action; and the secretion of pus or sanies by the vessels of the neurilema needs no observation to prove its inflammatory origin.

Some have questioned whether this inflammation can extend to the medullary filaments themselves; but the presumptive and positive evidence upon the subject, in my estimation, far outweighs the difficulties and doubts which some may have felt or entertained upon the subject. The presumptive proofs are derived from a consideration of the structure of these filaments, of the functions to which they contribute, and the analogy of diseases of the brain and spinal marrow. It will be readily conceded, that all parts upon which blood is distributed are susceptible of inflammation; and if it can be proved, therefore, that the medulla of nerves is vascular, we may predicate the occasional occurrence of inflammation of that texture. The statements of different writers upon this very difficult point of minute anatomy are not very precise or clear. Bichat, indeed, describes the vessels of nerves as pursuing a serpentine course upon the neurilematous investiture of the separate filaments; then penetrating the membrane, and continuing their course, together with the filaments, to the medullary substance; a disposition which, as he represents, is more obvious in the spinal marrow. In this part of the nervous system, after ramifying extensively upon the pia mater, which has a near relation to the neurilema, the vessels dip into the medullary substance, and there are lost, as they are continued with the exhalants*. Meckel says, the blood-vessels are large and numerous in proportion to the nerves which they supply; they generally enter nearly at a right angle with the trunk of the nerve, then divide into ascending and descending branches, which are tortuous in their course, subdivide into numerous ramifications, penetrate the tissue of the nerve, and anastomose freely not only with each other, but with the contiguous branches; the frequency of these anastomoses and the great number of blood-vessels having for their object to prevent the slightest interruption to the circulation. This, he adds, is a disposition which prevails in every part of the ner-

* *Revue Médicale*, 1824.

† *Tr. of a Soc. for the Improvement of Med. and Chir. Knowledge*, vol. ii. p. 157.

* *Anat. Gen.* vol. i. p. 154.

vous system, and is strikingly exemplified in the cerebral circulation*.

It thus appears to be established that the medullary substance of nerves receives blood from the vessels of the neurilema; but if further proof be required, it may suffice to refer to the change of colour in the nervous matter itself consequent upon inflammation, and ascertained, as in the experiment of Reil, by dissolving in acids the neurilema, and thus insulating and exposing to view the medullary filaments; and still more conclusively to one of the cases, recorded by M. Martinet, in which the filaments were penetrated by a multitude of small vessels, which gave the red appearance to the nerves.

It is a general pathological principle, admitting of few exceptions, that when the function of a given part, organ, or tissue, is long and continuously impaired, the diseased condition, be it either functional or structural, is in the part, organ, or tissue, affected. Now the observations and experiments of Haller and Bichat satisfactorily demonstrate that the sentient principle is exclusively confined to the medullary filaments, and does not extend to the neurilematous covering, which is but the matrix upon which the vessels ramify before they supply the medullary filaments: thus performing an office similar to that, to which, within the cranium, the pia mater—of which the neurilema is but a continuation—is subservient, and acting as a sort of cushion for the protection of those filaments. “La membrane de chaque filet est véritablement une espèce d’abri qui protège sa substance médullaire, dans laquelle siège éminemment la sensibilité†.” “Sed nervi sentiant et soli quidem sentiunt. Est autem nervorum medulla sola quæ sentit‡.” The French anatomist states this more in detail. Having asserted with truth, that sensibility exists principally in the medullary substance of each nervous filament, and that the neurilema has little sensibility, he adds that this is the reason why simple contact, without compression, with a nerve, is little painful—why a nerve may, almost with impunity, be bathed in purulent matter, in an ichorous fluid, or even the sanies of cancer; why the con-

tact of air is little perceived when the nerve is simply exposed, without separating its enveloping membrane; and why, in a variety of cases, different tumors, situated immediately contiguous to nerves, produce no influence upon the latter, the membrane in each of these cases protecting the medullary substance, which is eminently the seat of sensibility. As to the cellular tissue, which enters into the composition of a nerve, it is nearly devoid of the property of sensibility. Hence it is that, according to experiments in the living animal, frequently repeated by Bichat, the fibres of a nerve may be insulated, and separated from each other with a very fine scalpel, provided they are simply exposed, and not deprived of their neurilema, the animal being little sensible of it. In these experiments, Bichat further adds, it is easy to convince oneself of the degree of sensibility belonging to the envelope of each nervous filament. “Il faut la traverser, et arriver à la substance médullaire, pour produire de la douleur*.” Since, therefore, the medullary substance, to the exclusion of its enveloping membrane, is the seat of sensibility, the exaltation of this function in cases of inflamed nerve, manifest in the excruciating pain which attends it, affords strong presumptive evidence that such medullary matter is the seat of the disease.

The analogy of the diseases of the brain and spinal marrow is also greatly in favour of the supposition that the medulla of nerves may be inflamed. Scarcely any one now hesitates to admit that the medullary substance of those important subdivisions of the nervous system is liable to inflammation; but if a doubt upon the subject could still lurk in the mind of the most incredulous, the pathological researches of Dr. Abercrombie, and the work of M. Ollivier upon the diseases of the spinal marrow, should, if he remain accessible to reason, altogether dispel that doubt. These important organs have a direct connection with the nerves by continuity of substance, by similarity of structure and identity of office, and we might safely infer that both would be subject to the same diseases; and this is conclusively established by inflammation producing the same organic changes in all.

In proving the existence, and tracing

* Anat. Gen. vol. i. p. 163.

the consequences of inflammation of nerves, I have alluded to one very common change—that of the effusion of lymph, attended with thickening and induration. I believe this to be the result principally of inflammation of the membranous investiture of the filaments, though, from what is often observed in the brain, it is far from improbable that the medullary substance itself may partake of the change. In encysted abscess of the brain, there can be little doubt that, as in other parts of the body, the cyst, which insulates it, is the result of the deposit of lymph, which becomes organized, and in some instances constitutes “a firm white membrane*,” although in general it is not so well defined. The induration, also, occasionally observed in epileptic patients, and in maniacal cases†, is probably from a similar deposit, which becomes organized. At all events, Andral, whose opinion upon the subject is much corroborated by the researches of M. Bouillaud‡, considers both the general and partial indurations of the cerebral substance as the results of inflammation—the former of its acute, the latter of its chronic form. Morgagni has recorded no less than fifteen instances of induration occurring principally in maniacal or epileptic subjects; in one there were violent headaches only; and one was a case of sudden death in the course of fever. The majority of these were attended with increased vascularity, some with alteration of colour, and some with serous effusion,—appearances abundantly characteristic of previous inflammation§. Luntaud also quotes, amongst numerous instances, one from Fournier, in which a portion of brain, as large as a fist, was of a stony hardness||. In two instances also (all he has recorded) of chronic inflammation of the brain, noticed by Dr. Abercrombie, a portion of the brain was firmer than natural. M. Andral describes three degrees of this induration: in the first, it is like that of a portion of brain which has been long steeped in diluted nitric acid; in the second, the indurated portion of brain is like wax, or Gruyere cheese; in the third, it has the consistence and elasticity of a fibro-

cartilaginous substance. In diseases of the brain these various degrees may be traced, as the accompanying increase of vascularity or irritation, amounting, according to Andral, Bouillaud, and others, to “encéphalite,” and may destroy the patient in its various stages. In nerves, also, such induration occurs; but the disease is seldom examined until its long continuance has tempted the patient to submit to an operation, or death has closed the scene; and then the swelling of the nerve has commonly assumed a circumscribed form, and is of a fibro-cartilaginous hardness; blunting, as Meckel has observed of the inflamed nerves of stumps, the knife which cuts it, and producing a sound in cutting like that of cartilage.

The change of colour, also, in an inflamed brain, is very similar to that noticed by M. Martinet, Reil, and others, in inflammation of nerves. The “*dark red colour*” mentioned by Dr. Abercrombie in two cases of “inflammation of the cerebral substance, fatal in the inflammatory stage,” with “the bright red colour” in the portion of brain near to the surface, which seemed firmer than natural; the “*deeper red colour*” of “a similar portion deeper in the substance of the brain,” and “the red colour approaching to purple” of the corpus striatum, in his only instance of “the affection in a chronic form,” are very similar to the “*couleur d’un rouge foncé*,” the “*rouge violacé*,” the “*couleur violacée*” of M. Martinet*, the “*couleur rouge ou violacée*” of M. Gendrin†.

The most characteristic change, however, consequent upon inflammation of the medullary substance of the brain and spinal marrow, is “*ramollissement*,” of which endless examples might be accumulated. The same change of texture is not very unfrequently seen in nerves, and, as in the brain, is probably nearly allied to gangrene. When a question can arise as to the vascularity of a part, at all events the vessels must be few and minute. There is no doubt as to the vessels being numerous in the neurilema, but they must be very small in the white medullary filaments; and this slight vascularity renders these little able to bear active inflammation.

† Hist. Anat. des inflammations tom. ii.

Like the cornea of the eye, and tendons of the extremities, which are peculiarly prone to slough when inflamed, nerves, when their medulla is implicated, are also apt to become gangrenous; and hence the ramollissement of nerves consequent on inflammation. In the interesting example related by M. Serres, of epilepsy depending upon chronic disease of the brain, which was very extensively disorganized, the patient having also a local palsy from disease of the ganglionic or sentient portion, to the exclusion of the motor branch of the fifth pair, "the nerve was found soft, yellowish, and almost like jelly; the same change of texture extending a line or two into the substance of the annular protuberance*." In another instance, related by M. Gallereux, after a continuation of blindness of one eye for six months, the optic nerve, through half its extent, had lost entirely its consistence, being reduced to the state of a fluid of a whitish colour†. This change was probably the cause of the blindness, for the appearance was altogether different from that of the atrophy of a nerve, which is consequent upon the loss of the organ which it supplies. There is in these cases of "atrophy" no softening of texture, but the nerve is often diminished to a fourth or fifth of its natural size; the medullary substance disappears; there is only a gray semi-transparent matter in its interior; sometimes the neurilema is even thicker and more consistent than natural; the nerve looks like a fibrous and almost cartilaginous cord, and sometimes nothing remains but mere cellular substance‡.

Suppurative inflammation of nerves, to which I have already adverted as the result of inflammation of the neurilema, bears a very striking resemblance in its character to the undefined suppuration from inflammation of the brain, described with such accuracy by Dr. Abercrombie, who represents the part of the brain affected in one case, as "reduced to a mass of fetid pus;" and in a second, says that "the whole of the posterior part of the left hemisphere of the brain was one mass of undefined suppuration." This resembles strongly Martinet's seventh case, in which three inches of the

sciatic nerve were infiltrated with purulent matter, which penetrated amongst its most minute filaments; as well as another instance, communicated by M. Goupil, in which the left sciatic nerve was bathed, as it were, in sanious pus, which was also found amongst its fibrils*.

One other consequence of inflammation may be noticed, as common both to the nervous centre, and to individual nerves—ulceration. Two interesting examples of this morbid condition within the cranium are referred to by Dr. Abercrombie: in the one, under the anterior lobe of the right hemisphere, "there was a superficial ulcer, measuring thirteen lines by seven†;" in the other, "there appeared upon the upper surface of the cerebellum an ulcerated superficial excavation, the size of a shilling, containing an ichorous matter‡." In nerves, also, ulceration has been occasionally traced. It has been distinctly recognized by Mr. Swan; but the examples of this state recorded by him are more prominently instances of thickening from inflammation, than actual ulceration; or, at all events, the phenomena are those of the former rather than of the latter state. In one, indeed, of the three cases related by Mr. Swan, there was distinct evidence of ulceration in the dorsal branch of the peroneal nerve; "an inch of this appeared rather smaller, and in a state of ulceration, and in one place nearly divided§." The extent of ulceration, however, in this example, confined as it was within such narrow limits, affords no satisfactory explanation of symptom, which presented themselves in other parts of the limb, and far above the seat of the ulceration. The pain of which this patient complained, and for which, on account of its violence and extent, he readily submitted to amputation, was in the course of other nerves. "in the thigh and leg as far as the ankle." Dissection, however, of the limb after its removal cleared up all obscurity, for there was scarcely a nerve of the limb which had not been considerably enlarged by inflammation. In neither of the other instances recorded as having occurred within the observation of Mr. Swan, was

* Archives de Médecine, vol. v. Quoted also by Descot, Bell, and Andral.

‡ Howship, in Med. and Phys. Journ. March 1810.

§ On the Diseases of Nerves, p. 69.

there, as he candidly admits, any ulceration of nerves, although they have been introduced into his chapter on that subject; but in these, as in that of William Sharpe, it was evident upon dissection that the nerves had become inflamed, and that this had given rise to the symptoms. In one case only was there ulceration; in all the appearances of previous inflammation were manifest; the phenomena common to all were those which are notoriously the result of inflammation, from whatever cause arising; and to this morbid condition, therefore, common to them all, the symptoms should have undoubtedly been referred. The case quoted from Morgagni is an unequivocal instance of ulceration; for upon examining the limb, a few fibres of the nerve only remained, by which parts above and below the ulcerated portion preserved their communication. As I shall have occasion to advert to this case hereafter for another purpose, I shall then consider more at large the symptoms and their cause. I may content myself for the present with stating, that the explanation offered by Mr. Swan differs materially from that of Morgagni himself, and does not seem to me to be altogether satisfactory, and with pointing at the resemblance between the state of the brain, in which, in the case of my able colleague, Mr. Howship, "there appeared an ulcerated superficial excavation, containing an ichorous matter," with that of ulceration of nerves, "some of which were unusually soft and easily torn," one of which "was in a state of ulceration and nearly divided," and another "so much eroded that a few fibres hardly remained."

The concurrent testimony of all the principal writers upon the diseases of nerves, including Descot, Martinet, Jolly, perhaps Abercrombie, and Swan, prove that the changes which I have described are the ordinary consequences of inflammation; and they appear conclusive as to the occurrence, not only in the neurilema, but even in the medullary filaments themselves, of that pathological condition, the existence and treatment of which were not altogether unknown to Galen, who says upon this subject, "quin et nervo inflammato non pauci spasmus correpti sunt et mente alienati, quorum quidam sic affecti, cum sapientiores medicum nacti essent, nervo inciso, spasmus et mentis alienatione liberati sunt; sed postea musculum, in

quem nervus insertus erat, insensibilem, atque inutilem ad motum, habuerunt*."

This inflammation of nerves, it is said, may be either acute or chronic; but the distinction between the two has not been drawn with precision or accuracy. Both are represented by Mr. Swan as generally taking place "in nerves contiguous to inflamed parts;" and they may therefore partake of the character of the inflammation by which the nerve affected is surrounded. But the symptoms are very similar in both; and as both require similar treatment, the discrimination, which is not always easy, is perhaps, after all, of no great moment.

[To be continued.]

ON THE DECUSSATION OF THE POSTERIOR COLUMNS OF THE CRUS CEREBRI.

To the Editor of the Medical Gazette.

SIR,
I HAVE no objection to your reprinting my last paper from the Philosophical Transactions; and I shall take the opportunity thus afforded me of making a few observations. I regret that I should have expressed myself so indistinctly on the subject of the decussation of the posterior columns of the crus cerebri, as to lead any one inconsiderately to deny it. I say, I take blame to myself; for if I had described it in another manner, it could not have been misunderstood. For example:—

Make a transverse section of the crus cerebri, half an inch anterior to the pons. Looking on the cut surface of the lower portion, a discoloured line, of a semi-circular figure, will be seen: anterior to this line is the motor column; posterior to it, the sensitive. Put the ivory handle of the knife into this discoloured part; it will prove softer than the part anterior and posterior to it. Thrust back the posterior column until it is seen descending behind the posterior transverse septum of the pons (the anterior column passing before.) You have now a very large portion of nervous matter, which you trace towards the medulla oblongata, and between the processes of the cerebellum. Now observe the two convexities, which are distinct columns, and which pass under the valvula cerebri, and the corpora quadrigemina, and

* De Motu Musculorum, lib. i. cap. 1.

by their approximation form the central slit of the calamus scriptorius. These columns are nearly as large, and as distinct, as the pen I hold.

It is not every person who has the delicacy of hand to display the septum which is between the columns; but even with a coarse hand, let him put in the probe between the columns, he finds it easy to separate them down to the delicate ligaments which form the point of the calamus. This point is firm; it is covered with a triangular-shaped layer, of a gray colour. Here he will find that there is a very firm union, not only of the two sides, but of this superficial layer, to the parts beneath.

This is so plain a matter, that a blind man may find it. I mean not this tauntingly; but if the dissector were blindfolded, or looking another way, on putting the probe, or curette (for that is the instrument I use), either between the columns above or below, and moving it towards the decussation, he would feel the resistance; so firm is the texture where the decussation takes place.

So far there can be no mistake. Let the dissector push aside the processes called posterior pyramids, and the inferior pedunculi of the cerebellum; and thus opening the spinal marrow, prosecute the cerebral columns, which he had previously traced from the crus cerebri.

Dissecting up the coloured matter (which is itself a firm bond), he finds just under this that the columns coalesce, and form a sort of neck. The narrowness here is owing to the closer union of the fasciculi where they decussate. After this union they separate, and proceed down the spinal marrow; and it is easy to trace their filaments into the posterior roots of the spinal nerves.

When this view is made, the course and decussation of these columns is much more distinct than that of the anterior, or motor column, and the union and separation of a different form, and more easily demonstrated, than the decussation of the anterior columns.—These columns are larger than the anterior pyramids; they cannot be the product of a part of the anterior, or true pyramidal bodies; they are seen descending continuously in their whole length, from the back of the pons to the spinal nerves; and a most interesting portion of the medulla oblongata is interposed at this part between the columns of motion and sensation.

There is another very satisfactory mode of displaying the course of the posterior cerebral columns, which is, by opening the sheath in which they run, and taking away the longitudinal fibres altogether, leaving the septum between them. At the point where, in my paper, I have described the septum as terminating, its texture rather opens, and forms oblique passages, through which divisions of the columns pass from side to side.

In the sheath, as seen on lifting the mass of the posterior column, a passage is left for a process to join this posterior column, and if this be followed through, it will be traced from the superior and central portion of the anterior pyramidal body. The connexions between the anterior, posterior, and intermediate columns of nervous matter, as I have observed in my paper, are subjects of great interest. It is this part of the anatomy which will form the subject of my next paper to the Royal Society.

Let me apologise to your readers for entering into no controversy here, but referring them to the original papers.

I am, sir,

Your very obedient servant,

CHARLES BELL.

Brook-Street, Jan. 21, 1835.

CALCULI IN THE LACHRYMAL DUCTS.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case, which I met with in the country a few weeks back, of sufficient interest, from its rarity, to merit a place in your valuable journal, you will oblige me by its insertion.—I am, sir,

Your obedient servant,

R. H. MEADE,

Student at St. Bartholomew's Hospital.

January 23, 1835.

Ann Clarke, aged 19, servant in a gentleman's family in Buckinghamshire, had been in a bad state of health for some months, and frequently complained of a severe pain in the head, particularly across the forehead, and over the left eye, for which she had been bled in the arm, and had leeches applied to the temples, but without obtaining any permanent relief.

On the 22d of December last, inflammation came on suddenly in the left eye, attended with a good deal of pain: this increased on the following day, and towards the afternoon she felt a most severe lancinating pain in the upper and outer part of the orbit, accompanied with a sudden and profuse discharge of tears; immediately after which she perceived something in her eye, which, on removing, she found to be a small hard body, resembling a fragment of mortar. At first she supposed it to be some extraneous substance which had accidentally got into the organ; but in the course of an hour, the pain, which had remitted on the removal of this mass, returned, and another exactly similar came away. During the three or four following days, as many as twenty-three altogether were discharged, with the same symptoms; after which the pain and inflammation gradually abated.—No other application but that of hot water was made to the eye.

I did not see the patient during the time that these bodies were escaping; but she said that there was no bleeding, or purulent discharge. On the day following the removal of the last of them, there were slight appearances of conjunctival inflammation; but on everting the upper eye-lid, no ulceration or other

lesion of the mucous membrane could be perceived there, or on other parts of the eye. She complained of slight tenderness on pressure in the situation of the lachrymal gland. I could not learn from the previous history of the patient that she had ever suffered from calculous deposits in other parts of the body.

On examining some of these substances which had been preserved, I found them to be small, rough, and very hard bodies, of a dirty white colour; the largest about a line in diameter. On viewing them in the field of the microscope, they looked like rough pieces of chalk, with small portions of silex imbedded in them.

By analysis they were found to consist principally of phosphate of lime, with a small quantity of carbonate of lime, and traces of animal matter.

On hearing the particulars of the case, and seeing the substances passed from the eye, it immediately struck me that they must be lachrymal calculi; but the consideration was, where they could have been formed, and how have found their way into the eye. From the circumstances accompanying their discharge, it seems most probable that they were lodged in the minute ducts, which convey the tears from the lachrymal gland to the under and outer surface of the upper eye-lid. It seems to be hardly possible that canals so minute as in the normal state not to be visible without a microscope, should admit of sufficient distention to contain bodies some of them a twelfth of an inch in diameter; but we know that mucous passages in other parts of the body will dilate sufficiently to contain substances proportionally large with the above to the lachrymal ducts, as is frequently seen in the passage of biliary concretions along the gall-duct, and of calculi from the kidney along the ureter to the bladder; therefore, reasoning from analogy, I think that in the case which I have described, the calculi formed in the ducts leading from the lachrymal gland, and at last produced, from their size, so much irritation, as to be discharged with a gush of tears.

On referring to various works on ophthalmic surgery, the only case which I can find at all similar is related in Gräfe and Walther's German Journal (vol. i. p. 163. Berlin, 1820.) But the concretions are there described by Professor Walther as forming in the folds

of the conjunctiva, attended with great irritation and inflammation of the eye, lasting for a long time, and being of a soft crumbling consistence.

In the same journal a case is mentioned by Dr. Krimer, where the nasal duct was obstructed by a calculus supposed to have been deposited by the tears; but they never before appear to have been met with in the lachrymal ducts.

POPULATION AND MORTALITY.

To the Editor of the Medical Gazette.

SIR,

My attention having lately been drawn to the articles in your periodical regarding the laws of population and mortality, and to the discussions there arising from the several statements of Messrs. Rickman, Villerme, and Sir Francis d'Ivernois, I am induced to trouble you with a copy of my work on those subjects, and entitled, "*On the Natural and Mathematical Laws concerning Population, Vitality, and Mortality.*" If you have leisure and inclination to peruse it, you may possibly there find the solution, upon definite principles, of many questions respecting which the opinions have long remained unsettled. That work not having been printed with a view to selling, and therefore no publisher's name being affixed to it, it is probably not extensively known; and I am not aware of any public notice having been taken of it, by persons any way competent to discuss either its merits or demerits.

Having, for express purposes, confined my views of those subjects to certain generalities, which I have been at no small trouble to investigate, I do not feel disposed to enter here into any debate of the particular points on which the above-named gentlemen have dwelt at more or less length. Their labours and research, which they probably will carry further on, entitle them to my utmost respect, independently of that which arises from my being honoured with the personal acquaintance of several among them. I shall patiently await, therefore, the further development of their conclusions, before I venture to plunge into any such partial details.

In the meantime, allow me to call your attention to a few leading remarks, sufficiently enlarged upon in my little volume: they are perfectly independent of all conjecture, and rest not on those vague and versatile grounds which are too often admitted as capable of leading to correct results.

1st. The Law of mortality, whether it refer to an indiscriminate population or to any select portion of it (a distinction always of the utmost importance in applying that law for practical purposes), cannot otherwise be constructed than on an assumption of such total or partial population being of a stationary character. It then exhibits at once the rates of mortality at each year of age; the probabilities, at any age, of outliving any other; the sum total of the living at all ages, together with the distribution of such population into respective quantities of individuals existing at each age in particular;—and from those fundamental statements are to be concluded, with great accuracy, a train of consequences susceptible of being tabulated; amongst which the measures of life's intensity at the birth, or at any other age, and misnamed "*Expectation of life*," as also the "*Equation of life*," denominated in French "*la vie probable*," being the term which, according to any given age, there is an equal probability of attaining or not, and therefore more properly constituting the real "*expectation*."

2dly. When the considered population has been, during any material period, in progress of increase or of decrease, all natural proportions of the just mentioned *distribution* become disturbed. If the population increase, the younger lives will exist in greater or less excess relatively to the whole; and the contrary will occur when such population is on the decrease. Those distinctions, which I always find are overlooked in the arguments and conclusions of authors, have nevertheless a very considerable influence upon results which are the usual objects of research respecting these matters. The difference of distribution materially affects the *general* rate of mortality, and thereby often induces false inferences on that particular point, whilst it is astonishing to see the extent to which those false inferences are sometimes carried. It also affects the ratio of periodic mar-

riages, compared with the quantity of population; together with the average age at which the marriages take place, and consequently the average births to each marriage. Again, and for obvious reasons, that difference of distribution has a material influence, independently of other causes, upon the greater or less proportion of illegitimate births, compared with the legitimate; and in this last respect, I shall merely observe, by the way, that the stated proportion of one-twentieth only, with reference to this country, appears to me much below the mark. It is, however, very difficult to ascertain such a point, under our most miserable system of registries.

3dly. When it is inquired of the “*absolute intensity of life*,”—in French,

“*la vie moyenne*,” with reference to the birth or age zero, and in English mis-called the “*expectation of life*,”—which is, in fact, the precise measure of a *generation*—that intensity is neither to be represented by the quotient of a population, divided by the annual births, nor by the annual deaths, which yield very different results; but is in all cases expressible by a geometrical proportional between those two quotients. The nonsense that has been uttered, printed, and taken for granted, respecting such measures of intensity, as also (as a consequence) respecting the presumed increase of vitality within the last century, is quite amazing.

I shall close this letter by stating two interesting series, the grounds

of which you will find discussed in my book : the first is expressive of the distribution of one million of marriages, into proportionate quantities of those occurring at each age of the wife; and the second is the average of births attributable to each marriage contracted at those respective ages. Observe, however, that such distribution of marriages involves, in each thousand, 18 contracted at ages that exceed 53 years, taken as the limit of child-bearing; that $3\frac{3}{4}$ children then issue on a general average of each marriage within that limit of age; and that if a more considerable average should appear (which I very much doubt to be in any sensible degree the case, even in this country), it must be imputed to a more elevated proportion of early marriages than is shewn by this statement, rather than to any other cause.

The latter series has never been printed, nor have I hitherto communicated it any where, it being an essential datum towards computing the Tables for an Institution I am about to form, for the purpose of granting, at the time of any marriage, endowments to the children who may issue therefrom.

In connexion with my latter statement, a question arises, which I have not hitherto been able to solve to my satisfaction: it is of the *proportion of barren marriages*. Amongst the whole number, I am aware that such proportions vary in different countries. In France, it appears to be *one in fourteen*, or thereabouts, according to the information I have been able to gather there amongst gentlemen of the faculty, and averaging their various statements; but what that proportion may be in Great Britain, I never could discover, our medical men not seeming to have any opinion on the subject. I apprehend that the barren marriages are here in a smaller proportion; and if any of your readers could help me by solving the question, with tolerable approximation to the truth, I should feel very much obliged to them.

I am, sir,
Your most obedient servant,
FRANCIS CORBAUX, F.R.S.

CICERO.

ENGLISH AND FRENCH HOSPITAL SYSTEM.

ONE of the latest productions of the French press is an interesting volume by M. Ferrus, the physician in ordinary of the Bicêtre, who, it will probably be recollected, visited this country a few years ago in a demi-official capacity. The special object of the author's mission was to inspect our arrangements for the treatment of the insane: he was commissioned for the purpose, at his own request, by the *Conseil Général des Hospices de Paris*; and the present work* is the Rapport, giving an account of his proceedings and observations.

There must be always something—curious, at least, if not valuable—in the remarks made by foreigners on our institutions. We can scarcely fail to be more or less profited by such remarks; for by habit we become so familiarized to what is every day passing under our inspection, that we are apt to allow many things, even growing abuses, to go forward unnoticed, until we are, perhaps, awakened to a sort of consciousness of them by the observations of others. To the eye of an intelligent stranger much that to ordinary observers among ourselves possesses little or no interest, is presented with all the air of novelty, and often with no small measure of attraction. This is the case with M. Ferrus, who, while performing the task for which he was specially commissioned, could not help seeing various

* *Des Aliénés.—Considerations* 1. *Sur l'état des Maisons qui leur sont destinées tant en France qu'en Angleterre.* 2. *Sur le Régime hygiénique, &c. &c.* Par G. Ferrus, Médecin de l'Hospice de Bicêtre, &c.

circumstances in our general system of hospital management which struck him as peculiarly deserving of notice. The comprehensive glance which he bestows on our charitable establishments generally, as compared with those of his own country, shews a "learned spirit" of observation. He has just as much impartiality as can be expected from a liberal and well-educated Frenchman: his candour we see no reason to impeach; nor have we any thing to complain of in respect to prolixity or tediousness of style—that besetting sin of most of his compatriot authors: in fact, within a very moderate compass, we find a considerable number of important subjects ably touched upon in the present volume, and treated in a manner at once animated and concise.

The curious contrast afforded by the very different mode in which public charity is administered in the two rival nations, is briefly noticed by M. Ferrus. He traces the charitable principle which actuates the benevolent in both to that motive which, in individuals, constitutes what is denominated *egoism* in masses, a national pride. In England, he says, this national pride, conjoined with the prevailing *fierté*, which inspires so large a portion of the community, and which, in his opinion, is often carried to excess even with charity for its object, works wonders and prodigies. The proof of this, he continues, shews itself every where in the numerous establishments of every description which are thrown open to the destitute and the unfortunate in this country. It is, however, more particularly in reference to the means of education afforded to the young, and to those precluded from the enjoyment of that blessing through the ordinary sources, by reason of some infirmity, that those advantages are thus abundantly supplied: witness the multitude of schools on the Bell and Lancas-

ter system, the establishments for the deaf and dumb, and the institutes for the working classes in all the great towns. Here M. Ferrus candidly confesses, that though France may have shown the way in some of these arrangements, yet that England has far surpassed her in diffusing the benefits that arise from their adoption. "Among our neighbours (he says) the spirit of emulation and enterprise is general, whilst, in France, it scarcely is to be found beyond the precincts of our large towns. In England, according to the common saying, London is found every where. Among us, in point of institutions, Paris is, in too many respects, without rivals."

But the author honestly confesses the difficulty of instituting a comparison between two countries which so essentially differ in their mode of managing their respective institutions. In France, the whole business, financial as well as administrative, in the hospital and asylum system, is conducted under the authority of government: even where an establishment has been raised from funds supplied by the liberality of private individuals, that establishment is as much subjected to government patronage and protection as where it has resulted from a general tax. Not so in England: with a very few exceptions, the state interferes in no respect with the foundation or the direction of public charitable institutions. How then, says M. Ferrus, can any analogy be fairly drawn; much less how can it be pronounced which system is the better? It is probable, however, as the author adds, that *each is best* in its respective circumstances. "Taking into consideration the difference of manners and customs in each country, we should be inclined to conclude that that absence of interference on the part of government, to which the English character is so well

adapted, would be productive of very serious evils among us; whilst, on the other hand, the English would scarcely tolerate a surveillance which they would regard as vexatious, and opposed to all their ideas of liberty, as affects the financial and administrative arrangements of their charities."

We shall not stay to notice some other peculiarities which he observes among us, and describes with a lively vein of humour; our system of making collections at the auspicious moment after a sumptuous public dinner; the periodical meeting of governors of charities in the rich apartments allotted for the purpose; the custom, in most of our establishments, of confiding the direction to one or two individuals on whom an extraordinary degree of reliance is placed;—all this he points out as affording marked contrast between the English and the French, in their respective modes of conducting hospital business; and we think, that, upon the whole, the author is more than half inclined to give his decided preference to the French system. He is a strong advocate for the existence of an active surveillance, as most conducive to uniformity and steadiness of purpose, and to the repressing or reforming of abuses as they arise.

With regard to the *matériel* of our hospitals, we find some pertinent observations, tinctured with a just severity. The author notices what, to him, appears a curious fact—the want of any system in erecting English hospitals. No two are ever built alike; and ground-plan, elevation, and internal economy, all seem dependent on caprice or accidental circumstances. In respect to the supply of baths in our institutions, where there is no reason whatever to complain of an inadequate supply of water, M. Ferrus cannot help expressing his surprise. He found, he says, in

but few of our hospitals a *service* of baths proportioned to the number of patients; and it was with pain that in the Manchester Infirmary, to which, in other respects, he gives due praise, he was informed there was but one *baig-noire* for 170 beds. This palpable and extraordinary deficiency, we presume, has been remedied since the author's visit. Of late years, we know that great improvements have been adopted in many of our hospitals in the construction of suitable bath-rooms.

M. Ferrus gives us great credit for our general cleanliness, and the care taken in our frequent paintings and white-washings—a practice in which he allows we greatly surpass his countrymen. In noticing the general adoption of hammered or cast-iron bedsteads in this country, he says that in St. Bartholomew's hospital alone did he find wooden ones still in use; and the *Directeur* told him, absurdly and ludicrously enough (*par une assez étonnante bizarrerie*), that wooden bedsteads were to be preferred, because they were most easily washed!

In noticing the *personnel* and internal management of our hospitals, he condemns the system of requiring letters of admission from patients—the existence of the disease being the sole passport necessary in France; but he rightly accounts for the maintenance of the system, from the nature of the patronage by which those establishments are supported. Another thing which he censures, with no small show of reason, is the want of arrangement in most of our charities—patients of different ages, as well as of totally different complaints, being found in the same wards: this he very properly conceives to be at once injurious to the *morale* of the inmates, and to their chances of recovery. Rather a remarkable fact is mentioned by our author in his notice of the internal

arrangements : after complaining of the undue freedom with which patients are allowed to go about from ward to ward, and to receive the visits of strangers at all hours, he says he saw, when at Guy's, people selling bad fruit going among the patients, and openly disposing of their wares!* We do not question the author's veracity; but the reader will observe that seven or eight years probably have elapsed since M. Ferrus's visit, within which time great changes for the better in every respect have taken place in the London hospitals, and we presume in those through the country at large.

The *service médical* of our establishments meets with much of the author's commendation. But among those things which he seems to consider as blemishes, we observe that he sets down the late hour of the day at which the *visit* is paid in England, whereas in France, it is, as is well known, the first thing done in the hospitals, to go round the wards early in the morning. We have not room to give the author's remarks on this subject, nor to discuss the reasonableness of the alteration he would suggest; but it may be amusing to state, that he attributes the practice just mentioned to the obstinate *laziness* of the students!

We had intended to give some further specimens of M. Ferrus, for whom we entertain much respect; but our limits for the present prevent us. We have not yet introduced him to the reader on his proper ground — relative to the arrangements for the insane: that subject we reserve for another opportunity, when we shall set forth the best things that are to be said regarding the mad-houses of England and France.

* "Nous avons vu dans l'hôpital de Guy à Londres, des marchands de mauvais fruits parcourir les salles des malades, et se livrer sans obstacle à leur commerce."

COLLEGE OF PHYSICIANS.

THE first meeting for the season took place on Monday, and was attended by between six and seven hundred persons. On the right of the President's chair was seated the Archbishop of Canterbury, on the left the Lord Chancellor. Sir Robert Peel, and others of his Majesty's ministers, as well as most of the judges, and several of the bishops, were also present. A paper was read by Sir Henry Hallford, on the deaths of some eminent persons of modern times, and appeared to excite very general interest. The subject was well suited to a mixed assembly, the language classical, and the delivery excellent.

On the Deaths of some Eminent Persons of Modern Times.

Sir Henry alluded to the attention with which his paper on the Deaths of some Illustrious Persons of Antiquity had been received, as the motive for selecting his present subject, and laying before the meeting some details connected with the decease of some distinguished men of more modern times.

The learned President began his narrative by some remarks upon the monarch in whose reign the College was founded, referring to the pictures of Holbein in illustration of KING HENRY's manly beauty, and to the remains of him which he had seen in his coffin, and to his large arm-chair at Windsor, in proof of his stature. The state of his health in more advanced life, when he became corpulent and unwieldy, made Henry the Eighth a great dabbler in medicine; in fact, he not only prescribed as opportunity occurred, but compounded the drugs himself, as appears by a volume in the British Museum, containing a large collection of the royal *recipes*. The monarch, however, could not avert from himself the evils of mortality, and died at the age of 56, dropsical, and covered with sores.

To WOLSEY, the King gave some excellent instructions how to avoid the sweating sickness; but the Cardinal, who escaped that epidemic, died of a malady which the royal physician might more easily have prevented, had he chosen — a broken heart, to which was added in his last hours an

attack of dysentery. The Earl of Shrewsbury, at whose house he had been on his road from Yorkshire, encouraged his distinguished guest to think more favourably of his health; but the Cardinal, in reply to his cheering speeches, assured the Earl that he could not live,—discoursing learnedly about his ailment, which he said within eight days, if there were no change, would necessarily produce “excoriation of the entrails, or delirium, or death.” This was on the eighth day, when he confidently expected his death, and expired after the clock had struck eight, according to his own prediction—“the very hour (says Shakspeare) himself foretold would be his last.”

EDWARD THE SIXTH was carried off by disease of the lungs, having had measles, as well as small-pox, the preceding year, which left an obstinate cough behind. He was put under the care of an ignorant woman by the Earl of Northumberland, by whose treatment his end seems to have been much accelerated. Sir Henry paid a high tribute to the memory of this intelligent and amiable young king, whose bodily powers bore no proportion to the extraordinary energies of his mind; in this respect reminding the learned author of many examples he has met with, wherein ill health in young persons has led to great powers of reflection, the precocity of their intellectual development “compensating them for the brevity of their earthly existence.”

MARY inherited a delicate constitution from her mother. The peculiarities of her sex being irregular, and requiring frequent medical treatment, bleeding very frequently repeated, and horse exercise, seem chiefly to have been trusted to. After her marriage the symptoms were referred to pregnancy; but she became pale and exsanguine, and at length died of dropsy.

OLIVER CROMWELL, in his last illness, one morning asked a physician who had sat up with him why he looked so sad; and being answered, that it became any one to look grave who had the care of *his* life to answer for, immediately replied—“Ye physicians think I shall die: I tell you I shall not die this time; I am sure of it. Do not think I am mad; I speak the words of truth upon surer grounds than your Galen or Hippocrates furnish you with. God Al-

mighty himself hath given that answer.” Under this confident expectation of recovering, Cromwell allowed himself to be removed from Hampton Court to London. On the following day he became worse—grew lethargic—then delirious—and died September 3, 1658. The spleen was much diseased, and filled with matter “like lees of oil.” It is difficult, continued Sir Henry, to read the history of this period without entertaining a strong suspicion that Cromwell used those solemn aspirations—that affected intercourse with the Almighty—hypocritically, and with political views. Archbishop Tillotson has remarked, that the above is a specimen of that enthusiasm which superseded hypocrisy with Cromwell; but in modern days, when we meet with such allegations in our intercourse with patients, and find them influencing their conduct, “we think ourselves justified in applying to the Lord Chancellor for a writ *de lunatico inquirendo*.”

KING CHARLES II. (according to the account of his physician, Sir C. Scarborough) had just risen from his bed when he experienced an unusual sensation in his head; shortly after which he fell down speechless, and without the power of motion. An army surgeon, who happened to be at hand, bled him to the extent of 16 ounces; after which, on the arrival of the royal physician, his majesty was enpped, and other remedies used—such as an emetic, purgatives, &c.; but he expired on the fourth day. “Had there been safety in a multitude of counsellors, the king’s life must have been preserved; for (added Sir Henry) I perceive the signatures of not less than fourteen physicians to one of the prescriptions.” Among the remedies prescribed when he was sinking, was the *spiritus cranii humani*, 25 drops; which certainly has been improved upon in our modern preparations of ammonia. The learned Baronet here mentioned that he had lately seen a prescription in which a portion of the human skull was ordered, in a powder, for Sir Nicholas Throckmorton. It was dug out of the ruins of a house, in Duke-street, Westminster, which had belonged to Oliver Cromwell’s apothecary. On examining King Charles’s head, a copious effusion of lymph was found in the ventricles and at the base of the cranium; from which Sir Henry is disposed to think

that he might have been still farther bled with advantage; adding, that the result of his experience had convinced him, that, if large depletion be not adopted in the first instance, every thing else attempted afterwards will be unavailing. It is quite evident, from Sir Henry's account, that Charles II. died of apoplexy, and consequently that his indifference to the solicitations of those about him, on religious matters, can only, with charity, be attributed to the effects of his disease.

KING WILLIAM, the Prince of Orange, had a weak frame, and was asthmatic, with a constant cough. He died, at length, of an enormous secretion into the lungs, which first embarrassed, and ultimately prevented, respiration. The lungs were adherent to the pleura costalis, and a fall from his horse, which he had shortly before met with in Hampton Court Park, and by which he had broken his collar-bone, had detached a portion of the adhesion and excited inflammation.

MARY, the consort of William, died of small-pox, and it is remarkable that Bishop Burnet blames Dr. Radcliffe in rather harsh terms, for his treatment of her case. The learned prelate mentions that Marshall Schomberg advised him never to give an opinion upon a military subject; and "I wish (said Sir Henry) that he had received similar council from a physician, and had abstained from remarking on medical affairs." The censure of the Bishop seems to have been quite uncalled for.

DRYDEN died of ossification of the arteries of the extremities, such as produces mortification. His body "lay in state, in the College of Physicians, during ten days, and was then conveyed to Westminster Abbey with great ceremony."

The disease which occasioned DEAN SWIFT to expire "a driveller and a shew," was of a paralytic nature; to which circumstance Sir Henry is inclined to attribute that aberration, not to say depravity of mind, which have excited so much scandal.

"Now I believe," said he, "this irritability was bodily disease; and so far from considering the unsocial and untoward mind as influencing the body to its detriment, I would contend that the corporal distemper was the cause of the perverse and unhappy state of the

mind; that Swift's irritability was of that peculiar nature which accompanies palsy, the seat of which generally is in the brain. Swift was in the habit of suffering severe attacks of headache, and of dizziness, and occasional deafness, when young; even so early in his life as during his sojournment with Sir William Temple. In process of time, there ensued that plethoric state of the vessels of the brain which required frequent cupping; and at length the obstruction became so great as to occasion an effusion of water into the ventricles, and the loss of his faculties by apoplectic pressure. This appeared on examination of the head after death. No doubt this effusion had been preceded by inflammation of the membranes of the brain, and by phrensy. Under these attacks of inflammation and phrensy, he dealt forth his angry denunciations largely; and probably it was in one of these unhappy moments that he composed the Epitaph so injudiciously inscribed on his tombstone in St. Patrick's Cathedral."

KING GEORGE I. died of apoplexy; GEORGE II. of rupture of the right ventricle of the heart.

On the affliction which attended the latter years of GEORGE III., Sir Henry did not dilate. One of his latest hours of rational life was employed in dictating a letter to the Princess Amelia, which he committed to the charge of Sir Henry Halford. It was to express his satisfaction that she had received the sacrament, and sought for comfort in religion. The Princess died within two days afterwards, and her august father was deprived of his reason.

Of the last member of the royal family who has departed this life, Sir Henry spoke in the following terms:—

"A kindred spirit to that of King George III. has lately left us, and has been received, we humbly hope, into the mansions of the blessed.

"The DUKE OF GLOUCESTER's disease was seated in the liver, and involved the stomach in so much irritability as incapacitated it for receiving the smallest supply of nourishment. His powers failed, therefore, and were unequal to the completion of those processes by which his enfeebled constitution attempted in vain to disengage itself from the malady, and to terminate it.

"As the brain was not affected, his mind was left at liberty to indulge its

natural propensity to look into futurity, and to anticipate the fatal issue of the struggle of the body with the disease. With a hope, then, full of immortality, and with an entire confidence in the promises of the Gospel, the Duke easily detached himself from this world, and *desired* to begin the life to come. Never, in all my converse with the dying, did I remark more calm resignation, or a warmer piety. The pain of separation was theirs only who hung over his sick bed; to every one of whom, and to those also who were dear to him at a distance, he bequeathed his blessing, leaving to us all the *rich inheritance of his example*.

“Upon the Duke of Gloucester’s merit as a soldier, it becomes not me to descant; but as a specimen of that bravery which belongs so remarkably to the House of Brunswick (I have it from the highest authority), that when the brigade which he commanded in Holland, in the revolutionary war, was drawn up before the enemy, and could not restrain its fire until it might be given with the best effect, the Duke, that he might prevent it, stepped forth before his soldiers, and interposing himself between his own troops and the enemy, walked deliberately between the two armies.

“Of his conduct in civil life, let the University of Cambridge bear testimony to the prudence and to the spirit with which he defended its privileges in parliament as its Chancellor. His memory will be cherished by that learned body long, I am persuaded, and with a most respectful attachment.

“His private virtues, which gave a dignity and a grace to his interior and domestic habits, were manifested by the steadiness of his personal friendship, by his humane care of the poor in the neighbourhood of his residence, and by his patronage and protection of a thousand charitable institutions; and were recognized and assured by the manner of his departure from life—for, in the spirit of his prayers, ‘he died the death of the righteous, and his last end was like theirs.’”

In conclusion, Sir Henry adverted to the disadvantage under which unprofessional writers necessarily labour, in their attempt to develop the motives of human conduct, on account of their inability to appreciate the effects of disease on the mind.

ROYAL INSTITUTION.

Friday, Jan. 23, 1835.

Melloni’s Experiments on Radiant Heat.

THE evening meetings for the season were begun on Friday last, when Professor Faraday explained to a large audience the nature of those interesting experiments on heat which have recently attracted so much attention on the Continent. M. Melloni, to whose ingenuity the scientific world is indebted for this last, and not least valuable addition to its stores, is, we believe, a professor at Pavia; but the researches which have given him such celebrity have been conducted, or at all events first published, at Paris. The object of Melloni was to experiment on heat, and to procure it, if possible, independent of light; and this he effected by the previous invention of an instrument for measuring the most delicate effects of radiant heat. The differential thermometer wholly failed to answer his purpose; but by the combination of dissimilar metals, forming a pile which, upon the application of heat, should become electric, and operate on a magnetic indicator, his design was accomplished. We shall not at present enter further into an account of the construction of this instrument—the *thermo-multiplier*, as it is called: we hope to have more space at our disposal next week; but we shall mention a few of the effects of radiant heat, as indicated by Melloni’s contrivance. In the first place, it is shewn that heat is transmitted through mediums not in proportion to their transparency or their thinness. Common glass, for example, intercepts 50 per cent. of heat, while rock salt, though five or six times thicker, scarcely intercepts any, or at most but 8 per cent. And so it is with other substances also, according to their structure and colour; as may be seen at once by the following extract from an extensive table:—

Suppose 100 rays to pass from a body, no screen being interposed, the number of rays transmitted when screens of different sorts are used, are these—

Rock salt.....	92
Iceland spar	62
Flint glass	65
Plate ditto	60
Crown ditto	50
Violet stained ditto	53
Red ditto	47
Yellow ditto	34
Blue ditto	33
Green ditto.....	23
Sulphate of copper	0

This last is a very curious fact: sulphate of copper, it appears, though used in

the form of a beautiful transparent blue crystal, extinguishes heat, or transmits none. There are probably other substances which have the same property,—at least the analogy of a great many, which have low transmitting powers, warrants us in coming to such a conclusion. It would further appear from Melloni's experiments, as demonstrated by Dr. Faraday, that heat has its own laws of refraction, as light has; and that a prism of rock salt, through which a ray of heat is transmitted, decomposes the radiant matter, and presents phenomena analogous to those of the spectrum. But with regard to polarization, we believe it has been shewn by Professor Forbes, of Edinburgh, that no property similar to that of double refraction belongs to radiant heat. It is, we understand, the opinion of M. Melloni, founded upon his series of brilliant experiments, that heat is a substance perfectly distinct and independent of light; but Dr. Faraday conceives that he is not warranted in jumping to such a conclusion: heat and light may still be only properties of one and the same general nature, though we have no evidence of what that general nature is.

The bust of the late Mr. Fuller, by Chantrey, an admirable performance, and a fine picture of the late Lord Speneer, the gift of Pickersgill, were presented this evening to the members of the institution. The library was, as usual, plentifully supplied with articles rare and curious, for the gratification of the numerous visitors: there were specimens of zineography, anatomical wax models, new German works, &c. Dr. Ritchie was announced for next Friday (last) evening, On the Newtonian and Undulatory Theories of Light.

MOSCOW HOSPITAL.

Case of Chorea, terminating fatally; with the appearances on Dissection.

MARK VASSILIEFF, aged 13, affected with symptoms of *Chorea St. Viti*, was admitted a patient into Sheremetieff's Hospital on the 23d December, 1833, and transferred on the 10th of January to the Clinical Institution.

The disease exists in a great degree. His body is small and puny-looking, much emaciated, and he has a fatuous appearance; the whole countenance appears as if swollen, and it is red, the upper lip swelled, the nostrils flattened, and his features distorted, which, with the irregular motions to be immediately described, and his impotency, communicates, at first sight, an impression of disgust to the spectator, at

the same time that it excites compassion for his unfortunate and helpless condition. The whole body is affected with the peculiar motions which characterise this complaint; his head is bent downwards, so as sometimes nearly to touch his feet.

In order to prevent his falling from his bed, he has been placed on a mattress on the floor, where he is now rolling himself about in all directions. When spoken to, he understands what is said, but does not speak. The skin is dry, and covered with a dry itch-looking eruption; the skin of the larger joints is thickened and hard, and the abdomen feels hard and tense, from the contraction of the muscles; its volume is moderate; he admits of no covering on his body excepting his shirt, though the temperature of the surface is low, particularly in the extremities, which not rarely appear almost livid. The tongue is moist; his appetite voracious; the pulse at the wrist weak, hardly to be felt; nothing very particular remarked in his breathing.

He is not in a state to communicate any information on the origin of his complaint, but the following has been collected from those with whom he lived.

The boy is an orphan, and has every appearance of having been little attended to. He does not appear to have formerly suffered from any other disease, or to have been exposed to any particular cause to which his present ailment might with probability be referred. About the beginning of his tenth year, his voice became hoarse, and, from time to time, various nervous symptoms, but particularly irregular movements of the muscles, began to be observed. Two years ago these symptoms increased, and gradually became worse, till about the month of October 1833; since then they have continued nearly in their present state. There is no external mark of disease about the spine, and his bowels are said to be regular. During sleep, the irregular movements nearly cease. On the evening of his admission, the following was prescribed by Mr. Ramich, one of the surgeons of the hospital.

R Tinet. Opii, gtt. viii.; Ph. Edin.; Castorei, gtt. xii.; Aquæ Lauracerasi, gtt. xiv.; Liq. Cornu Cervi Succinati, gtt. vi.; Aq. Puræ, ʒi.; M. Pro haustu ad noctem. Balneum tepidum cum furfure omni biduo. Frictio Spinæ dorsæ cum Balsamo anodyno mane et vespere.

31st. — No change for the better, excepting that he sleeps more than formerly.

R Carbonatis Ferri, ʒi.; Pulv. Rhei, gr. vi.; Mellis, ʒi. M. tribus dosibus quotidie consumat.

January 7th, 1834. — State of the patient

improved; unnatural movements less remarkable; he can now stand without help on his feet, supporting himself on the side of his bed; bowels appear to be sufficiently open; faces are more or less coloured by the medicine in use; affection of the skin much as before.—Pergat.

23d.—The state of the patient continues improved; he can now pronounce a few words.

Adaugeatur quantitis Carbonatis Ferri ad ʒiiss. quotidie.

26th.—The state of the patient has undergone a change for the worse; he has passed a restless night, and has been almost constantly crying out; the unnatural movements are increased; the skin is harder than formerly, particularly in the extremities, about the joints; bowels are moved twice in twenty-four hours; voracious appetite continues.

Omit. Carbonas Ferri. Alia contin.

28th.—Increase of symptoms continues; unnatural movements seem to have increased; he passes restless nights. The skin of the right wrist and about the buttocks is incrustated, and affected with fissures. In the lower part of the spine, about the lower dorsal vertebrae, a swelling has appeared, which is rather soft and diffused, about four inches long, and two broad; it does not fluctuate perceptibly, nor does pressure on it appear to excite pain; the skin which covers it is not inflamed. The other symptoms continue.

Omit. frictio cum Balsamo Anodyno; Fricetur pars superior Spinæ dorsæ Ungt. e Tartaro emetico. Balneum in usu contin.

29th.—He has had no stool for twenty-four hours.

Infus laxativi Viennensis, ʒij. Sumat pro dosi. Alia contin.

30th.—After the use of the laxative infusion, he had two stools; slimy, but otherwise little changed from the natural appearance. The cutaneous affection seems rather to increase. The increase which had taken place these last days in the spasmodic symptoms has again subsided, and he is now nearly in the same state in which he was when he was brought to the clinical ward. He is said to be considerably incommoded by the itching of the cutaneous affection; his tongue is quite clean.

R Florum Sulphuris, ʒss.; Mellis despumati, q.s. ut fiat electuarium, ejus datur moles cochlearis thearii, pro dosi bis in die. Omit. medicamentum eum Tinet. Thebaica et Aqua Laurocerasi, vice ejus pulverum sequentem sumat ad noctem. Ext. Opii aquosi,

gr. ij.; Aleo-sacchari Menthae, gr. xvi. Intime miscantur et dividantur in partes viii. quarum anam capiat pro dosi ut supra praescriptum.

7th Feb.—The cutaneous affection seems rather to diminish; there is but little change in the state of the unnatural movements; sometimes, however, he is able to walk a little; he passes the night pretty well; unnatural appetite for food continues; the stools passed yesterday are strong smelling, have a less natural appearance than the last described, and contain an *Ascaris lumbricoides*.

Repetat. frictio cum Ungt. e Tartaro stibiato, et quaque vice utatur, ʒi. pro frictione ad totum tractum Spinæ dorsæ, mane et vespere. Contin balneum.

12th.—From continued friction of the skin on the breast, the skin under the first is excoriated; he is said daily in the morning to walk about for some time without assistance, but not during any other part of the day.

R Sulphatis Kininae, gr. i.; Amyli, gr. i. M. bis in die sumat ex melasse. Alia contin.

16th.—The emaciation of the body and general debility are increased; the bowels are open, the stools of a very vitiated nature. From the irritation of the tartar-emetic ointment, a copious eruption of pustules (which, however, in a great measure are now dried up), has been produced.

Elect. in usu semel in die tantum sumat; alia contin. Omit. pro tempore frictio cum Ungt. e Tartaro stibiato.

18th.—The convulsive movements have ceased; no pulse to be felt at the wrist.

Omit. medicamenta in usu.

R Vini albi Hispan. ʒiij. detur cochlearim cum aqua tepida ex tempore ad tempus.

19th.—Died about four o'clock this morning.

Dissection.—The examination of the body took place thirty-six hours after death.

Hardly any remains of the cutaneous eruption described in the history and progress of the case are to be seen in the dead body, unless it be in the hands, where some rhagades are still visible. The body in general is very much emaciated; the upper part of the abdomen collapsed, and its skin livid, the under part in some degree swelled. The swelling is soft, but not tense.

The pericranium was unusually pale, and hardly a blood vessel is perceived. The thorax was rather more than usually

prominent. The substance of the brain was in general perhaps somewhat softer than common, but no other morbid appearances observed in this organ. The muscles of the back were of a moderately red colour, and no remains of the swelling mentioned in the report of the 28th January appear.

On opening the vertebral canal, there was observed on the external surface of the coverings of the spinal cord, through their whole course, an unusual redness, which seemed to arise partly from congestion of venous blood in the vessels of the cellular membrane of these parts, and partly from effusion of blood into it, the whole cord appearing as if imbedded in a soft coagulum of blood; in certain parts the colour of the blood was arterial. The coverings of the cord being laid open, the watery fluid of this part was discharged prettily copiously; the colour of the cord was much less red than the external surface of its membrane, and its substance generally softened into a pulp.

On laying open the abdomen, the swelling of the lower part was seen to have been produced by the distention of the urinary bladder. The convex surface of the liver, particularly the right lobe, adhered to the diaphragm by firm, evidently not recent, adhesions; the smaller intestines were empty nearly through their whole course; the colon contained liquid bilious faeces in moderate quantity, of different colours, and of the same nature with what had been discharged during the last days of his life; no organic disease appeared to have existed in the internal surface of the stomach and intestines; the rugæ of the former were very prominent; seven *Ascarides lumbricoides* were found in the cavity of the intestine ileum.

The liver had a deep dull-red colour, but no notable congestion appeared in this organ, its volume small, and its substance not differing much from its common consistence, though the look of the organ was unhealthy. The heart was unusually small for a subject of 13 years, though proportioned to his stature in some degree; its internal structure natural; partial old adhesions of the *pleura costalis cum pulmonali* existed. The lungs and other organs were nearly natural*.

DESTRUCTION OF THE SHEFFIELD MEDICAL SCHOOL.

WE regret to learn that the Medical School at Sheffield was entirely destroyed a few days ago by the populace, who, in one of those paroxysms of ignorant phrensy which occasionally seize them with respect to in-

stitutions of this nature, broke into the building on two successive days, threw the books, papers, preparations, and whatever they met with, into the street, and ended by breaking the window frames and tearing up the staircases and floors, which they deliberately burnt before the door. We must add, that our accounts of this disgraceful riot, which at last required the intervention of the military to quell, lead us to suppose that a great want of arrangement and energy is attributable to the civil authorities.

LITERARY NOTICE.

In the ensuing autumn will be published, in one vol. 8vo. a *System of Human Anatomy*; compiled from the Works of Cruveilhier, Meckel, and other Authors of celebrity, with Notes, by Mark Noble Bower, M.R.C.S.

NOTICES.

DR. LYONS ON CLUB-FOOT.—There were some sketches sent with the paper on Club foot, which we lately published; but we did not think them necessary for the elucidation of the subject, and could not well afford space for their insertion. The name of the second patient, by the way, we are requested to state was Filler, not Triller.

MR. RICKMAN'S paper has been received. It shall appear in our next.

The very extraordinary account of the Nose operation, "done" at the Valetudinarianum on Saturday last, has reached us.

ERRATUM.—In the case of Henry Ingram, published in our last number, page 604, col. 1, in the second prescription, the quantity of nitrate of silver ought to have been gr. i. instead of gr. iv.; and in the third prescription, the dose of liq. arsenical. $\text{℥} \text{iv}$. instead of $\text{℥} \text{x}$.

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE XIX.

SIGNS OF PLEURISY.

WE now, gentlemen, proceed to consider the signs of the different stages of pleurisy.

1. *Red, or Acute Stage.*

Local signs—Pain.—One of the most constant signs of this stage is a violent pain in the side. It occurs generally at the point corresponding to the inflamed part, which is usually along the line of the 6th, 7th, or 8th ribs. Laennec observes that this sensation sometimes is felt on the healthy side only. I cannot say that I have ever yet distinctly met with an instance of this variation. The pain is always augmented by inspiration and coughing, in consequence of the lungs being pressed against the inflamed pleura by these movements.

Rheumatism of the muscles of the chest, or *pleurodynia*, often produces pain similar to that from pleurisy. The diagnosis may easily be determined by desiring the patient to move his arm in various directions: these acts will be rendered difficult if the pain be caused by *pleurodynia*, but not so if it arise from pleurisy. The inflamed muscles are also tender upon pressure, and there is generally rheumatism in some other part of the body at the same time.

In severe cases of pleurisy, the patient endeavours to breathe with the healthy lung only, in consequence of the pain

which the inflation of the organ on the diseased side occasions. Examine the affected side, and you will perceive that the ribs are almost immovable. The same circumstances occur also in *pleurodynia*.

Respiratory murmur.—As the patient rarely fully dilates the lung corresponding to the inflamed pleura, the respiratory murmur becomes very obscure and indistinct.

Functional signs.—*Dyspnœa* is always present, but it varies greatly in its intensity, according to the degree and extent of the inflammation. This sign depends not upon any disease of the lung itself, but upon the pain which a full or even ordinary dilatation of it gives, so that the patient breathes by short inspirations, which must necessarily be frequently repeated to establish the balance between the quantity of air and the quantity of blood in the lungs. It is in this case that the inspirations are shorter in their duration than the expirations.

The *dyspnœa* would, of course, be more severe if any disease of the bronchial tubes, or pulmonary structure, were combined with the pleurisy.

Cough is by no means a constant sign of this stage of the disease; if it be present, it is usually slight, dry, and infrequent, except there be catarrhal combination; then there will be an expectoration, more or less abundant, of mucous or pituitous fluids.

General signs—Fever.—Intense inflammatory fever frequently accompanies this stage; it usually lasts but a few days, and ceases upon the disappearance of the pain in the side. It does not follow, however, because the fever and pain cease, that the disease is cured; for effusion will frequently still continue. The *dyspnœa* then slowly increases, a slight febrile action reappears, and upon a local examination of the chest, you will find the signs of effusion becoming daily more manifest. The slightest *dyspnœa* and fever occurring after the apparent

cure of acute pleurisy, require your utmost attention.

2. Stage of Effusion.

We shall first describe the signs of the increase and accumulation of the fluid, and secondly of its decrease.

Local signs; Increase.—Respiratory murmur.—As soon as a thin layer of fluid is formed between the pleuræ, the respiratory murmur almost instantly ceases; its cessation is so sudden, that it would appear that the lung was at once arrested in its movements by a sort of suffocation. The fluid may even afterwards slightly increase in quantity, and the respiration be occasionally heard, although at a distance, appearing as if the organ had accommodated itself to the pressure to a certain degree, so that it could perform its movements, although to a slighter extent than natural. As the fluid increases considerably, the lung becomes so compressed, that very little air enters it, and the sound of the respiratory murmur is then totally lost.

There is, however, a certain point of the chest at which the respiratory murmur is almost always present during this stage; it is between the base of the scapulæ and the vertebral column. This space corresponds to that occupied by the compressed lung. Whenever, also, the organ is retained at a spot by previous adhesions, there also the murmur may be heard: thus it is sometimes distinct at the summit of the lung, or even at the side of the chest; in the latter case it is generally circumscribed to a space of inconsiderable dimensions. Occasionally, too, the effusion is so slight as not to reach as high as the upper lobe, to compress it. In that case the sound is there distinct also.

In proportion to the diminution of the respiratory murmur on the diseased side, the necessity for respiration increases in the healthy lung; the functions of the latter become more energetic; its movements quicker; the expansion and contraction of its cells more active, and consequently the respiratory murmur is louder, and assimilates to that of children, from whence it is called *puerile respiration*. The respiratory sounds of the healthy lung are sometimes so intense, that they may be even slightly heard through the accumulated fluid, giving the sensation of their arising from the compressed lung. A little practice will soon, however, correct any error that might arise from this circumstance.

As a total absence of the respiratory murmur occurs also in a hepatized lung, it is necessary to observe, that in the latter case it is never sudden, and is always preceded by crepitation, the sign of pulmonary engorgement.

(Ægophony.—When a slight layer of fluid

exists between the pleuræ, ægophony becomes its sign. I have entered so largely upon this sign in my lecture on Auscultation, that it is unnecessary to repeat it here; but I refer you to that lecture. I shall, however, state, that ægophony appears when the effusion commences; that it disappears when it becomes abundant; that it may remain for many months when the fluid continues in a small quantity; that it is most complete at the upper edge of the effusion, or where the layer of fluid is thinnest; that it may be accompanied by *tracheophony*; and, finally, when the sound is heard all over the chest, it may be affirmed that the effusion is slight, and uniformly spread all over the lung. In the latter case the respiratory murmur may still be slightly heard, because the layer of fluid is not sufficient to compress the lung, so as to prevent the air penetrating it; and if these latter circumstances continue during the whole period of the disease, you may be certain also that the lung is retained at a small distance from the ribs by cellular bands disposed here and there between their surfaces.

Percussion.—Although the sound on percussion is usually loud in proportion to the quantity of air contained in the lungs, yet in this case, a small quantity of fluid placed between the pleuræ seems as effectually to destroy the natural sound as a larger. Thus it is, that as soon as a thin layer of fluid is formed, indicated by ægophony, percussion gives a perfectly dull and fleshy sound, which, of course, remains during the augmentation of the fluid.

Signs arising from the pressure of the fluid upon the surrounding parts.—You recollect, gentlemen, that when I described the morbid anatomy of this stage of pleuritis, I described also the effects of the pressure of the fluid upon the surrounding parts. We must now attend to the signs of these effects.

The lung is first acted upon, diminished in volume, and pressed against the vertebral column, accounting therefore for some of the signs we have just mentioned, as the absence of the respiratory murmur all over the affected side of the chest, excepting the space comprised between the base of the scapula and corresponding vertebræ; accounting, too, for the dullness of sound on percussion. The heart is also pushed from its situation, so that if the effusion exists in the left side of the chest, that viscus is forced over to the right, consequently the sounds of its beatings are often entirely lost at its natural position, and are heard only immediately beneath the sternum and at the right side of that bone. If the fluid be on the right side, the heart is forced beyond its na-

tural position to the left, and the sounds are heard farther in that direction. The fluid then depresses the diaphragm, but that pressure is resisted on the right side by the liver, so that the latter organ is rarely sufficiently displaced to force its anterior edge below the margins of the cartilages of the false ribs; but when the left side of the diaphragm is pressed down by the fluid accumulated upon its superior surface, it forces the stomach before it, and a considerable irregular and diffused swelling is produced below the margins of the cartilages of the left false ribs.

In examining the effects of the pressure of the fluid outwards, you will remember that I stated that the internal surfaces of the intercostal muscles were brought to a level with the external surface of the ribs, by which all appearance of intercostal depressions between the ribs is entirely effaced, giving to the whole side a general smoothness singularly contrasting with the healthy side of the chest. The ancients considered œdema of the surface to be a sign of effusion, but I have no doubt they have confounded that state with the smoothness and fulness I have just mentioned. Be that as it may, I have never seen the skin pit upon pressure in more than two or three instances in above thirty cases. You will recollect also, gentlemen, that I described the ribs as projecting outwards, whereby the diseased side becomes more or less enlarged: this may readily be detected by the eye. Confirm this sign by measuring the chest as I have directed, and you will find that the difference in the circumferences of the two sides will often be considerable. I have seen it from a quarter of an inch to two inches. These variations of course arise from the different quantities of fluid contained.

Immobility of the ribs.—Another valuable sign of effusion is the immobility of the ribs of the diseased side. The reason of this is obvious: if the lung be so compressed as to receive no atmospheric air, the respiratory functions are not carried on in it, and of course the action of the ribs is unnecessary. If the quantity of fluid be large, you will see that the side affected is perfectly immoveable, forming a striking contrast with the opposite, where the ribs are elevated and depressed with considerable rapidity, in consequence of the respiration being carried on in the healthy lung only.

Position of the patient.—If the patient place himself upon the healthy side, the fluid compresses the mediastinum and opposite lung, and produces a sense of suffocation. He almost invariably, therefore, places himself upon the diseased side.

Such, gentlemen, are the signs of effu-

sion, upon its increase and utmost accumulation. I will now mention those by which its diminution can be ascertained, and the formation of cellular membrane or fibro-cartilage determined.

Signs of formation of cellular tissue, or fibro-cartilage, or of decrease of effusion.—As the absorption of the effused fluid takes place, if the lung be not bound down too firmly by a false membrane, that organ gradually dilates, and in proportion to its expansion the respiratory murmur becomes again audible: the sound is at first most distinct where it had never entirely ceased—that is, between the base of the scapula and the corresponding vertebræ. As the fluid recedes from the upper part of the pleuritic cavity, the murmur is heard at the anterior-superior part of the lung, on the summit of the shoulder, and in the axilla; and as the secretion still farther diminishes, it becomes distinct successively at the various parts of the chest, from above downwards. If, however, any previous adhesions exist, such as I have already described, the murmur is first heard at the points corresponding to them.

Let us suppose that the absorption continues: the layer of fluid between the pleura then becomes thinner, and the ægophony returns; the *ægophonia redux* of Laennec. This sign ceases with the total disappearance of the fluid.

The sound on percussion is often a long time before it becomes natural, and in some cases, perhaps, never.

The mobility of the ribs returns in proportion to the degree of expansion of the lung.

All the symptoms I have described are proofs of the absorption of the effused fluid; but the only pathognomonic sign I am aware of, denoting the union of the pleuritic surfaces by cellular tissue, and not by fibro-cartilage, is, that in the first case the chest does not contract, nor do the sternum and vertebræ deviate from their natural position on the median line; while, in the second case, the contraction and deviations are always more or less considerable. The reasons of this difference appear to me to be as follow:—

If the adhesions be of a fibro-cartilaginous character, it is always a proof that the original false membranes were thick, that the lungs were bound down proportionably, and that consequently the freedom of the expansion of that organ was diminished. It is under these circumstances that nature makes her great effort to approximate the parietes of the chest to the compressed lung; and when that is effected, which it occasionally is, then the union of the two false membranes form fibro-cartilage. As the extent of the contraction is in some degree a measure of the

compression of the lung, and of the thickness of the membrane binding it down, so it becomes a sort of measure of the thickness of the united false membranes.

On the other hand, when the lung fully dilates, the compression inwards of the diseased side of the chest is unnecessary; the false membranes then do not exist at all, or are very thin. Thin false membranes do not form fibro-cartilage, but cellular tissue; therefore, when you find that after the signs of effusion have disappeared, the chest is not contracted, you may pretty certainly infer that the adhesions are of cellular tissue. Look to this subject for yourselves, gentlemen, and you will find your post-mortem examinations will bear me out in my assertion.

Functional signs of effusion.—The principal functional sign of effusion into the cavity of the pleura, is *dyspnœa*; which is generally of an intensity proportionate to the quantity of fluid accumulated. As, however, the disease becomes chronic, the general emaciation of the body and diminution of the mass of the blood is so great, that a less quantity of that fluid is sent into the lung than in the healthy state, and consequently less air is required; and for this reason the difficulty of breathing is not always in proportion to the quantity of fluid effused. If a catarrh co-exist, the *dyspnœa* is of course increased. *Cough*, if it be present at all, is usually dry, or the expectoration consists only of a small quantity of pituitous matter.

General signs of effusion.—As the effusion becomes chronic, great emaciation is the consequence. I know of no disease in which the body becomes so attenuated, except in phthisis, or after fevers of long duration.

Causes of pleurisy.

The causes of pleurisy are the same as those of other inflammatory affections. The disease may take place in individuals of all temperaments and ages; those of thin stature and of narrow chests are the most predisposed. Excesses of all kinds favour the action of the external causes, by diminishing the general powers of the system. The external causes are exposure to long-continued cold, or sudden transitions from heat to cold, or from cold to heat; suppression of habitual evacuations, blows, fractured ribs, &c.

Treatment of Pleurisy.

Acute or red stage.—Our indication here is to destroy the inflammatory organism, and one of the most powerful means of effecting it is by resection: the moment, therefore, that the pain in the side presents itself, a bleeding should be practised proportionate to the intensity of the disease

and to the power of the patient. I need not repeat here, that one copious bleeding is more effectual than a number of small ones; thus it is the practice in this country to bleed until the patient be completely relieved, so that he can breathe freely and without pain, or until he faints; and it often occurs that by this bold proceeding a farther abstraction of blood is unnecessary. This means should be repeated while the pain and fever continue with any degree of intensity. When the force of the pulse is diminished, and the pain in the side, although lessened, nevertheless continues, topical bleedings are useful—as cupping, or leeches; these may be followed by hot fomentations, although the latter are of little use unless they be continued for a considerable time, as an hour or two, or until the patient falls into a copious perspiration.

The tartar emetic has been employed in this stage of the disease, but its effects are not equal to those produced by mercury; and I state here, what I believe I have mentioned before, that the tartar emetic seems to have most power in reducing inflammation of the parenchymatous structures, and mercury that of the serous membranes; at least such is the result of my experience.

From the commencement of the disease, after clearing the bowels, I begin the free use of mercury, by administering calomel every three hours, in doses of two or three grains, combined with a quarter of a grain of opium, if the bowels are irritable; if that irritability be great, the safest method is, then, to rub in freely the strong mercurial ointment instead, and you will almost invariably find that when the mouth becomes tender, the inflammatory symptoms are all subdued.

Blisters are also advantageous, when some relics of pain are left, and when the inflammatory fever has subsided; but if the pulse be quick and full, and the skin hot, I think they only irritate, without producing any good effect upon the disease. Mustard cataplasms are the best applications for children.

It is hardly necessary to state, that during the treatment of this stage the diet should be strictly antiphlogistic.

Stage of effusion.—But, gentlemen, when we arrive at the stage of effusion, and when that state has become chronic, our indication is altogether changed: we have no longer an inflammatory action to subdue, but we have to facilitate the absorption of a fluid. Nature is most frequently sufficient to effect this herself; but when the fluid largely accumulates, and especially when the false membranes form, then her process is too slow to be compatible with the safety of the patient, and art must

supply the remedies, which frequently, although not always, are successful.

The indication, then, is to cause the absorption of the effused fluid. Various means have been adopted with this view, as purgatives, particularly the claterium. Mercury, powerful as it usually is in effecting absorption, rarely succeeds in this case; diuretics, too, are but faithless remedies here. The acetate and nitrate of potash, the squills, digitalis, &c., have all been successively used, but they have not fulfilled the indication. Counter-stimulants, as blisters, setons, and cauteries, rarely either render much service.

Why are these means, usually so active in promoting absorption, so powerless in these cases? It is because the false membranes lining the inflamed parts, and enclosing the fluid as in a bag, are themselves inorganic, or nearly so. How is the function to be performed through so thick a structure of inorganic lymph? It is scarcely possible. If, then, after having tried these remedies,—and it is proper you should try them, for you cannot be certain at this moment that the false membranes exist at all,—you find you make no progress, and that the patient daily becomes worse, you should then evacuate the fluid by mechanical means—by performing the operation of *paracentesis thoracis*. As I have had occasion to direct this operation frequently, and have proposed certain modifications in effecting it, perhaps I may be excused from entering into some details upon the subject.

Paracentesis thoracis.—Our time does not permit us to enter into the history of this operation: it was evidently performed by Hippocrates, and those of his school; for the directions they give are too practical not to have depended upon actual experience. The history of the operation of *paracentesis thoracis* resolves itself into the description of the various opinions as to the place where it should be performed, and the means by which the chest should be perforated. I refer those who wish for information upon this subject to the ninth volume of Sprengel's History of Medicine. I have proposed the following means of evacuating fluid from the chest.

In the first place, re-examine your patient with the utmost care; satisfy yourself that the percussion gives a dull sound; that there is no respiratory murmur; that the heart is pushed out of its situation; that the movements of the affected side are nearly or wholly lost; that the intercostal spaces are effaced, giving to the whole side a round and smooth appearance; and, finally, assure yourself by mensuration that the diseased side is the larger. If all these signs co-exist, you may be certain that fluid is present.

I have proposed an instrument by which you may prove the existence of the fluid with but little pain, and no danger, to the patient: it is the needle I present to you: it is somewhat thicker than that used for acupuncturation; it is about two inches in length, pointed like a trocar, and has a groove running nearly to its point: the groove should be made as deep and as wide as the thickness of the instrument permits. Selecting the centre of the most bulging part of the chest, which is usually between the seventh and eighth ribs, and about a hand's breadth from the spine, I then carefully examine for the intercostal space by feeling for the edges of the ribs (for you recollect that the appearances of these spaces are lost to the sight), and introduce the instrument as nearly as possible into the centre; for if you pass it upon the superior edge of a rib, you will find that the moment the intercostal muscles are pricked by it, they will contract and bring the two ribs together, so that instead of penetrating the space, the point of the instrument will strike the bone itself, be thrown up, and you may be foiled in your attempt, simple as it is, and endanger also the intercostal artery. If, however, you perforate the centre of the intercostal space, you can easily penetrate into the chest.

The needle being introduced to about three-quarters of its length into the pleuritic cavity, determines at once the presence of the fluid, and, what is equally important to the future steps of the operation, its nature; for if it be serous, it will pass readily along the groove, and trickle down the back of the patient; if it be puriform and thick, it will not freely flow, but a thick drop or two will be seen at the external orifice; and on withdrawing the instrument you will find its groove filled with pus. In the first case, you may satisfy yourself that the false membranes scarcely exist at all, or at least are so slight that the lung may expand freely, and therefore more fluid may at once be evacuated; in the second, the probability is that the membranes are of greater thickness—that the lung will consequently be less free in its movements—and therefore that but a small quantity of fluid should be allowed to flow at a time. The different degrees of thickness of the matter shew you also the size of the trochar you should subsequently use, as a small one is sufficient for the evacuation of a serous fluid, but a large one only permits the continuous flow of thick puriform matter.

The advantage of this instrument is, that it demonstrates the presence of the fluid, and allows, therefore, the future steps of the operation to be conducted unhesitatingly; that it causes but little pain to the

patient; and is as harmless in its effects as an acupuncture needle.

Having withdrawn the needle, you may then introduce a trochar, the size of which, as I have already hinted, should be according to the thickness of the fluid you have discovered; if it be mere serum, a small hydrocele trochar is sufficient; if it be a thick puriform matter, a much larger instrument must be introduced, otherwise the flow will be tedious. I recommend you, gentlemen, to be extremely careful in having the instruments sharply pointed, for if they be not, after the pleura has been penetrated by them, the false membrane, from its imperfect attachment, may be driven before the point, and the operator foiled.

The quantity of fluid you should permit to escape must be according to its thickness; if it be mere serum, you may evacuate two or three pints, and the lung will freely expand; if puriform, I generally allow from twelve to sixteen ounces to flow before I stop it,—recollecting that the lung is then, to a certain degree, bound down by the false membranes.

It now becomes necessary to establish a communication between the pleuritic cavity and the exterior; for this purpose, I fit a portion of gum-elastic catheter, previously cutting off its rounded extremity, into the canula of the trochar, and pass it through that instrument into the chest, to the distance of about three inches; the canula may then be withdrawn, allowing about four inches of the catheter to remain at the exterior, which may be secured in its position by tapes attached to it, and passed round the body: the whole should be still farther secured by adhesive plaisters.

The fluid now passes through the catheter instead of the canula of the trochar, and you may stop the flow by introducing a small plug, made of a portion of bougie, into the external extremity of the former instrument. Having thus a free communication at will, I daily evacuate a certain quantity of fluid, retaining the catheter in the wound for two, three, or four weeks; in fact, until I can obtain no more fluid. You need not be apprehensive of the presence of the gum-elastic catheter in the cavity of the pleura; I have never seen it do harm. From its elastic nature, it soon bends, and places itself closely to the inside of the ribs.

You will often find that after the second day sufficient ulceration is effected, by the presence of the catheter in the wound, to enlarge it; in that case the fluid flows, though very slowly, by the side of the instrument. I endeavour to favour this by directing the patient to lie upon the diseased side. Often, after the instrument is entirely withdrawn, a fistulous orifice will

remain for some weeks, from which a slight discharge passes. I have always seen that this circumstance is favourable, and have never observed danger to arise from it. Some have feared that air would enter, and occasion inflammation. No doubt air frequently does enter into the cavity, but I have not perceived it produce this result; indeed, the slightest reflection must shew us, that the false membranes are as yet incapable of inflammation, in consequence of their inorganic nature.

Lacnec states that the operation for empyema is rarely attended with success. I cannot agree with him in that opinion. If he had said that the operation, when performed for the cure of pneumothorax combined with effusion, was generally unsuccessful, I most fully agree; for it has occurred to me, that out of sixteen individuals in whom paracentesis thoracis has been performed for simple effusion of serum, or puriform matters in the chest, twelve have perfectly recovered, and four only have died. Where, however, there has been a combination of pneumo-thorax and effusion of fluid, the operation has been invariably unfortunate in its results. The reason of this difference will be rendered obvious when I treat of the latter disease.

The causes which render the operation for simple effusion unsuccessful, are the existence of tubercular or other disease in the lungs, and above all, the degree of thickness of the false membrane, which prevents the contracted lung from expanding. I have found that children most frequently recover, probably from the lungs being more commonly healthy in them, and from the great pliability of their chests, by which the parietes fall in more readily upon the contracted lung.

I shall in the next lecture offer a tabular view of these operations, with their results.

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Continued from page 626.]

Causes of Inflammation of Nerves.

INFLAMMATION may be produced by a variety of causes, amongst which may

be enumerated exposure to cold, exemplified in the painful affections of the face which occasionally arise from that cause. It is, however, in my estimation, very doubtful whether in these cases the direct impression is made upon the nerve. It appears, upon the whole, more probable that surrounding textures are first attacked, and that the nerves become implicated by simple extension of disease. It is rare to observe, from such cause, the affection of nerve without preceding swelling of the face; whilst the swelling of the face is of every day occurrence, without being attended or followed by any neuralgic affection. The symptoms vary according to the nerve which is affected. The sensitive branches of the fifth pair being the most superficial, are most liable to inflammation; and hence the frequency of tenderness of the cheek, teeth, jaws, and even complete facial neuralgia, which will generally subside with the subsidence of the inflammation. Sometimes, however, the portio dura has been affected either primarily or secondarily, when convulsive movements supervene, as has been remarked by M. Jolly with respect to the "*névralgie sous orbitaire*," which, he says, is sometimes accompanied with convulsive movements of the lower eye-lid, the cheeks, and the upper lip, and in the "*névralgie maxillaire*," which is often attended with partial convulsive movements, producing deformity of the mouth and eye-lids*. Still more frequent examples of the direct influence of cold in producing neuralgic complaints will be found in that form of ischias, first particularly noticed by Coteugno, under the appellation of the "*ischias nervosa*†." This is constantly the result of exposure either of the whole body when heated, or of the part itself—as in sitting upon damp grass—to cold; and the symptoms, treatment, and dissection, all tend to prove that, in such cases, both the neurilema of the nerve, and frequently the medullary filaments themselves, are inflamed.

M. Martinet, in his very interesting memoir on Inflammation of Nerves, has given a striking instance of the influence of cold. It is stated that pain in the course of the right sciatic nerve began

soon after exposure to cold when in a state of perspiration; and dissection exhibited the nerve thickened to double its natural size, for an inch and a half after its escape from the pelvis, of a violet colour, and dotted with ecchymoses; the neurilema connecting the medullary filaments being in a state of congestion and inflammation*.

The ulnar nerve also, from its superficial situation, is subject to a similar malady from the same cause, the frequent operation of which in occasioning neuralgia has been particularly noticed by M. Jolly. "*Les individus qui, par état, sont habituellement soumis aux effets du froid et de l'humidité, tels que les pêcheurs, les marins, etc. ceux qui habitent des contrées marécageuses, qui s'exposent à l'impression d'un vent froid et piquant, à l'effet des vicissitudes atmosphériques, sont particulièrement exposés aux névralgies. En cela, l'axiome si connu des anciens: 'le froid est l'ennemi des nerfs' est d'une exactitude parfaite.*"

Mechanical violence is no unfrequent cause of inflammation of nerves, and this whether the injury be a contusion, or consist in the partial division of a nerve by a pointed or cutting instrument. A blow upon the eye-brow has produced *tic douloureux* in all the parts supplied by the supra-orbital branch of the fifth pair‡. A laceration of the scalp by a fall from a horse, implying some contusion of the nerves, has produced "*headache and pain along the course of the nerves on one side of the head, a tenderness and indescribable sensation on the scalp, a puffing of all that side of the face, and swelling of the eye-lids of the same side*§." A gunshot wound of the arm, implicating the biceps and coraco-brachialis muscles, as well as the radial and internal cutaneous nerves, has caused severe neuralgia, afterwards attended with convulsive movements||. An injury also from a gunshot wound, upon the outside of the leg, has been the cause of very severe neuralgia, with convulsive movements of the limb, which continued eight years, until relieved by the division of the nerve¶. Of

a similar kind is the interesting example of "symptoms resembling the *douloureux*, from a wounded nerve," related by Mr. Denmark*. The fragment of a musket ball, lodging amongst the posterior filaments of the radial nerve, "produced such exquisite torture" as to induce the patient not only cheerfully to submit to, but even to court, amputation, which afforded some chance of relief to his suffering. A small tumor could be felt on the site of the wound on the anterior part of the arm, which he could not bear to be touched without evincing additional torture. He described the sensation of pain as beginning at the extremities of the thumb and all the fingers, except the little one, and extending up the arm to the part wounded. It was of a burning nature, he said, and so violent as to cause a continual perspiration from his face. His agonies, he observed, were insufferable, depriving him of sleep, and the enjoyment of his food. The little sleep he had, if it could be called such, was disturbed by frightful dreams and starting. All movement gave him great pain; but he had little control over the action of the muscles. The fore-arm was constantly bent in the supine posture, and supported by the firm grasp of the other hand; the wrist was also bent, being unable to move it in any other position by the voluntary exertion of its own muscles. He could bear the extension of the hand, but with increased pain. It always, however, upon the removal of the extending power, fell into its former bent situation. The act of pronation he could also bear to be performed by Mr. Denmark, but in like manner with increase of pain. Amputation above the elbow gave instantaneous relief, and he was discharged from the hospital (Hasler) cured in three weeks, having in that time rapidly recovered both his health and strength. On dissecting the arm, the radial nerve was found *blended with, and intimately attached to, the wounded parts, for the extent of an inch*. It had been wounded, and at the place of the injury was "*thickened to twice its natural diameter*," and seemed as if contracted in its length. A small portion of the ball, which had been driven off by grazing the bone, was firmly imbedded amongst the fibres in the posterior part of the wounded nerve. The nerve was *evi-*

dently thickened both above and below the wound.

This case presents to our notice several points of very considerable interest. It is clear, in the first place, that the symptoms were not the result either simply of the mechanical injury, or of the mere lodgment of the fragment of ball amongst the filaments of the nerve; for after receiving the wound, a considerable interval elapsed before the symptoms occurred. "The wound soon healed, and without manifesting any particular symptoms during the cure." The period which elapsed between the infliction of the injury and the occurrence of the symptoms is not mentioned by Mr. Denmark; but in one of the two cases just referred to, eight days, and in the other eighteen, elapsed after receiving the wound, before the symptoms of inflamed nerve manifested themselves. Secondly, the sensations of the patient presented the well-marked characters of inflamed nerve. Such was the inordinate sensibility, that the torture from touching the tumor was exquisite; the pain also at other times being such, that "the largest doses of opium could not assuage it," and was "of a burning nature;" and, lastly, the case seems to confirm the principle so amply and aptly illustrated by Sir Charles Bell, Magendie, and others, that the fibrils of sensation are, throughout their whole course, distinct, though contained within the same external covering, from those of motion; for it does not appear that there were any convulsive movements throughout the progress of the disease, although "the symptoms resembling the *douloureux*" were so insupportable. Upon the whole, the case is an admirable illustration of inflammation of a nerve, producing its ordinary symptoms, occasioned by severe mechanical violence done to the nerve itself.

Ligatures upon nerves may be considered as modes of mechanical violence, nearly allied to contusions. If these are so thick as not completely to destroy the continuity of the nerve, or to intercept altogether the transmission of nervous influence, the symptoms during life, and the appearances upon dissection after death, or after a surgical operation implying the removal of the injured portion, abundantly establish the existence of inflammation. This appears from the experiments of Swan, Descot, and others, and from the occasional re-

* Med.-Chir. Trans. vol. iv. p. 48.

sults of some operations in surgery. In the experiments above adverted to, an almost invariable consequence of the application of a ligature around the trunk of a nerve was thickening, with increased vascularity, and the effusion of coagulable lymph; but the most interesting illustrations are those which occasionally present themselves in amputated limbs, where the ligatures applied to bleeding vessels have, in the hurry, confusion, and want of proper assistance immediately after an action, or upon the field of battle, also entangled their accompanying nerves. In such cases the symptoms are often inordinately severe; the neuralgia is insufferable, the convulsions violent, and in some instances it would seem that even tetanus has been the result, and has been checked *in limine* by the removal of the ligature*.

Punctured wounds also afford illustrations of the effects of an inflamed condition of a nerve, and this even more frequently than contusions; for nature has generally taken care to protect nerves against the ordinary accidents of life, although they are not beyond the reach of such great violence as will fracture and splinter bones†, or of gun-shot wounds‡, or of such sharp and penetrating wounds as the prick of a gooseberry thorn§, an angular piece of porcelain||, or the point of a lancet in one of "the occasional ill consequences of venesection¶."

It was long thought, that, where a nerve suffered from a punctured wound, the symptoms arose from its partial division; and this opinion has received, to a certain extent, the sanction of one of our most recent and industrious writers upon the diseases and injuries of nerves. "If," says Mr. Swan, "a fibril be partially divided, or if it be wholly divided, and at the point of division it be connected with the adjoining fibril by filaments, the retraction of the divided parts will stretch these filaments, and thereby cause considerable pain." But a subsequent observation of this judicious author goes far to prove that his confidence in this speculative opinion is not implicit; and it seems scarcely to be borne out even by his own experience, the results of which he thus states:—"By far the greatest number

of injured nerves in venesection, is made troublesome by using the arm too soon, and bringing on inflammation; for I have never seen any bad consequences in those patients who have been so ill as to be unable to do any thing." Soemmering was well acquainted with the fact, that nerves might be partially divided without being attended with serious results, and he must therefore have been equally aware, that the mere partial division could not have been the cause of the symptoms; but it is to the late Mr. Abernethy that we are principally indebted for the more correct views now entertained upon the subject. His acute and inquiring mind led him, "with the eye of reason as well as of observation," (to adopt one of his own eloquent expressions,) to see in the period which commonly elapses between the infliction of the injury and the appearance of its occasional serious consequences, time for, and the probable occurrence of, some intermediate state to which the symptoms should be referred. He was well aware that numerous instances occur, in which the nerve has been wounded in bleeding, without being followed by any particular symptoms. He also well knew, that, when evil consequences are the direct result of an injury inflicted upon a nerve, and not of the more remote effects of that injury, they are synchronous with the infliction of the injury—as in cases of paralysis from completely dividing, or convulsive movement from pricking a nerve with any pointed instrument;—whilst in partially divided nerves from bleeding, or other punctured wound, days commonly elapse before bad symptoms occur. It was therefore the opinion of this intelligent surgeon, that in the interval, from exposure to cold, or other causes extrinsic or internal, "an inflammation of the nerve may accidentally ensue, which would be aggravated if it were kept tense in consequence of imperfect division;" and further, "that the disease consists in inflammation of the injured nerve; and that this inflammation may happen with or without total division of the nervous cord*."

This opinion, which was with Mr. Abernethy but a shrewd conjecture, deriving confirmation, however, from the observations of Pott and Monro upon

* M. Larrey.

§ Wardrop.

¶ Abernethy.

* Abernethy's Surgical Works, v. ii. p. 161.

the same point, subsequent inquiries have essentially corroborated. The instructive cases of partially divided nerve collected by Mr. Swan, all tend to the same conclusion. In all, the symptoms were similar in kind, although they varied in degree; they were those obviously of excitement, as pain or convulsive movement, and commonly days elapsed, in one case even a fortnight, before the characteristic symptoms supervened. In one case dissection conclusively established the nature of the malady, for "the finger being amputated, a small fibril of the digital nerve was found divided; the end of this next the tip was incorporated with the cicatrix; the other was formed into a small bulb."

But the total division of a nerve by a clean incised wound may be also followed by inflammation, which in the form in which it commonly presents itself in stumps, is, according to Mr. Swan, chronic in its character; and this opinion is adopted by M. Descot. Such inflammation, according to Mr. Langstaff, generally arises from exposure of the cut extremity of the nerve either to atmospheric influence, or to contact with parts already in a state of inflammation, as during the healing process of stumps; and so confident is this eminent and original pathologist of the accuracy of the explanation, that he makes it the foundation of an important practical rule, of the propriety of which my information is too limited to entitle me even to form an opinion (although it seems reasonable), namely, that of drawing the nerves beyond the surface of the stump with a tenaculum, and removing a portion, generally equal to half an inch, when the extremity of the nerve will recede beyond the reach of atmospheric influence, or, perhaps, of the surrounding inflammatory process. Mr. Swan much commends this practice, and strongly advises it in all cases of painful stump requiring a second operation, whilst Mr. Langstaff restricts his recommendation of it to those cases in which a sufficient quantity of skin cannot be preserved, and in which, therefore, the ends of the nerves are likely to be included whilst the cicatrization is going on. It is an additional ground for commendation of this proceeding, that it does not appear to be very painful*.

Mr. Abernethy, as well as Mr. Swan and others, are of opinion that the exposure to air of denuded filaments is, in these cases, the cause of the inflammation. The impression of Bichat upon the subject was probably very similar. By experiments upon animals, he ascertained that "when a nerve was simply exposed, without denuding its medullary filaments, it was little sensible to the access of air, or to the agency of slight mechanical irritation; the membrane of each filament being, in such cases, a sort of protection to the medullary substance, which is peculiarly the seat of sensibility." "In these experiments," he adds, "it is easy to assure oneself of the little sensibility inherent in the enveloping membrane of each nervous filament. It is necessary to cross this membrane, and arrive at the medullary substance, to produce pain." Hence, reasoning *e converso*, it appears not unfair to conclude, that Bichat believed in the injurious effects of the exposure to atmospheric influence of the denuded medulla of nerves, and that amongst these pain would be a prominent symptom.

When this inflammation occurs in the nerves of a stump, it commonly produces a bulbous enlargement of their extremities. Meckel, indeed, asserts that all divided nerves have small bulbous tubercles near their extremity; but those which are the result of diseased action are of much larger size, and these, when influenced by compression or other mechanical violence—by atmospheric changes, or internal ailment—are apt to produce frequent and violent attacks of agonizing pains and excruciating spasms. When a student in the Borough, I witnessed a second amputation on account of this peculiar morbid condition. The united force of all the attendants was insufficient completely to control the struggling (apparently convulsive) of a child, not above thirteen years of age, when an attempt was made to steady the remnant of an arm by holding firmly the original stump. These bulbous enlargements of the extremity of a divided nerve have a peculiar character: "il est souvent si solide et si dur que le scalpel s'émousse en le coupant, et fait entendre un bruit semblable à celui que produiroit son action sur un cartilage*."

* Med.-Chir. Trans. vol. xvi. p. 141.

* Meckel's Manuel, vol. i. p. 283.

A nerve passing through a part which is the subject of inflammation, not unfrequently becomes implicated in the morbid condition of the surrounding textures; and this may happen whether the inflammation be simply phlegmonous, or specific in character. Professor Thomson remarks upon this subject, "in the neighbourhood of parts which had often been inflamed, I have observed that the nerves are sometimes more vascular and much thicker than usual*;" and M. Delpech assures us, that, in cancerous diseases, nerves are apt to become thickened, and to take on the particular character of that disease†. It is probably to this cause, the extension to the nerve of inflammation from a cancerous ulcer, or even in cases of common inflammation, that much of the pain may be owing. Blood, it is well known, may be collected in parts abundantly sensitive; there may be increased arterial action, accompanied with heat, as in blushing; nay, there may be actual inflammation of the cuticular tissue, as in erysipelas, and yet each of these states may be unaccompanied with suffering. But if phlegmonous inflammation attack the subcutaneous tissue, as in whitlow, the patient's sufferings, it is well known, are abundantly severe, and this because the disease implicates the very seat of the sentient extremities of the nerves. The pain of cancer, too, is very excruciating in a large numerical majority of instances; but I have recently witnessed the termination of a well-marked case of this disease in the breast, of a circular form, and not less than four inches in diameter, which it was my painful duty to watch for above twelve months, and in which, throughout the whole course of the malady to its fatal conclusion, the pain rarely exceeded that of any other ulcer of equal depth and superficial dimensions. The explanation of this is not perhaps easy. This individual, however, was, with the exception of her cancer, peculiarly healthy; and throughout the whole course of her malady there was little either of constitutional disturbance or surrounding thickening. No hardened lymphatics could be traced in the direction of the shoulder, and there were no enlarged

glands in the axilla. Much also of the progress of the complaint was to be ascribed rather to the separation of minute sloughs than to what has been commonly called ulcerative absorption. These little sloughs probably destroyed the sentient organs as the disease proceeded; the nerves in the surrounding textures were little exposed to the extension to their trunks of inflammation, and the result was much less pain than usual. I offer this, however, only as a plausible and probable explanation of an unquestionable fact.

Mr. Swan, who has collected much valuable information upon this subject, considers that inflammation of nerves is commonly the result of the simple extension of disease from contiguous parts; and Descot confirms his opinion by adoption. "Nerves," he says, "are subject to inflammation, which takes place generally in those contiguous to inflamed parts. When a nerve partakes of the inflammation of the part in which it is situated, it becomes increased in size, from a deposit of coagulable lymph amongst its fibres." And again: "chronic inflammation of the nerves generally arises from a communication of diseased actions from surrounding parts, or sometimes from injuries*."

There is much confusion in the statements of even the best writers upon the subject of the symptoms of inflammation, when it is the result of extension of disease; and this has probably arisen from want of sufficient discrimination between the pain which arises from inflammation of the nerve and that from inflammation of contiguous textures; or between inflammation and its more remote consequences. Mr. Swan alleges that "it is generally attended by much pain, and a *paralysis, or imperfect sensation*, in the parts supplied by it;" thus imputing to the same morbid condition opposite effects, as "much pain, and imperfect sensation;"—and yet, in speaking of the chronic inflammation of the nerves in stumps, he adds, "when the nerves are in this state, the patient suffers so much pain, and *especially from the least touch*, as to be obliged to submit to a second amputation." At the first glance this may seem to be contradiction; but it is an apparent only, not a real contradiction. Both

* Lectures on Inflammation, p. 153.

† Diction. des Sciences Médicales, art. *Cancer*.

* On the Diseases of Nerves.

statements may be true, and admit of explanation. Where the continuity of a diseased nerve is perfect—where the nervous influence is not interrupted in its course, either by the destruction of the nerve itself or by the pressure of surrounding thickening—there is increased sensibility through its whole course. So, in many instances of neuralgia, the slightest touch of the part—a current of air, the movements of mastication, will constantly excite a paroxysm. There is morbid sensibility, with heat and increased secretion, in the remote distribution of the nerve; but in other cases when the nervous influence is intercepted by any cause, there may be pain referred to the part upon which the nerve is distributed, as occurs also in stumps, and yet there may be paralysis of the muscles, and defective sensibility to the touch upon the surface. Dr. Hennen seems to have been aware of this distinction, which he illustrates by cases of secondary paralysis after gun-shot wounds, without immediate injury to the nerve; “as in those cases when a ball has passed so close to a large one, or the plexus from which it proceeds, as to occasion an inflammation and consequent thickening of the neurilema, or investing membrane; or where, in a more distant transit of the ball, the tube formed by its passage swells to an extent sufficient to press on the nerve or plexus.” In the case also of David Franklyn, related by Mr. Swan, there was great pain in the wrist and the palm of the hand, but the sense of touch in the thumb and three fingers was lost. The median nerve, where it passes under the annular ligament, was much enlarged, and *its natural connexion with the sheath of the tendons of the flexor*

muscles of the fingers thickened. The cutaneous branches of the wrist and palm coming from an inflamed nerve, but escaping the pressure of contiguous parts, produced great pain; but the surrounding cellular connexion with the sheath and tendons compressed the digital nerves, and in conformity with what I have before advanced, strangled the nerves in their course, and impaired their function of ministering to natural sensibility.

[To be continued.]

ON THE INFANT MORTALITY IN LARGE TOWNS.

To the Editor of the Medical Gazette.

SIR,

In pursuing the inquiry, whether the mortality of infants is exclusively attributable to the prevalence of manufactures, I have turned to the several tables which are inserted in the second volume of Dr. Price's Treatise on Reversionary Payments or Annuities, and having arranged such of them in one view as furnish facts to the purpose, I subjoin the results, chiefly because the two first years of life are so variously expressed as to mislead an inquirer on cursory reference; 1 and 2 years, 0 and 1 year, and even 1 to 3 years, denoting the same period of life in various tables. These tables, and calculations on the modern Population Abstract, seem equally to prove that if misery is justly imputable according to the rate of infant mortality, all large towns are miserable abodes, whether they contain manufactures or not.

From Dr. Price. (Edition 1812.)

On the foregoing table a few explanatory remarks seem to be requisite. In treating of the mortality of London in the years 1759-1768, Dr. Price adverts to the effect of considerable immigration into London, such as is noticed in your last number, p. 500, as operating a difference of 3 per cent. in calculating infant mortality in Lancashire; but he carries his assumption of facts so far as to represent (in his Table xv.) the true probability of mortality in the two first years of life at 68 per cent. instead of 34 per cent.; in fact, he doubles the apparent mortality in every year from birth to fourteen years of age: thus precluding the possibility of comparing London with any other place in the known world. Dr. Price avows that he has made the same kind of addition (on assumed data) to the mortality of Vienna and Berlin (in his Tables iii. and iv.), wherefore they are omitted in the foregoing table.

The limits of the Bills of Mortality, under the title LONDON, represented the metropolis with tolerable accuracy until the year 1780; since that time the accretion of suburbs in the parishes of Mary-le-bone, Pancras, Kensington, and Paddington, has required a larger definition of the metropolis; and in the Population Abstract (vol. iii. p. 494), the infant mortality appears to be 30 per cent. on males, 26 per cent. on females, little surpassing the average mortality of England and Wales. The health of

London beyond many provincial towns in England is explained (p. 497 of the same volume), space having become more valuable for counting-houses and warehouses than for human habitation; so that the population of the once crowded part of the metropolis diminished one-half in the last century, and since 1801 has further diminished one-third.

The mortality of infants in the years 1813-1830, at various places, stands thus:—At Leeds and Nottingham, 37 per cent.; at Liverpool, 34½ per cent.; at Norwich, 33½ per cent.; at Birmingham, 33 per cent.; at Halifax, 31 per cent.; at Hull, 30½ per cent. It is supposed that Manchester would exhibit a large proportion of infant mortality; but this cannot be ascertained, because more than half the number of burials take place where the ages of the dead are not recorded; and all the other burials would produce a fallacious result, because they consist of the more opulent classes of the community.

Some of the agricultural counties of England, and the entire of Wales, give infant mortality of the two first years of life at 20 per cent., or one-fifth part.

I am, sir,

Your obedient servant,

J. RICKMAN.

January 27, 1835.

P.S.—The letter on the Mortality of Manufacturing Districts, in your last

number, is accurately printed, except that (page 589, line 30) 416 children should be said to spring from 100 marriages, not 104; and the computation is not unworthy of more distinct statement. The registered marriages average at 105,209 annually; add for the marriages among 25,000 Jews in England and Wales, 198; among as many Quakers, 198 marriages; for Scottish Border marriages, and a few omissions of registry, say 1000 annually; and all the marriages amount to 106,605. Deduct from the total births (page 589 of your last number) the illegitimate births ($463,690 - 20,039 = 443,561$), and the result, divided by the above number of marriages, assigns 416 births to 100 marriages.

CASE OF DIABETES MELLITUS;

WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case of diabetes mellitus, with remarks, be deemed sufficiently interesting and important, I have to request the insertion of it in an early number of your valuable journal.—I remain, sir,

Your obedient servant,

JOHN ANDERSON,
Clinical Clerk.

Guy's Hospital, Jan. 27, 1835.

John M.—, ætat. 52, a short, meagre-looking man, of pale complexion, very temperate habits, and by trade a cooper, was admitted into the clinical ward, November 27, 1834, under the care of Dr. Chalmers. He stated that he had been ill twenty weeks, but had previously enjoyed tolerably good health; though, ever since a boy, he had been in the habit of making water oftener and in greater quantity than most persons. His first complaints were those of general weakness, insatiable thirst (often drinking off a quart or two of fluid at a time), and a more frequent desire to pass his urine, sometimes to the amount of five or six gallons in the course of the day. To this succeeded increased debility, wasting of the body, and a total loss of sexual power and desire; excessive dryness of the tongue, mouth, and fauces; a constant craving for drink; inordinate appetite; and a

confined and costive state of the bowels. On the day of his admission, the most prominent symptoms were great emaciation, loss of power and muscular energy, impaired memory, extreme thirst and hunger, with a collection of tough mucus about the fauces; tongue clammy, and of a dirty white colour; skin dry and parched; no perspiration; a desire to pass water every half hour, which is of a pale straw colour and sweetish taste, diminished in quantity, though still much greater than natural, specific gravity 1.032; bowels very much confined; pulse 72, and feeble; occasional flatulent evacuations of an acid taste, and a peculiarly sweet smell of the breath. Gums not sore, or spongy; no phymosis or inflammation at the orifice of the urethra, and no tendency to oedema. Chest healthy; the resonance and the respiratory murmur being quite natural in every part.

R Hyd. Submur. gr. j. c. Pulv. Jacobi, gr. iij. 6tis horis. Enema Saponis statim. Drink, Milk and Water, O. iv. Food, Beef Steak, 1lbss.; no bread, or vegetables.

28th, morning.—Passed water seven or eight times in the night; bowels scantily moved; urine 15 oz., specific gravity, 1.032; pulse 84, fuller.

R Haust. Sennæ st. et pergat.

29th, morning.—Had a restless night, being disturbed six or seven times to make water. Mouth and tongue dry; thirst excessive; had slight vomiting; bowels opened twice copiously; pulse 90.

R Magn. Ust. ʒss. 6is horis, ex jul. Mentha, ʒjss. Pergat Pil. bis in die.

30th, morning.—No sleep; tongue dirty and clammy; mouth not so dry, and thirst less; skin dry; sickness and eructations relieved by the medicine; pulse 98, compressible; urine 88 oz., specific gravity 1.035. There is an eruption over the chest and back, and some pediculi, which occasion great itching.

Emp. Canthar. Thoraci.

4th, morning.—Feels generally better; bowels well opened; urine 84 oz. Pain relieved by the blister.

Augatur dosis Pulv. Opii, ad gr. iij. h. s.
P. Pil. bis die et M. Magn. 6tis horis
ut antea.

5th, morning.—Disturbed only three or four times in the night to pass water; thirst less; urine 79 oz.; pulse 66; no pain in the chest; no headache.

Aug. dosis P. Opii ad gr. iv. h. s. et P.

6th, morning.—Appetite increasing; feels weak; bowels well opened; urine 82 oz., specific gravity 1.035; no pain in the head; pulse 66, compressible.

Aug. dosis P. Opii ad gr. v. h. s. et Pergat.

7th, morning.—Continues much the same; had several copious solid motions.

Aug. dosis P. Opii ad gr. vi. h. s. et Pergat.

8th, morning.—Had a good night; no headache or giddiness; thirst and appetite the same; urine 62 oz., specific gravity 1.035.

Aug. dosis P. Opii ad gr. vij. h. s. et Pergat.

9th, morning.—Head light and rather giddy; thirst increased; no perspiration; bowels open; dejections of a light chocolate colour; urine 140 oz.; pulse 66, not feeble.

R Pulv. Opii, gr. vj. h. s. et Pergat.
Ordered Tea, O. iiss. The quantity of fluid taken each day is now 104 oz.

10th, morning.—No head-ache; bowels open; urine higher coloured, depositing a white flaky sediment, 40 oz., specific gravity, 1.035.

Pergat.

11th, morning.—Thirst less; tongue and lips moist; urine 59 oz.

Pergat.

12th, morning.—Appetite increased; bowels open; dejections of a light colour; urine 60 oz., specific gravity 1.038.

Omit. Pil. mane et Pergat.

13th, morning.—Mouth moist;

thirst less; skin dry; urine 72 oz. rather higher coloured, smell not so sweet.

Aug. dosis P. Opii ad gr. viiss. et Pergat.

14th, Morning.—Bowels opened copiously; dejections of a light colour; urine 80 oz., specific gravity 1.035; gums not tender; feels chilly.

Pergat.

15th, morning.—Thirst increased; appetite craving; skin dry; bowels open; urine 180 oz.; pulse 61.

Pergat. Ordered 2 bottles of Soda Water, amounting to about 18 oz. of fluid, and increasing the amount of liquid to 122 oz. per day.

16th, morning.—Thirst increasing; tongue very dry; dejections copious, and rather dark coloured; urine 84 oz., specific gravity 1.040.

Pergat. Mist. ter die et Pulv. Opii, gr. viiss. h. s. ut antea præscrip. Omit. Pilula vespere.

17th, morning.—Bowels opened copiously; urine 150 oz., specific gravity 1.037; thirst diminished.

Pergat. Ordered one bottle only of Soda Water, making the amount of fluid 113 oz.

19th, morning.—Skin very irritable and dry. There is an eruption over some parts of the body.

Pergat. Habeat Balneum Calidum eras.

21st, morning.—Passed a good night. Perspired profusely for four hours after coming out of the bath; tongue moister; thirst less; appetite craving; itching better; bowels open; urine 90 oz., specific gravity 1.038; pulse 66.

Pergat. Omit. Soda Water. Lac. c. Sævo. ʒj. making the amount of fluid taken 120 oz.

23d, morning.—Tongue much moister; thirst greatly diminished; dejections solid, and clay-coloured; urine less sweet in taste, 75 oz., specific gravity 1.025. General health better; had a slight return of sexual desire, for the first time since his illness.

Pergat. Habeat Balneum Calidum st.

24th, morning.—Tongue moist; thirst quite gone; no desire for drink; appetite great; perspired profusely from the effect of the warm bath; urine 102 oz., specific gravity 1.025.

Pergat.

25th, morning.—Tongue a little clammy, and thirst increased; perspiration only slight; had six solid copious de-

jections; urine 142 oz., specific gravity 1·036.—Pergat.

26th, morning.—Thirst very much complained of; perspiration very slight; urine 200 oz.; pulse 72.

Aug. dosis P. Opii ad gr. vij. h. s. et Pergat.

27th, morning.—Continues much the same; urine 112 oz., specific gravity 1·040.

Inflicetur Ung. Sulph. bis die, et Pergat.

28th, morning.—Urine 92 oz., specific gravity 1·039.—Pergat.

29th, morning.—Urine 114 oz., specific gravity 1·035.—Pergat.

30th, morning.—Urine 100 oz., specific gravity 1·035.—Pergat.

31st, morning.—Has continued improving a little: perspiration gradually returning more profusely; tongue moister and thirst less. Had two solid dejections; urine 93 oz., specific gravity 1·033.—Pergat.

1835, January 1st, morning.—Urine 96 oz., specific gravity 1·036.—Pergat.

2d, morning.—Urine 105 oz., specific gravity 1·036.—Pergat.

3d, morning.—Urine 92 oz., specific gravity 1·036.—Pergat.

4th, morning.—Urine 100 oz., specific gravity 1·030.—Pergat.

5th, morning.—Urine 100 oz., specific gravity 1·030.—Pergat.

6th, morning.—Has continued almost free from thirst up to the present time; the tongue has been uniformly moister; the perspiration has continued increasing, and is to-day very profuse; the dejections have been of the same solid heavy character and light colour; pulse 64, rather feeble.—Pergat.

Dr. Cholmeley's term having expired, the patient came under the care of Dr. Bright, who felt inclined to try again the effects of the warm bath.

7th, morning.—Urine 102 oz., specific gravity 1·035.—Pergat.

8th, morning.—Urine 80 oz., specific gravity 1·035.

Habeat Balneum Calidum, et Pergat.

9th, morning.—Tongue and lips moister; has perspired profusely; thirst less; pulse 70; urine 92 oz., specific gravity 1·027; had slight return of sexual desire.

Pergat. Food, mutton chop in addition.

10th, morning.—Expresses himself as feeling stronger; appearance of body not so emaciated; countenance improved; perspiration moderate; urine 118 oz., specific gravity 1·026.

Habeat Balneum Calidum et Pergat.

11th, morning.—Tongue slightly rough, but moist; thirst scarcely at all complained of; appetite satisfied; bowels open, dejections solid, heavy, and light coloured; urine 152 oz., specific gravity 1·033; slight increase of virility.

Aug. dosis P. Opii ad gr. viij. h. s. et Pergat.

12th, morning.—Tongue clammy and not so moist; thirst greater; perspiration slight; bowels rather confined; urine 132 oz., specific gravity 1·034.

R Pulv. Rhei. c. Cal. ʒj. statim, et Pergat.

13th, morning.—Tongue moister, and thirst less; appetite satisfied; perspiration moderate; bowels open once, dejection hard and lumpy; urine 132 oz., specific gravity 1·036.

Habeat Balneum Calidum, et Pergat.

14th, morning.—Thirst and appetite the same; bowels open twice, dejections hard and lumpy, and slightly stained with blood; urine 150 oz., specific gravity 1·034; pulse 68, compressible.

R Sulph. Lot. ʒss. ter die. Loco Ung. Pergat.

15th, morning.—Thirst and appetite continue satiated; urine 130 oz., specific gravity 1·035.—Pergat.

16th, morning.—Had some profuse perspiration; tongue moist; no thirst; bowels open three times, dejections solid and heavy; urine 132 oz., specific gravity 1·037; sexual desire increased; general health and strength much improved.

In the evening I discovered that he had been exchanging half his meat for some bread with a neighbouring patient, since 9th instant; in consequence of which disclosure he abruptly left the hospital.

REMARKS.—The above case shews that much may be done to lessen the intensity of the disease and mitigate the sufferings of the patient, though an entire and permanent cure is seldom attainable. With regard to food, a strict animal regimen, and total abstinence from all vegetable diet, or any thing of a saccharine tendency, seems

the most desirable plan; difficult often to pursue, from the loathing of the patient, who requires to be strictly watched. In this instance, however, I am quite convinced that animal diet solely was strictly adhered to, and that no bread was taken until the last seven or eight days. Opium is allowed to exert a decided influence over this disease; probably by checking the secretion from the kidney, and altering the character of the urine, increasing the lithic acid and urea, and lessening the sugar. Its first effect, however, according to Dr. Prout, is to increase the specific gravity, this evidently depending on the greater concentration of the urine caused by its being diminished in quantity. As the remedy is persevered in, the original specific gravity returns, and even becomes less. It is astonishing the quantity of opium that can be borne: Dr. Cholmeley has increased the dose from a single grain up to 14 grains every night: 21 grains at bed-time have been given at this hospital; and a case is recorded by Dr. Elliotson, in which 45 grains were taken three times a-day. In the present instance, a dose above $7\frac{1}{2}$ grains produced headache and giddiness, and could not be borne; this, however, appeared to have some effect in diminishing the quantity of urine, though not much influence on its specific gravity. It is singular that it had no effect in constipating the bowels; the dejections were always very copious. When this disease has existed for some little time, may not the opium act by diminishing the irritability of the kidney caused by the increased demand on its functional power? and may it not alleviate the constitutional symptoms by diminishing the general irritation and want of power consequent upon the loss of so much solid matter, and the circulation of unhealthy blood? May it not act also by determining to the skin and promoting perspiration—a secretion so desirable in diabetes?

Magnesia has been found of great service, by correcting the acidity of the stomach which is generally prevalent in this disease; also by allaying the sickness, diminishing the thirst, and lessening the frequency of the eructations. In this instance it had a two-fold effect: it diminished the symptoms just enumerated, and regulated the state of the bowels.

Sulphur possesses the property of promoting the secretions and excretions of the body; and when taken up into the system, is very likely to excite perspiration. There is little doubt but that in the present case it assisted the other remedies in promoting this desirable secretion.

Repeated bleedings in small quantities have been recommended and pursued by several persons with various degrees of success; but as a general plan of treatment, it is open to many objections.

I was induced to request the trial of the warm bath (a vapour bath not being convenient), from reading an account of some cases related by Dr. Lefevre, and Dr. Wilson in reply, in Nos. 365 and 368 of the *MEDICAL GAZETTE*, and successfully treated by the vapour bath. Its efficacy appears to depend entirely on its power of promoting perspiration; and as this function of the skin is generally, if not always, suspended in this disease, its re-establishment would seem to indicate a good method of cure. On referring to the daily reports of the case, it will be seen that up to the trial of the bath the skin had been irritable, dry, and parched, the thirst excessive, the tongue dry and clammy; but these symptoms were very much mitigated by the profuse perspiration which followed the use of the bath; it did not appear, however, to have any marked effect upon the quantity of urine. This remedy was not persevered in sufficiently long to come to any conclusion as to the results of its effects; and in the latter trial of it, the bread taken was, I think, sufficient to account for the high specific gravity and increased flow of urine*; whilst the free secretion from the skin, together with the other remedies, very much alleviated the constitutional symptoms.

The dejections were of a singular appearance, and very characteristic of the disease; at one time they were soft, and of the colour of Roman cement; at another, of a very fine light colour, containing but little bile, and either in heavy solid compact masses, or in hard detached portions, resembling more the excrement of the horse than human faeces.

* A single piece of bread or biscuit has been known to increase the specific gravity eight or ten degrees.

The urine, though it often exceeded in quantity the amount of fluid taken, yet was never very abundant. Different cases are recorded, in which 30, 40, and even 52 pints, have been passed in the 24 hours. These are rare: the most usual amount is from 6 to 20 pints: occasionally not more than the natural quantity is passed. In this case, the highest measure of urine was 200 oz. (and that only once); the lowest 40 oz.; the average 100 oz. It was uniformly of a pale straw colour, occasionally with a white flaky sediment, sweet smell and taste; it was neither coagulable, nor even rendered opalescent by heat or nitric acid, as it is said to be sometimes towards the close of the disease, and the supervention of hectic fever, though on the other hand it is asserted that the appearance of albumen is the indication of a favourable change. The specific gravity varied, the highest being 1.040; the lowest 1.025; the average 1.035: the quantity of solid contents, therefore, passed daily, upon the average, was 5583 grains, or rather more than 11½ oz., according to Dr. Henry's table, which is very exact, and very useful for determining, in a given quantity of urine, of a known specific gravity, the solid matter it contains. I regret that I am not able to subjoin an analysis of the urine and perspiration; I was about to collect some of the latter when the patient so abruptly left the hospital. As to the general chemical characters of diabetic urine, there appears to be but a small quantity of lithic acid and of the usual salts, a great deficiency of urea, and an excess of saccharine matter; said by some to be abundant in proportion as the former is deficient.

The pathology of diabetes is very obscure, but future and more minute investigations may probably refer it more particularly to the kidney, though this organ may not be considered as the original seat of the disease. We know that the kidney need not necessarily be disorganized, to secrete albuminous urine, but merely disordered in function. Why may not, then, this latter cause operate in secreting saccharine urine, the material for the formation of the sugar being in the urea, which is present in the blood, and is nearly deficient in diabetic urine; and the elements of which urea being differently arranged, give rise to the formation of sugar? It

is but fair to state (as partly opposing this), that a large quantity of urea has been found, though very rarely, in diabetic urine; however, the chemical relation between the urea and sugar* would seem to favour the former hypothesis, as also a case which is recorded by Dr. Bostock, in which the solid matter of the urine at first consisted only of urea, but afterwards became converted into saccharine matter. The experiments of several eminent chemists have not yet detected sugar in the blood, nor any where else than in the urine—a fact considered by some very much against the theory of considering a derangement of the general system as a cause of diabetes. But as the formation of urea is proved by Prévost and Dumas (and more recently by Gmelin and Tiedemann†), to be commenced in the blood, these experiments are by no means conclusive. May not, therefore, the primary source of the disease be in a disordered state of the assimilatory functions, by which an undue quantity of urea is formed; and that the conversion of this urea into sugar depends on disordered action of the kidney? There appears to be a partial analogy in the pathology of the albuminous and saccharine secretions; and as we know and prove that the kidney is deranged in the former instance, why may it not be so in the latter? But we have no evidence of this after death, for we should expect that long-continued functional derangement would produce equally in both cases disorganization; and yet no morbid appearance corroborative of this has as yet been discovered, but merely a hard, or soft, or hypertrophied state of kidney; just as we should expect to find from the long-continued irritation of that organ. It is just possible that there yet remains to be discovered some morbid appearance—some unnatural state of kidney, that has hitherto eluded the search of the most vigilant pathologist.

This disease often runs on for a considerable time, and at length terminates by exhaustion, or by the supervention of phthisis, or some other disease; sometimes the patient is suddenly cut off by apoplexy.

* These two substances contain exactly the same proportions of hydrogen, but sugar contains twice as much oxygen and carbon as urea.

† See Med. Gaz. for Jan. 24, p. 605.

ON THE
PATHOLOGY OF THE SECOND
STAGE OF FEVER.

To the Editor of the Medical Gazette.

SIR,

THE various theories which have been urged regarding the proximate cause of fever, from the time of Hippocrates to the present period, and the modifications of exploded hypotheses which in later times have been revived, evince the very small progress which has been made towards elucidating the real nature of the *occult causes* of this disease. The doctrine of Cullen, for example, is a mere version of the Themisonian theory, which, as we learn from Celsus, regarded fevers as originating from a too rigid state of the solids. Hoffman, again, supposed that the proximate cause of fever arose from an universal spasm of the fibrous and nervous system; and this was the prevailing theory until lately, when the slumbering ghost of the humoral pathology has been again invoked. Dr. Fordyce, however, has remarked, that "what the real derangement of the system is which produces the external appearances in fevers, is not at all known; it is a disease the essence of which is not understood." Lieutaud also observes, "In Cimmeriis latet tenebris genuina febris indoles; nec forte dilucidius patent ejus differentie;" and many other celebrated pathologists have recorded a similar testimony. Quitting, then, such unsatisfactory and disputed ground, I wish to draw attention to facts which are more apparent.

The first stage of idiopathic fever, as it is presented to our view, is essentially a state of *depression*. The vascular system is paralysed; the heart grows sluggish; the skin cold; shiverings occur, with fulness and a sense of oppression at the præcordia; urine flows in small quantity, and all the secretions are more or less suspended, and thrown into the mass of the circulating current.

The second stage has been termed that of *re-action*, a word of vague and indefinite import, and, like many other expressions in medicine and science, come to afford a convenient shelter for an unexplained mystery. It is well known that the urine and perspiration contain a large proportion of saline in-

gredients. In following up the experiments of Dr. Stevens, I immersed a clot of venous blood in a vessel of fresh-drawn urine, and the result was such as I had anticipated: the surface of the clot became *completely arterialized*—as completely, but somewhat by a slower progress, as that which had been submerged in a solution of nitre, or of common salt. Here, then, we arrive at something like a knowledge of the nature of the second stage of fever. The elements of the secretions, not being removed by the various excretories from the body, accumulate in the blood, which consequently becomes surcharged and poisoned with the saline and excrementitious matter of the perspiration—the urine and the bile. The vascular system is stimulated to violent and undue exertion; the pulse throbs; respiration is accelerated; increased animal heat engendered; the vital current is in a state of *hyper-oxygenation*, and delicate organs which maintained a predisposition become the seat of local injuries; and it is not until the various functions of the system begin to assume a healthy state—until the secretions are eliminated from the blood, and the urine flows, and the perspiration returns—that these phenomena cease, or that we look with confidence for the period of convalescence.

I am, sir,

Your obedient servant,

R. H. ALLNATT, M.D.

Wallingford, Jan. 30, 1835.

SODA A REMEDY FOR
TOOTH-ACHE.

To the Editor of the Medical Gazette.

SIR,

HAVING found the alkalis to possess singular power in relieving tooth-ache, I beg you will have the goodness to give this a corner in your extensively-diffused journal, that many sleepless nights may be avoided.

The most pleasant and agreeable, soda, will either immediately or in a few minutes cause the entire cessation of pain, by carefully filling the decayed tooth with the powdered carbonate, so that it may descend to the nerve, which its solution in the saliva will soon after allow it to do. I am not aware that

this will permanently cure, although it will effectually relieve the sufferer, and for many hours; and it does not seem to lose its efficacy by frequency of application. It cannot be expected to be useful where pain has arisen from the formation of matter. A strip of litmus paper, put into a decayed tooth, will at once explain the rationale of its action, and why pain so removed may recur.

I have the honour to be, sir,
Your obedient servant,
JOHN S. GASKOIN.

32, Clarges-Street,
Jan. 30, 1835.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Ueber die Anlegung und Einrichtung von Irren-Heilanstalten, mit ausführlicher Darstellung der Irren-Heilanstalt zu Siegburg. Von Dr. MAXIMILIAN JACOBI. Berlin, 1834. Schloss.

(*On the Structure and Arrangement of Lunatic Asylums, with a full account of the establishment at Siegburg.*)

WE have examined this volume with some attention, and think it cannot but be very acceptable to all who take an interest in the treatment of the insane. In this country we have numerous establishments for the reception of such patients; but there is nothing systematic in our plans, and we believe opinions are much divided among us as to the best forms and methods of arrangement to be adopted in erecting new asylums, and in reforming old ones. The experience of Dr. Jacobi here offers its assistance; and the present work, coming from a person of so high a reputation, must command both respect and gratitude.

The first of the two parts into which the work is divided treats of principles and generalities; it discusses several important questions touching the objects and advantages of special institutions for the management of the unsound of mind. The author's opinions, on the whole, are favourable to large establishments, in contradistinction to houses set apart for the reception of a small

number of patients; yet 200, he thinks, ought to be the limit of those collected into any one locality. It is to be observed, that Dr. Jacobi does not countenance the reception of *incurables*; moreover, when he has no hope of a patient's recovery, he sends him away. Among those of the latter class he ranks such as have become mad from lesions of the brain, or from morbid changes in the tissues within the skull; confirmed idiots, or persons affected with dementia and idiocy in consequence of apoplexy, or in combination with paralysis, or where mania comes on after acute or chronic encephalitis.

We cannot enter into the details of the sort of structure which Dr. Jacobi thinks best adapted for an asylum: suffice it that it must be simple and cheerful; neither like a castle nor a monastery, nor in anywise calculated to overawe the inmates. The church, the baths, the kitchen, the wash-houses, and other offices, he would have arranged in the central part of the building. Here also the chief overseer and resident physician should have their abode; but the other *employés* should be beyond the wings or main body of the establishment.

Supposing 200 to be the number of patients, Dr. Jacobi thinks they might best be divided into five classes—1, of those who are dangerous and outrageous; 2, the noisy and troublesome; 3, those labouring under idiocy and dementia; 4, the melancholic and hypochondriacal, requiring special care, as being apt to commit suicide; and the 5th and last division, comprehending by far the largest portion of the patients—namely, the tranquil and orderly—should have abundant accommodation. It is worthy of notice, that the author does not approve of having the convalescents separate from the other people in the house: their being permitted to go amongst the latter he thinks is attended with auspicious circumstances, conducing as well to their own recovery as that of others.

In the chapters on treatment we find much excellent matter, relating first to the corporeal and mental exercises suited to lunatic patients; then to the medical management; next noticing the coercion which is occasionally required; and lastly, the diet and regimen of the insane.

The second part of the work is practical and descriptive: it gives abundance

of information relative to the establishment at Siegburg; but for particulars we must refer those interested in the detail to the work itself. Meantime we have much pleasure in laying before our readers an account of the admirable working of Jacobi's system, as given by a gentleman who recently visited the Siegburg asylum.

"Nature has peculiarly favoured the locality of Siegburg, the site of which is far preferable to that of any asylum which I have visited, either in my own or foreign countries. The insulated rock, on which stands the Irrenanstalt, rises abruptly from the plain, and commands a rich and romantic view, bounded towards the south by the peaks of the *sieben gebirge*,—towards the north by undulations over which the towers of Cologne are just discernible,—on the east by a chain of low wooded hills,—whilst, towards the west, the eye is attracted to the wide expanse of Rhine, which flows so majestically amidst gardens and vineyards, spired villages, and ruined castles. At the foot of the rock stands the old town of Siegburg, whose crumbling ramparts are bathed by the Sieg, a mountain torrent that, after meandering a couple of leagues, precipitates itself into the Rhine. In the eleventh century, the mountain, or rather craggy hill, of Siegburg was crowned by a castle belonging to the Count Palatine Henry, who presented it to the Archbishop Annon. The latter established there a Benedictine monastery, erecting for this purpose a vast and stately edifice. Napoleon, who every where appropriated monastic properties to the purposes of the state, expelled the humble Benedictines from their splendid residence; and after the peace, the Prussian government having failed in finding a purchaser, the building was, by a few additions and alterations, converted into an Irrenanstalt, or asylum for the insane of the Rhenish provinces. Nothing can be better adapted to such an institution than the long corridors and separate cells which form the interior of a monastery. The edifice is nearly quadrangular, but its great central court is divided by a noble church, which towers above the rest of the structure. On three sides the ground floor is almost entirely occupied by the kitchen, baths, and offices. The cells of the first floor are principally devoted to the poor patients, whilst those of the second are inhabited by the *pensionnaires*, or persons of a higher class, who are admitted on terms proportioned to the accommodation which they require. The fourth side of the quadrangle, which offers the advantage of being a little separated from the others, has for its inmates the more restless or noisy patients of all classes, the ground-

floor being assigned to the men, and that above to the women. At present there are about two hundred patients, of which only eighty are females.

"There is one peculiarity in the moral treatment adopted in this institution, which is especially worthy of notice—the employment of labours, either mental or bodily, as a remedial measure. With this view, a distinction is made as to the habits and relative education of the patients. Of the poorer inmates, the males are, with but few exceptions, employed six hours every day in the cultivation of the gardens and fields which surround the hill; whilst the females either spin or are actively engaged in the domestic arrangements. In their leisure hours, those who are recovering meet in rooms set apart for society, in which mechanical games, the journals, and works of a light and instructive character, are introduced for their amusement. The *pensionnaires*, in general persons of good education, are also called into activity—the ladies to exercise themselves in needlework, reading, or music—the gentlemen to pursue literary or arithmetical studies proportioned to their abilities, and adapted to the peculiarities of their cases. The occupations of both are carefully superintended by well-informed persons of both sexes, the literary exercises being more particularly revised and corrected by the Protestant and Catholic clergymen of the establishment. One gentleman, whom I visited, was translating Cæsar's Commentaries; a second learning a new piece of music; and a third, observing that I was a foreigner, conversed with me in Latin. The private apartments of the *pensionnaires* are supplied with every necessary comfort, and the courts and gardens afford ample space for recreation and exercise. There is a library, and in the public rooms billiards, and various kinds of games and musical instruments, serve to while away the few hours which are not expressly devoted either to bodily exercise or to study. Idleness is banished, and with it much of the melancholy which is so usually observable among the insane: order, neatness, and industry, reign in every branch of this interesting establishment, the arrangements of which reflect infinite credit on its learned and scientific director, Dr. Jacobi*."

We should add, that Dr. Jacobi's volume is very handsomely got up: there are fifteen illustrative lithographs accompanying the text—two of them presenting views of Siegburg, with its lofty and imposing scenery; the re-

mainder consist of sketches and plans of the most celebrated asylums in different parts of Europe.

An Inquiry into the Nature of Sleep and Death, &c. &c. By A. P. W. PHILIP, M.D. F.R.S. L. & E. &c.

[SECOND NOTICE.]

IN our former notice of this work, we were prevented by want of space from completing the subject;—the passages which we now subjoin are those to which we then alluded.

Cause of the Growth of the Body.

“Although the sleep of each day restores the sensitive system from the exhaustion which causes it, the daily recurrence of the exhaustion has the effect of permanently lessening the excitability of that system; a change not to be perceived from day to day, but which, from many phenomena, becomes sensible in the course of years. As the sensitive system becomes less excitable as the day advances than on first awaking, in like manner it becomes less excitable as life advances than in childhood; and in like manner, as the repeated excitement of the sensitive system tends to the final decay of its sensibility, the continued excitement of the vital system, as we might *à priori* have supposed, has a similar tendency with respect to the excitability of this system. We find the pulse becoming slower as we advance in life, in consequence of the lessened excitability of the heart and bloodvessels, and the vital organs less readily influenced by the parts of the nervous system associated with them, proving that their functions are also under the process of decay. On these parts and the powers of circulation all the assimilating processes depend; and the shrinking frames of the aged indicate their weakened state, and the approach of their final extinction; for those were deceived who taught that there is nothing in the laws of our frame which should lead us to believe that it is not formed to last forever.

“The greatest degree of excitability, either in the sensitive or vital system, is not that which produces the most vigorous state of health. We may be too excitable as well as too little so. Many of the more serious diseases of children arise from this cause. The derangement of the digestive organs, which in the adult produces the nervous irritations of indigestion, produces in the infant inflammation of, and effusion on, the brain. The irritation of the gums, which produces pain and restlessness in the former, in the latter produces convulsions and death. Thus it is that the habit of the child is less firm and vigorous than that of the adult, which has acquired stea-

diness by the diminution of its excitability, in consequence of the continued action of the stimulants of life; but, after a certain period, the fault is a deficiency, not a redundancy, of excitability, a defect apparently the necessary consequence of the laws of our frame, and to which every day unavoidably adds.

“The redundancy of excitability in children, the cause of many evils, we may be assured answers some important end. There is reason to believe that it is on it that the growth of the body depends, and that the due proportion between the excitability and the stimulants of life, by the gradual diminution of the former, determines the period at which the growth is completed in each individual. While the excitability continues redundant, the ordinary stimulants of life necessarily support a greater activity of the functions than is required for the mere maintenance of the body, and thus its volume enlarges, on the same principle that we have just seen it shrinks in the aged, in consequence of their excitability having become defective. It seems to be on this principle, namely, by a premature exhaustion of the excitability, that the hardships of life, (that is, the greater than usual application of its stimulants,) check the growth. On the same principle we should expect to find that the growth would cease soonest in the most excitable habits, because in them the excitability will soonest be reduced to a due balance with the stimulants of life. Thus it seems to be that the growth of women, who are more excitable than men, generally stops sooner, and consequently that they are of shorter stature, large women, for the most part, having less of the habit peculiar to their sex; and that by far the greater number of the most excitable men, who, in consequence of this constitution, make the greatest figure in their day, are men of short stature, while giants are generally of an opposite habit of body. There must, of course, to such rules be many exceptions. Where so many causes are operating, no result can be uniform.”

In our account of the Treatise before us, we stated that the opinion of the identity of the nervous influence and voltaic electricity receives much support from Dr. Faraday's doctrine of Electro-Chemical Equivalents, the necessary inference from which being that all chemical changes depend on electric action. Dr. Philip enters at length into the nature of the functions of the animal body in his paper on Death, to which we must refer the reader, the passages being too long for quotation. The following are the concluding paragraphs:—

"While the results of these experiments remain undisputed, if we assert that the nervous influence is a vital power, we must allow that such a power may exist in a mechanism wholly different from that to which it belongs in the living animal, and that all the functions of a living power may be performed by an agent which operates in inanimate nature; positions, which I believe no man, acquainted with the laws of the living animal, will be hardy enough to maintain."

* * * * *

"Life, without much violence done to language, has been called a forced state. It consists of excitable parts called into action by suitable stimulants. These stimulants, it appears from what has been said, are all of an inanimate nature, for although the sensorial can only be excited through the nervous system, the action of the former, it is evident, equally, though not so immediately, depends on the agents which excite the latter. Hence the harmony which exists between the living powers of the animal body and the powers of inanimate nature. There is nothing in common in the nature of these powers; but the organs of the former, being composed of the same materials with the world which surrounds us, can be excited by no means but the agents which operate in that world; and on what principle could we expect any other result?"

"These organs themselves are a part of inanimate nature. Deprived of their vital powers, they may still, as far as we see, be perfect in all their parts. On what their vital powers depend, we know not. In the study of these powers, and the relation they bear to the other powers of nature, we must be satisfied to take the facts as we find them. And what other knowledge have we of the inanimate powers themselves? Do we know more of the nature of gravitation or electricity than of life? It is the properties, not the essences, of things which are the objects of our senses. Our nature must be changed before the latter can be made a subject of inquiry. Life is a certain train of phenomena, depending on the peculiar state of its organs produced by the action of the same agents, which operate in other parts of nature, on the material organs of our frame. We may range these phenomena in the way that best assists the memory, and best shews their relation to each other and the other phenomena of nature; but no task can be more hopeless than the attempt to proceed one step further, either with respect to the living powers or any other principle of action. Such an attempt is beyond, not merely the limits, but the na-

ture of our minds. It is the blind attempting a knowledge of colours.

"When we say we understand any of the phenomena of nature, we only mean that we are able to class them with other similar phenomena. We say that we know why a stone falls to the ground, because we class its fall with the other phenomena of gravitation. With regard to the phenomena of animal life, we at once see the limit of our inquiries, because it is self evident that these phenomena exist no where but in the living animal, and consequently that there is no more general principle to which they can be referred—a position so evident that is difficult to understand how it could ever have been overlooked.

"It is customary to speak of life as a subject of peculiar mystery. But if what has just been said be correct, we have precisely the same means of acquaintance with it as with the other powers of nature. Its phenomena are as open to observation and experiment as the phenomena of any of these powers; and we possess no information respecting any of them but such as is derived from those sources. The greater appearance of mystery arises, not from the greater obscurity of the nature of life, but from its phenomena bearing less analogy to those of the other powers of nature than these bear to each other; in consequence of which the former are less familiar objects of contemplation. Simple as such observations are, they cannot be regarded as superfluous, when we see them overlooked by such writers as Hartley, Hunter, and others of almost equal name.

"We cannot be surprised that the inanimate agents, which are incapable of any change that unfits them for their office, should at length effect a permanent change in the vital parts on which they operate of all parts of nature the most changeable. Hence the death of old age.

"The sensorial functions we have seen fail first, because their organs are removed from the immediate action of the inanimate agents which still excite the organs to which they are directly applied; but for the same reason, it is in the latter, the organs of the nervous and muscular system, that the decay begins. Their powers are gradually impaired by the operation of the inanimate agents which excite them, and the sensorial powers, as appears from all the phenomena of our decay, only fail in consequence of their failure; but as a certain vigour is necessary to render the latter capable of maintaining the sensorial functions, these necessarily cease before the total extinction of those which maintain them."

MEDICAL GAZETTE.

Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

PROPOSED CHANGES IN THE COLLEGE OF PHYSICIANS.

THE reforms which we lately stated were about to be made in the Inns of Court, and in the College of Physicians, are already in progress. The lawyers have taken the lead, and promulgated their plan of putting the dissenters on a footing with the students from the Universities. The additional two years heretofore demanded of the former are to be dispensed with, while the preliminary step of making a deposit of 100*l.*, from which the University-man has until now been exempt, is hereafter to be required of him. This, we suppose, may be taken as illustrating the meaning of the terms "levelling upwards" and "levelling downwards," which have made such strange confusion in some men's minds;—taking something from the one and adding something to the other: thus the dissenter is levelled *downwards*, *quoad* time, and the University man *upwards*, *quoad* money; and so the parties are brought to the same elevation.

The Physicians have more to do: with them the levelling process is by no means so simple. They did not content themselves with exacting an additional period of study or probation from those not educated at the Universities—but they required a degree in medicine; and thus, though placed by their charter in possession of independent powers, they voluntarily consented to become subordinate to, or at least dependent upon, the Universities. While the Surgeons have regulated the studies of those desirous of becoming members of *their* "College," and the Apothecaries have appointed the

course of study to be pursued by those seeking admission into *their* "Society." And while they have each severally improved the standard of acquirement, and raised the grade of their order, the Physicians alone have remained unmoved observers of the progress of society and of the signs of the times. But we do them wrong: they have indeed been reluctant to change, and jealous of innovation; they have been slow to stir, but being moved at length, let us hope that, as with respect to other heavy bodies, if the *vis inertiae* be great, the impetus is proportionally strong when this has been fairly overcome.

The College of Physicians, first in nominal rank, and last in professional influence, of all the medical corporations, owes its present unpopularity and comparative insignificance partly to the exclusive and invidious nature of its bye-laws, and partly to having neglected—nay, positively declined—to exercise that jurisdiction to which it was entitled by its charter, and of which a specific offer was made by the government in 1815, before their present great and extensive powers were conferred on the Society of Apothecaries. If we be right in regarding these as the chief points in which the College has erred, then are the remedies apparent—the *exclusive* principle must be abandoned, and a course of education laid down by which, and by which alone, with *or without* a degree from a University, any individual may become a physician. Evidence of having possessed ample opportunities, and proof of having adequately profited by them, ought clearly to be required of every one; and the College ought to specify the former in a curriculum of their own, and to judge of the latter circumstance not merely by verbal examination, but by testing the practical knowledge of the aspirant in the wards of an hospital. That the highest medical institution in the realm should re-

quize, or rather that it should admit, a degree, though from a place where any kind or where no kind of medical school exists, as a proof of sufficient education,—that it should examine and license, as we assert it has done, after a shorter curriculum and inferior education to that demanded of the aspirant at Apothecaries' Hall,—is an absurdity the most preposterous—an incongruity the most injurious to their own interests, and the most mischievous to medical science.

But let us not attach more blame to the present Fellows of the College than they deserve. Many among them, we know, are aware of the folly of their predecessors; and, accordingly, proposals of reform, though hitherto unsuccessful, have at different times been made. The questions to be decided, however, are by no means free from embarrassment in the detail; and it is upon those details, rather than upon the necessity for some change, that opinions have been divided. A committee was appointed last year, and certain resolutions, evincing more liberality than any thing which had previously been thought of, actually passed the College: meantime the Parliamentary investigation was begun, and the Fellows, apparently irritated at the treatment they experienced, rejected at a second sitting the conciliatory resolutions which had been previously agreed to, but which required confirmation. Some of those who had taken a great deal of trouble on the former occasion have refused to have any thing farther to do with the business; nevertheless, another committee was lately nominated, to consider whether any changes should be made in the statutes; with particular reference, we believe, to the existing distinctions among the Members of the College.

At present it would be premature to speak confidently of the result, particularly after the experience of last year,

but we shall probably not mislead our readers in stating our conviction, that the first great changes in the shape of medical reform may be expected to emanate from the College of Physicians, and we have great reason to hope that they will be very much in conformity with the suggestions which have at various times been made in the pages of this journal. We do not mean that any thing which we have written has influenced the parties, but that our opinions have derived their weight simply from being found to correspond with those prevailing among the most intelligent members of the profession who have directed their attention to the subject. The improvements, which we greatly hope will have passed through their first stage before the present number of our journal is published, consist in establishing an educational curriculum, and in taking from the English graduate his admission to the Fellowship as a matter of course, and removing from other graduates the ban of exclusion which has so long been put upon them. All who have completed a certain course of study, and attained a certain age, would thus, in the first instance, be Licentiates, and all, after a certain time, be equally eligible to the Fellowship.

In any change so considerable as that which we have supposed, one difficulty in carrying it into effect will consist in the conversion of the existing Licentiates into Fellows. We would rather have seen these designations abandoned, as well as those of Candidates and Inceptor-Candidates, the only distinction retained being that of a governing body and commonalty; the former to be elected by the latter. But if we cannot get the best reform which is theoretically imaginable, we are not on that account disposed to reject the best which is found to be practically attainable. We trust, however, that a large and free admission into the

Fellowship will be made at the outset—say of all respectable men of ten years' standing in the College. It is at first starting on the new plan that the greatest jealousies will be felt, and the bitterest discontent excited, if a niggardly or a partial act of grace mark the commencement of the new arrangements; and therefore, if the College hope that its concession will be effectual to the purpose of pacification, it must be full, free, and liberal. The objections to admitting all the Licentiates are great and insurmountable, some of them being men who, never having had any adequate education, ought not to have been licensed by the College at all; but as the new regulations, if carried, will put an end to this abuse, so the number of persons thus circumstanced will progressively diminish, till they become extinct.—The College will then consist exclusively of men who have passed through an extensive course of medical education; and all of whom will be Fellows, or equally eligible to the Fellowship. Thus will much of the invidiousness of the distinction be got rid of.

It is quite clear that if the number of Fellows be considerably increased, some change must be made in the mode of government; indeed, business can never be carried on well where there are even so many as at present. Part of the contemplated plan, we believe, is to institute a committee or council, to limit the duties (or perhaps the privileges, if they will have it so) of the general body. Any such committee would of course be elected by the Fellows at large; and some arrangement of this kind would be so obviously required, that it is unnecessary to enlarge on its expediency.

The College, it would appear from what has been said above, has also at length opened its eyes to the absurdity of compelling students aspiring to the highest honours in medicine to leave the metropolis, where, more than in any other part

of the kingdom, opportunities of studying to advantage exist. The obvious dilemma here is caused by the established custom of requiring a degree. But the College, as we have reminded it over and over again, can license those who have no degree; and being *physicians* would place its members, in public estimation, on the same footing as Doctors in Medicine: a physician without a degree would, at most, be but a nine days' wonder. Besides, it is quite certain that the late government had it in serious contemplation to vest the power of granting degrees in physic in some Body in London; nor can we suppose that the present ministers will be indisposed to do so, if the College consent (as of course they will) to place dissenters on the same footing as members of the established Church. We cannot state it as a fact, but, nevertheless, we strongly suspect, that some understanding with the government on the subject of degrees has been the immediate exciting cause of the present renewed spirit of reform. If, then, the College of Physicians were to do away with the present invidious distinctions—if they were to require a certain and high standard of education—if they were to create, or constitute, the successful candidates "*physicians*," in the same manner as the gentlemen in Lincoln's-inn Fields make "*surgeons*," and those at Blackfriars do "*apothecaries*"—and, still more, if, as we confidently anticipate will be the case, they obtain the power of conferring degrees in physic, then, we say, here will be a real and valid "*reform*"—one calculated to improve medical science, and to enable the corporation in Pall-Mall once more to raise its head, and take its proper place among the learned, the useful, and the influential institutions of the country.

THE LAST NEWS OF PHRENOLOGY.

SINCE the memorable *first of April*, 1833, when a member of the London Phrenological Society announced to that learned body that he had discovered above sixty *new organs* in the head (which, added to Spurzheim's thirty odd, made up nearly the *century of inventions*), we have not heard a word about the *science* in England. Nor are we aware that even in Scotland it has latterly exhibited any signs of life, if we except the impudent attempt—perhaps the death struggle—of a small party who endeavoured to get a section of the British Association at Edinburgh set apart for the discussion of their skull doctrines! We almost regret the failure of these poor people, for it seems to have proved fatal to their existence—a thing we should be sorry for, were it only for our amusement sake.

Meantime the Paris worthies have not been idle. It is true, they have not fulfilled the lofty mission they had imposed on themselves—of perfecting Gall's revelations, and preaching them to all nations; but they have done something—they have, after years of most edifying small talk, and calling in from the high-ways and by-ways, from the shops and shambles, all who would be members, and take a part in the lectures on heads—they have issued a MANIFESTO.

Now then, at last, perhaps some reader may say, we have something tangible. We have so: but probably not exactly of the sort that might have been anticipated. Hear what is said in the very first paragraph. The learned society begin by stating their reasons for publishing a confession of faith: their object, it seems, is “to put a stop to the false attacks by which a science is assailed, *whose general principles have not been sufficiently fixed, or are not yet sufficiently understood*, in regard to the modifications of which they may be capable.”

This, surely, is what may well be called news; it takes us, we confess, quite by surprise, to hear the disciples of Gall announce that the fundamental principles of phrenology are yet unsettled. Why, Gall, and Spurzheim, and the most active of their followers, have done nothing else for the last thirty years but preach up *faith* in their system.

Have they not encompassed sea and land to make proselytes? Yet here we have the secret out at last—that the doctrines, the primary principles, of the *science* are nought; that they are *in nubibus*; and that, if phrenology is to be put on a sure footing, its adepts must begin *de novo*, take to their horn-books, or rather their bone and plaster primers, once more.

But are we sure that there is no mistake?—that the document is quite official? To this we can only say, that it comes before us drawn up by M. Mège, an editor of the Paris Journal of Phrenology; that it was regularly discussed and adopted at a grand and solemn meeting; is signed by M. de Valetti, the secretary, and by M. Fossati (not *Moseati*) the vice-president of the society. It must, therefore, be at least considered as the authentic, as well as the deliberate, opinion of the majority of that learned body.

Following the paragraph just quoted, we have seven others of almost equal interest, under the several heads of Phrenology, Method, Philosophy, Education, &c. We have, however, no room to spare for a lengthened statement of the *new light* opinions: let us be content with seeing how *phrenology* is at present to be defined. “Phrenology,” says the manifesto, “is the study of the nervous system generally, including that of the brain and nervous system in particular, both in man and animals; in other words, it is the *anatomy and physiology of the nervous system*.”

Indeed! How extremely kind of the *new* phrenologists to spread their mantle so wide as to cover (or their net to catch) the whole medical profession throughout the globe! There is, however, a loophole open in the succeeding passage, through which we beg leave to decline the proffered honour, and to make our escape. “The study of the brain and its annexes,” says the document, “puts *organology* on a solid foundation—organology, which marks out the special functions of the brain denoted by the form of the skull and by the *temperament* of individuals.”

Here is the old heaven again—maintaining the solid foundation of the bumps. But what is this to the heresy in the last clause? Is it not enough, we ask, to evoke the indignant shade of Gall, to introduce thus the *temperament* into the phrenological diagnosis of charac-

ter? To us it is matter of pure indifference—or if we have any preference, it is for the new modification. But what would Dr. Gall say to this adulteration of his pure Craniology?

In the paragraph on *Method*, the manifesto renounces all definitive enumeration of the organs, yet gives the lists of Gall and Spurzheim, without deciding in favour of either. Here again poor Gall is abandoned, and heresy is the order of the day.

The absurdities of the remainder of the manifesto cannot be allowed to pass unnoticed. All *philosophy*, past, present, and to come, is claimed as belonging to the domain of *phrenology*. Metaphysics, morals, theology, education, legislation—every science, in short, that has any connexion with man—belong by right (of assumption) to *phrenology*. Philosophers are gravely counselled to betake themselves to the study of the brain, while *they* might, we imagine, with better reason, send the phrenologists to study a little logic and language. The authors of the manifesto would probably not be the worse for studying a little mnemonics also. They forget that their lofty flights on phrenology are placed between their opening announcement of want of principles, and their *appeal* to all rational thinkers: so that this *unfounded*, this *conjectural*, this *as yet unreal* science, is extolled by our Parisian worthies as after all the science of sciences—the very keystone of the edifice of human knowledge! After this, we may surely congratulate ourselves on the progress made by the human mind during the last four or five thousand years!

HOPITAL DE LA CHARITÉ, PARIS.

Rupture of Viscera in the Cavities of the Body, without external appearance of lesion.

By M. ROGETTA.

DURING the summer of 1831, one day as M. Boyer was paying his visit at La Charité, a young mason was brought in, who had just fallen from a scaffold. He had breakfasted shortly before. His aspect shewed extreme anxiety; he was as pale as death; his pulse filiform. In half an hour he expired, having had nothing done for him in the hospital except being laid in bed. No mark of external injury was

observed on the body, except a large ecchymosis on the epigastric region, betokening a bruise of that part.

At the *post-mortem* examination, on opening the abdomen there was found on the intestinal mass a great quantity of fecal matter; it had made its way through a rupture of the transverse colon, which still contained a considerable quantity of the same substance. The opening in the gut was as smooth as if it had been made with a knife, and ran round nearly the whole calibre of the colon. All the other organs of the deceased were healthy; nor did there appear to be any thing unsound about the intestine which had given way. M. Boyer said that this was the second case he had seen of rupture of the great intestine from contusion, without any breach of continuity on the external parietes.

I took a note of this case at the time, as I thought it remarkable; but within the last few months another example has fallen in my way, which may, perhaps, be considered as still more curious and interesting. This was a case of laceration of the liver, without any rupture of the abdomen.

In September last, while M. Guersent, fils, did the duty of M. Roux at La Charité, a young man, 21 years of age, was taken in, labouring under the effects of bruises which he had just received from the wheel of a carriage that had passed over his body. The patient was the *conducteur* of one of those vehicles called *coucous*, and had fallen from the seat: there were ten persons in the *coucou* at the time, and the wheel passed over his body. The track made by the wheel was along the right side, from the groin to the shoulder; but the external injury appeared to be of no consequence. The patient, however, complained of his breathing, and of pain in the region of the liver. He was bled, and poultices were applied.

Some days after, jaundice made its appearance, and an effusion in the right side of the chest was detected posteriorly. Blisters were put to the part. The effusion continued; the breathing became more embarrassed; and fever set in.

About a fortnight after the accident a swelling was perceived over the liver; this spread, and extended from beneath the last false ribs to the median line of the body. Fluctuation in the swelling; jaundice and fever continue.

Most of those who saw the patient gave their opinion that there was clearly an abscess of the liver; but M. Guersent (I record it to his credit) rather conceived that there was a large collection of bile in the gall-bladder, or perhaps an aqueous cyst in the liver, but no abscess.

The tumor was cautiously opened with a bistoury, when a *litre* (two pints) of pure bile came forth. The opening remained fistulous for some time, giving issue to a coloured liquid supposed to be bile. No remarkable accident supervened.

When M. Roux returned to the hospital he saw the patient, when, upon maturely examining the case, he announced that it was the *stomach* that had been opened: the liquid that came forth, he said, proceeded from the interior of that viscus. The patient died shortly after, of confluent small-pox, when, upon holding a *post-mortem*, it was found that the large lobe of the liver had been ruptured. The extent of the laceration was about two inches in length, and as much in depth. A kind of cellular cyst had been formed about the ruptured part, into which the bile gathered; and this was the cyst that had been opened by the operation.

These cases are certainly not unique in surgical practice; yet, with respect to the first example, it is perhaps more usual in like circumstances to meet with rupture of the stomach than of the colon. As to the viscera of the chest and head, their laceration by simple pressure, without lesion of the solid walls that contain them, is difficult in adult age, unless we confound the effects of locomotion with those of pressure. It has, however, sometimes happened, in the case of young children, in consequence of the yielding nature of the walls just mentioned. Morgagni records such a case in his *Sed. et Caus.* Ep. liii. n. 33; and my colleague, M. Troncin, has treated with me a child, two years of age, whose brain was injured (*lésé*) by simple pressure, without any rupture or laceration of the external parts.

ST. GEORGE'S HOSPITAL.

Fractured Pelvis—Hæmorrhage—Suppuration within the Pelvis.

CHARLES WHITE, aged 17, was admitted January 13th, under the care of Mr. Cæsar Hawkins, having just before been knocked down upon his face by a horse, a loaded dung cart having then passed over the back of the pelvis. On his first admission he appeared to be dying of internal hæmorrhage, with much pain and distension of the abdomen; it was thought, however, that the bleeding was probably external to the peritoneum within the pelvis, as the pain and swelling were chiefly at the lower part of the abdomen; no blood, however, appeared externally except on the back of the nates, which were much contused. In a few hours, however, he

recovered from the hæmorrhagic collapse, though still complaining of much pain. He had made water an hour before the accident, and was unable to make water himself, on account of a rupture in the urethra. A gum-elastic catheter was in the evening passed with some difficulty into the bladder through the lacerated part, in which there seemed to be a good deal of coagulum, and it was fastened in the bladder, the water in which was quite clear, and free from blood.

Jan. 14th.—Seems comfortable, except from pain in the lower part of the abdomen, which was hard and tense, as if from blood in the muscles. Pulse frequent and sharp, as if from hæmorrhage; bowels confined.

R. Cal. gr. iij.; Jalapæ, gr. xvi. M. statim sumend.

15th.—Tolerably comfortable: skin rather hot; less tenderness and pain.

R. Haust. Salin. ʒiss.; Magnes. Sulph. ʒss. M. 6tis horis sumend.

Examination of the pelvis gave the sensation of obscure crepitus, as if of cartilaginous surfaces rubbing against each other in the right iliac synchondrosis, and a sensation of crepitus was also perceptible in the front of the pubes near the lacerated part of the urethra. Motion, especially of the right leg, gave him also very great pain.

16th.—He last night began to complain of more pain in the abdomen, and to-day has much tenderness and pain above the pubes; this continues to-day, and he has an expression of much anxiety of countenance, with a small thready pulse, at 116, and fever; bowels open. Mr. Hawkins believed that there was inflammation of the lower part of the peritoneum, and directed him to be bled, which was done to ten ounces. This gave him much relief, and the pulse became fuller and stronger, the blood being much buffed and cupped.

The water now containing some mucus from the bladder, Mr. Hawkins withdrew the catheter, and found it encrusted with phosphates; a new one was then passed in, and the bladder was injected with warm water once a day, from which he experienced much benefit, and the urine became again clear.

Vespere.—Pain continues, though less.

Hirud. xvi. abdomini.

R. Hydr. Submur. gr. ij.; Opii, gr. ʒth. M. Ft. Pil. 4tis horis sumenda.

17th.—Seems a good deal better, but the pulse has still some sharpness, and the pain is not gone.

V.S. ad ʒviii. Blood cupped and buffed, though less. Cont. Pil.

18th.—All expression and anxiety gone; much less pain and tenderness. Catheter again changed, and found slightly encrusted with phosphate of lime, a little mucus having also again been secreted in the urine.

Cont. Pil. Svis horis.

19th.—Omit. Pill. Beef tea, $\frac{1}{2}$ pint.

21st.—Still going on well, and free from pain.—Fish diet.

22d.—Does not seem so well, being weak and nervous, and losing his appetite, though not complaining when not moved. A good deal of foetid bloody pus coming away by the side of the catheter, and no difficulty being experienced in making water when this was tried, the catheter was withdrawn, and he was allowed to make water, so that the pus was not confined, and no irritation excited in the bladder, of which he made much complaint. Bowels somewhat purged, and the evacuations fetid and dark. Took castor oil yesterday.

R Calomel, gr. iij.; Opii, gr. ss. M. statim.

R Haust. Rhei. \mathfrak{z} j. post hor. iij.

23d.—Same symptoms, but increased; restless and anxious; unable to take any food; complains of much pain in the abdomen and perineum, in which last situation no swelling could be perceived; much bloody purulent fluid coming away by the urethra and by the catheter, the point of which entered a cavity communicating with the perineum, though not appearing externally, so that Mr. Hawkins believed that suppuration had taken place on the inside of the pelvis where the blood had been extravasated, probably about the period when the peritonitis had come on. He therefore passed a catheter with some difficulty into the bladder, the water in which was still quite clear, and made a large incision in the perineum, the cavity in which was not large; but an opening was found on the right side, going into the interior of the pelvis, which was enlarged by the knife, and a large quantity of the same putrid bloody pus was let out. The finger, passed into the pelvis through the opening, detected an extensive fracture across the thyroid foramen, on the right side, the broken portions being partly loose, and extensively deprived of periosteum, in the cavity from which the fluid had been evacuated.

Wine, arrow-root, &c. were given, but the prostration of strength went on increasing; the next day he had much vomiting, and died in the evening of the 24th.

Examination of the body.—Peritonitis only at the lower part of the abdomen, where the sigmoid flexure of the colon, the omen-

tum, and part of the small intestine, were firmly adherent to the peritoneum lining the parietes, and covering the bladder; and the bowel at this part was very soft, and easily lacerated. A large quantity of blood was extravasated on the outside of the peritoneum, chiefly around the pelvis and back of the abdomen, the peritoneum being every where raised and separated from the adjacent parts, the blood having even made its way along the mesentery to the coats of the intestines, and extending in the same way into the rectum and colon. The bladder was contracted and small, though uninjured, in the midst of a mass of coagulum above an inch thick, between the peritoneal and muscular coats, and nearly as much in front. The blood had also been driven a little into the substance of the iliac and psoæ muscles on both sides, and somewhat up the anterior parietes of the abdomen, chiefly, however, between the peritoneum and transversalis. There was very little blood in the adductor muscles of either side, and very little in the perineum, so that, although the source of the bleeding could not be ascertained, it did not appear at all likely to have been effused from the ruptured urethra, but from some of the vessels of the interior of the pelvis injured by the fractured bones.

The laceration of the urethra had taken place just under the symphysis, and was probably occasioned by the fracture of the left side.

The front of the pelvis, between the bladder and innominata, and deep in the pelvis, was occupied by a large cavity in a sloughy state, which reached up also some little way on the front of the abdomen. The suppuration had not extended, however, to the blood on the posterior part of the bladder, or among the intestines. In this cavity much of the fractured bones on the right side lay nearly loose and dead, so that the adductor muscles formed the boundary of the abscess. The right os innominatum was broken into several portions through the thyroid foramen, the transverse ramus of the pubes being separated at the symphysis, and loose and dead from the line of fracture. The ascending branch of the ischium was broken separately, nearly down to the tuberosity. The left innominatum was broken across the thyroid foramen in the same way, though to a less extent, and none of it seemed deprived of periosteum by the sloughing abscess. The ilium was separated from the sacrum at the synchondrosis on both sides, where a little blood had also been effused, but evidently from small vessels only, quite distinct from the great extravasation. On the left side a small portion of the sacrum had been broken off at the joint.

MIDDLESEX HOSPITAL.

Case of Tumor in the left Auricle.

SUSAN ROWLAND, on her admission into the hospital the 10th of December, stated herself to be 15 years of age, and single; that she had spit blood occasionally for five years, and had been afflicted with cough and palpitation for the last five months. She was anasarcaous, had a livid countenance, there was dyspnoea, orthopnoea, decubitus only on the left side, fainting, small pulse, throbbing of the jugulars, expectoration of blood (sometimes in small globules), crepitation in the lower lobe of the right lung, slight bronchophony; percussion dull.

Slight increase of impulse in the heart—sounds peculiar; between the first and second sound there is heard a supplementary one, which it is difficult to describe, but it suggests the impression of some obstruction in the aorta or in the mitral valve.

The patient speedily became worse: nights disturbed; more anasarca and orthopnoea, under which she rapidly sunk.

The sounds of the heart altered slightly a short time previous to her decease, the additional sound appearing to run more into the second, whilst originally it seemed to have been more closely connected with the first.

Post-mortem appearances.—Pulmonary apoplexy at the base and at the apex of the right lung.

Heart.—Right auricle and ventricle much dilated. In the left auricle, a tumor, as large as an egg, attached by a pedicle to the inner surface of that cavity, just below the opening of the pulmonary veins, and at the point of the fossa ovalis. The tumor was covered by a thin, smooth, shining membrane, a prolongation of that of the lining membrane of the auricle, which it in every respect resembled, and which gave to the pedicle (about the size of a quill), a degree of strength and resistance that enabled it to sustain the heart when raised by grasping the tumor.

The tumor felt solid, like spleen, when cut; its section presented a firm gelatinous substance, of uniform appearance, of a deep red colour, not unlike recently-coagulated blood, but as if contained in a fine cellular tissue*. On being for some hours exposed to the atmosphere, the investing membrane having become somewhat dry, blood-vessels of an arborescent form were perceptible therein, very similar to the appearance of the investing membrane of the chick as it leaves the shell.

CONGENITAL DEFICIENCY OF THE IRIS.

DR. E. CAZENTRE, of Bourdeaux, illustrates this rather rare vice of conformation by a case occurring in his own practice. M. M—, aged 36, of robust constitution and perfect health, has both his eyes deficient in the iris. In the right there cannot be detected the least vestige of that membrane; in the left there is merely a slight greyish crescent-shaped slip, which would seem to be a rudiment of the iris. Both corneas are a little more convex and somewhat smaller than ordinary; the ciliary ligaments also present an equally contracted circle, the inner circumference of which, in some measure, supplies in each organ the office of a pupil, and from which there is a bluish-black reflection of the pigment of the choroid. The deformity is congenital. M. M— has been remarked, from his earliest childhood, for the strange appearance of his eyes. He was thought blind at first, and it was not till after the lapse of some time that he was found sensible to the light. At present there is a considerable disturbance of the visual function. He cannot see objects distinctly unless they be very near. In the bright day-light his powers of vision are confused, his eyes watery, the lids nearly closed, and the pavé, or any bright substance reflecting the light on his eyes, gives him severe pain in the orbits and head. He cannot read by candle-light; all objects appearing to him then as encircled with a thick fog. In the shade, or after sunset, he can see best. Reading fatigues him much, though assisted by spectacles, which he constantly wears. He can, however, peruse a journal in a light, or rather a darkness, which would render the attempt useless in any other person. In short, the obscurity of night is the most convenient medium in which to conduct his movements and proceedings.

It is not difficult to account for the circumstances, from the anatomical state of the parts. The iris, with its suitable aperture, the pupil, is required for the ordinary function of sight; and the pupil must be endowed with the appropriate degrees of contractility and dilatation, in order that it may present to the rays of light an opening proportioned to the intensity and excitability of the retina. Without this, the harmony of the function is disturbed. But the state of the parts in M. M. is not so arranged. Through the central opening, which is always too large, a constant quantity of luminous rays enters; and the more active these rays, the more the vision is troubled. Thus the blaze of the fire, the light of the

* The writer of this account regrets not having had an opportunity of ascertaining by maceration what was the structure of this tumor.

BILLS OF MORTALITY.—METEOROLOGICAL JOURNAL.

candle, and the sunshine, produce the most uncomfortable feelings, which can be only very partially remedied by the almost total closure of the eyelids. There is reason, moreover, to suppose that there is in the present case a more than ordinary excitability and sensibility of the retina, since M. M. can easily read written characters in great obscurity, and the very darkest night seems well suited for directing his steps. May we not suppose this to be owing to the large and fixed aperture in the ciliary circle admitting a more considerable proportion of luminous rays than in the ordinary condition of the eye?—*Gaz. des Hôp.*

RETENTION OF URINE.

DR. SOMERVAIL, of Virginia, gives a mixture of three grains of camphor, with five of muriate of ammonia, in a gum-arabic julep, every two hours, in cases of retention of urine where the catheter cannot always be conveniently applied.—*American Journal.*

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,
Delivered at the London Hospital,
By THOS. DAVIES, M.D.

LECTURE XX.
DISEASES OF THE PLEURA.
HYDROTHORAX.

By hydrothorax we mean an effusion of limpid serosity into one or other, or both, the cavities of the pleura, not depending upon previous inflammation.

This disease has been denominated *Dropsy of the Chest*; more commonly also *Water in the Chest*; and has often been mistaken for other affections—as diseases of the heart, aneurism of the aorta, emphysema, and oedema of the lungs.

Hydrothorax may exist in the idiopathic or sympathetic forms: the first is so rare, that Laennec calculated he had not met with it more than once in 2000 post-mortem examinations. The fluid then occupies one side of the chest only. The sympathetic form usually affects both pleuritic cavities, and is a common consequence of acute and chronic diseases; especially of scarlatina, and, above all, of organic lesions of the heart. Laennec states that sympathetic hydrothorax indicates the rapid and fatal termination of the disease which is its cause; that it rarely commences to develop before a few days or hours preceding death, and that nothing is more uncommon, even in diseases of the heart accompanied by universal leucophlegmasia and ascites, than a hydrothorax whose signs have appeared eight days before death. I entirely differ from him upon this point, for I have seen the signs of the sympathetic affection presenting

themselves two or three months before the fatal termination of the disease, and have afforded temporary relief by tapping the chest in two individuals who had long laboured under sympathetic hydrothorax.

In both forms of the disease the effused fluid presents the same characters; it is limpid, and of a fawn colour: the pleurae are perfectly healthy. The quantity of the secretion varies from a few ounces to many pints, and the effects of its accumulation are precisely the same upon the surrounding parts as I have described in effusion from inflammation of the pleura; the signs are also similar. Thus there is absence of the respiratory murmur, dullness on percussion, ægophony, altered position of the heart, enlargement of the side affected, effacement of intercostal spaces, immobility of ribs, with dyspnoea and cough.

General signs.—Sympathetic hydrothorax is itself one of the general signs of some other disease—as of fevers of long duration, and of affections of the heart. I shall again advert to this subject when we arrive at the consideration of the latter class of disorders.

Treatment.—Idiopathic hydrothorax is so rare, that I have not had occasion to treat it, but the indications would be the same as for any other species of dropsy. The treatment of the sympathetic form should be subservient to that of the disease of which it is the consequence, and will be spoken of hereafter. I have twice directed the operation of paracentesis thoracis in these cases, and have thereby produced temporary relief.

PNEUMO-THORAX.

By pneumo-thorax is meant an effusion of aeriform fluids into the cavity of the pleura. This disease, in its simple form, is rare, although it is not very infrequent when combined with serous or puriform secretions in the same cavity. This affection was first mentioned by Riolanus, and

afterwards became the subject of the inaugural thesis of the celebrated Itard, physician to the hospital of "Sourds-Muets," at Paris.

The gases accumulated in the pleuritic cavity are sometimes inodorous, at others fetid, and similar to sulphuretted hydrogen. Their quantity is occasionally very considerable, and they then produce the same effects upon the surrounding parts as serous or puriform fluids placed in the same situation: the lung becomes compressed, the heart is pushed from its natural position, the thoracic parietes are dilated, and the diaphragm depressed.

Causes.—Air is frequently met with in the pleura, combined with fluids resulting from chronic pleurisy. In that case, when there is no communication between the pleura and the bronchial tubes, we must suppose that it is formed from the decomposition of that fluid: the gas then has a most fetid odour, assimilating to that of sulphuretted hydrogen.

A tubercular excavation has been seen to burst into the cavity of the pleura, producing a free communication between it and the bronchial tubes: atmospheric air then of course passes into the pleura, which in its turn produces pleurisy and consequent effusion of fluid. An excavation has also been seen to burst into the pleura, and not into the bronchial tubes; the softened tubercular matter then irritates and inflames the serous membrane, and a liquid secretion is again the result, the decomposition of which affords air sufficient to produce pneumo-thorax.

Gangrene of the lung causes pneumo-thorax; not only from the decomposition of the structure of the organ, but also from its establishing a communication between the bronchial tubes and the pleuritic cavity. Puriform secretions are always present in this case, the decomposition of which also produce aeriform exhalation.

Blood effused from any cause into the pleura, may decompose, and give rise to the formation of air.

A violent blow upon the chest may rupture the pulmonary pleura, and occasion extravasation of air into its cavity. Hewson and Laennec mention instances of this.

The rupture of an emphysematous lung may cause effusion of air into the pleura. I have seen a remarkable instance of this case in a child, in whom the necessity for respiration had so increased in one lung, in consequence of the total hepatization of the other, that it had become completely emphysematous; one or more of the enlarged air-vessels had ruptured, and air had effused and accumulated in the pleura, in such quantity that the lung was compressed to a very small size.

Finally, an aeriform fluid may be gene-

rated in the cavity of the pleura, without any visible change in the membrane, or appearance of any other effusion. The serous membrane has then occasionally appeared drier than usual: Laennec has seen it as dry as parchment.

You thus perceive, gentlemen, that simple pneumo-thorax is a rare affection, and that there are only two or three apparent causes of it—1st, from the rupture of an emphysematous lung; 2dly, from a blow rupturing the pleura pulmonalis; 3dly, from a spontaneous exhalation of air: while, on the other hand, the disease frequently arises from the decomposition of liquid effusions, or from the direct passage of air from the bronchi into the cavity of the pleura, constituting cases of what Laennec calls pneumo-thorax with effusion. Let us first examine the signs of simple pneumo-thorax, and then those of pneumo-thorax with effusion.

Signs of Pneumo-Thorax.

Functional.—Dyspnoea is a constant sign of this disease. Cough is not always present, except the bronchial tubes be also affected.

Local.—As the loudness of the sound upon percussion depends upon the quantity of air contained in the chest, so in this case the diseased side of the thorax is always more sonorous than natural. But this sign alone is insufficient to determine the nature of the affection, because the sound is also as loud upon percussion in emphysema of the lung. An error, too, might arise from the supposition that the most sonorous side was the most healthy one, when, in fact, it is that which is diseased.

But the conjunction of the signs derived from auscultation and percussion give certain proofs of the presence of air in the cavity of the pleura: thus, if the respiratory murmur be entirely absent on the side which is most sonorous by percussion, you may fairly infer that it is a case of pneumo-thorax. It is scarcely necessary to state, that the respiratory murmur may be heard, as in empyema, between the base of the scapula and the corresponding part of the vertebral column; and for the same reason, because of the lung being compressed against the vertebræ at that part.

In consequence, also, of the pressure of the air upon the intercostal muscles and ribs, the side affected becomes larger, and the degree of increase may be determined by measurement.

The only affection which produces similar signs is emphysema of the lungs; but there are differences which render the two diseases easily distinguishable: for in pneumo-thorax the absence of the respiratory murmur is complete, except at the

points indicated; but it may still be heard, although feebly, at different points of the chest, in emphysema. In the latter disease a slight rhoncus is occasionally apparent, even close to the ear, which never occurs in pneumo-thorax. The dry crepitating rhoncus is also pathognomonic of emphysema. Finally, pneumo-thorax is always a sudden affection; but dilatation of the air-cells is a chronic disease.

Signs of Pneumo-thorax with Effusion.

In this combination the respiratory murmur is absent all over the surface of the affected side, except at the part corresponding to the situation of the compressed lung. The sound on percussion varies: thus at the lower part of the chest, where the fluid has gravitated, it is dull; but at the upper part, where the air is accumulated, it is loud.

There are three other signs, which, when united, are pathognomonic of air and fluid matters co-existing in the pleura. These are the *hippocratic fluctuation*, the *tintement métallique*, and the *bourdonnement amphorique*.

Hippocratic fluctuation.—*Succession.*—Hippocrates proposed, for the purpose of discovering fluids in the chest, that the patient should be placed on a solid seat, his arms being extended by an assistant; and that he then should be shaken by the shoulder, to determine a fluctuation.

This method of succession had fallen entirely into disuse, although no doubt it had been often tried, but without success, in the great majority of cases. We have, however, several instances on record, in which a fluctuation has been felt by the patient himself upon a sudden and spontaneous movement of his own, as in turning quickly in bed, or in descending a staircase, or in riding on horseback. There can be no doubt that when a fluctuation is thus accidentally produced, it might also be caused by the Hippocratic mode of succession, as I have verified in a great number of cases.

What is the reason that succession will induce fluctuation in some cases of fluid in the chest, and not in others? The reasons are obvious. In empyema or hydro-thorax nothing is contained in the cavities of the pleura but liquids; no movement in such cases can produce fluctuation, no more than it could in a perfectly filled bottle; but if air co-exist with the fluid, as in pneumo-thorax with effusion, then the fluctuation becomes distinct, as it would upon shaking a bottle partly filled; for the fluctuating sound can only be produced by the reciprocal action of air and liquids upon each other in motion.

Fluctuation upon succession is, then, a sign of pneumo-thorax with effusion. The liquid matter should always of course be in a certain quantity; but the loudness of the

sound depends upon the air being in the greatest proportion, for we constantly find that if the pus or serum predominates, the sound of the fluctuation is slight; if the air be in excess, it is considerable.

This sound is always distinguishable by the stethoscope; and even when slight, it may be detected by it when it cannot be heard by the intermedium of the air. If the hand be also applied to the surface of the chest, the shock or vibration produced by the fluctuation may easily be felt.

There is another case in which air and fluid may co-exist in the same cavity, and in which, consequently, fluctuation should be produced by succussion;—I mean a very large tubercular excavation, containing a certain quantity of secretion within it. I have essayed in many of these cases to produce this sound, but never could effect it. I believe this arises from the fluid being in very small quantities in such cavities; perhaps also their soft parietes are not equally favourable to the production of fluctuation.

Tintement métallique.—I have already described the nature of this sound, in my lecture on auscultation. It is like that produced by frequently and gently striking a thin metallic or glass vessel with a pin. It is heard during the acts of respiration, speaking, or coughing. The tintement métallique indicates the presence of air and fluid in the pleuritic cavity; but Laennec asserts still more—that it is a proof of a fistulous communication between a pulmonary excavation, opening at once into the bronchi and pleura. I have often, it is true, met with a fistulous opening when the tintement métallique has been present, but often also I could not, after a most careful examination, discover any such fistulous communication. I have therefore arrived at the conclusion that this sign, although perfectly indicative of pneumo-thorax with effusion, is not pathognomonic of a fistulous opening between the bronchial tubes and the cavity of the pleura. The tintement métallique is also a sign of a large tubercular excavation, containing a certain quantity of fluid; for here the re-union of the circumstances necessary to its formation obtains—that is, there is a large cavity containing air and liquid.

Bourdonnement amphorique.—This is a sound like the buzzing of a bee in a large vase. There are, however, great varieties in this sign, especially in its loudness. It is always somewhat argentine, or metallic; it is occasionally like a thin, shrill, and scarcely audible, silvery whistle, softly resounding afterwards, as if echoing in a metallic vessel. This sound is always indicative of air and fluid contained in a large cavity in the lung, or of pneumo-

thorax with effusion. I believe *bourdonnement amphorique* never occurs in the latter disease, except where there is the fistulous communication before spoken of: it appears to me to be formed by the air passing into the bag of the pleura through the fistula, and resounding afterwards. It is produced during respiration, speaking, and coughing.

As the presence of a certain quantity of liquid and air in an excavation in the lungs, or in the pleuritic cavity, causes these sounds, have we any diagnostic signs by which we can distinguish whether they arise from one lesion or the other?

In the first place, I have never met with an instance of fluctuation in a tubercular excavation, although I have always attempted to produce it when I have heard the tintement métallique, or *bourdonnement amphorique*. I do not, however, deny the probability of its occurrence, but I may be fairly allowed to infer it must be very rare indeed. In the next place, when there is a tubercular excavation, the tintement métallique is usually confined to the upper half of the lung, and in pneumothorax with effusion it is much more extensive, although I once met with so large a tubercular cavity that scarcely any of the lung remained, except a small mass attached to the larger divisions of the bronchial tubes, and a thin lining of its

substance adhering to the costal pleura: in this case, these two sounds were audible all over the side affected, but still there was no fluctuation. Thirdly, I have observed that patients having tubercular excavations, however large, lie indifferently on either side, whilst those afflicted with pneumothorax and effusion prefer resting on the diseased side.

In the present state of medical science, we can effect but little, indeed, by any treatment, because the disease is almost constantly combined with phthisis; at least I have not met with a single instance in which it was not. I have very frequently tapped the chest on these occasions, but never produced any thing but temporary relief; in fact I have now ceased performing the operation of paracentesis thoracis in these cases, except the patient be very distressed by dyspnoea. I would recommend you, gentlemen, when you have determined upon evacuating the fluid, always to explain to the friends the nature of the case with as little technicality as possible; state that you cannot save, but may ease, the patient, and possibly protract his life for a little time.

I now present a tabular view of the number of times I have directed the operation of paracentesis thoracis, the nature of the case for which it was performed, the names of the operators, and the results:—

Nature of the Cases.	Operators.	Recovered	Under Treatment.	Died.	Observations.
Empyema	Mr. Sturkey, Lung Infirmary	1	<i>Empyema</i> .—Of the 16 cases, 12 have recovered, and 4 have died.
	Mr. Martin, Surgeon, R. N.	1	
	Mr. Headington	1	Of the 12 individuals cured, 5 were under 6 years, one at 11, one between 18 and 19, and 5 above 25 years of age.
	Mr. John Scott.....	4	..	1	
	Mr. Kiernan	2	In three of the unsuccessful cases, the lungs could not expand after the evacuation of the fluid, in consequence of the thickness of the false membranes covering them; of the third I have no account.
	Mr. Herring, Lung Infirmary	3	..	1	
	Dr. B. Babington....	1	
	Mr. Skey	1

Note.—This Table being revised in December 1854, varies in the number of cases from that given at the time the *Lancet* was published in May 1854.

Pleuro-Peripneumonia.

Inflammation of the pleura and of the substance of the lungs often co-exist. Laennec has considered these combinations under three forms or varieties. 1st. Peripneumonia complicated with slight pleurisy; 2d. Pleurisy with slight peripneumonia; 3d, where the inflammation of the pleura and the lungs is of nearly equal intensity.

1. *Peripneumonia combined with slight pleurisy.*

There are few cases of peripneumonia in which the pleura is not slightly affected, for when the inflammation of the lung has reached the surface of the organ, the pleura covering it inflames, and a thin false membrane is formed, and is exactly bounded to the part where the disease has gained the surface; sometimes even a false membrane is also formed upon the costal pleura, exactly opposite. When hepatization attacks a certain portion of the lung only, there will be effusion of fluid if the pleura be also inflamed; but if the organ be almost entirely consolidated, it presents so firm and incompressible a mass that there will be no effusion, but merely a very thin and incomplete false membrane; thicker, however, at the edges and fissures, and on some points, than on the generally inflamed surface.

Signs.—If the patient were seen for the first time in this state, it would be very difficult to distinguish whether he laboured under pleurisy with effusion, or hepatization of the lung; for the dulness on percussion, and the absence of the respiratory murmur, would be the same in both cases. But when a lung is completely hepatized, there is always a very loud and distinct bronchophony, almost similar to pectoriloquy, at various points, particularly at the summit and the root of the lung; a sign which does not exist, to the same extent or degree, either in pleurisy or pleuro-peripneumonia.

But if the disease has been seen from the beginning, it is almost impossible to mistake it, for the rhoncus crepitans always precedes the absence of the respiratory murmur, and the dulness of the sound on percussion only appears gradually. In pleurisy the dulness is sudden on the whole of the side affected. The orthophony also occurs, at least for a day or two, in pleurisy.

2. *Pleurisy, with slight Peripneumonia.*

It occasionally happens, when a pleurisy is severe, and accompanied by a considerable and rapid effusion, so that the lung is extensively and speedily compressed, that inflammation develops itself in some points of the organ, usually in the inferior lobe; these points are often isolated, and

of slight extent, constituting what has been called *lobular pneumonia*. It is probable that the inflammatory action in the lung is moderated by the pressure of the effused fluid, so that it is confined to a few lobules, and cannot extend farther. The lobular pneumonia rarely proceeds to the stage of purulent infiltration; its resolution is slower than that of simple peripneumonia, and it presents very peculiar anatomical characters: thus the lung is less firm, and more flabby, than when in a state of hepatization; the pulmonary tissue is of a red, violet, or gray tint; a section of it presents the granular appearance of hepatization; it has altogether the aspect and consistence of muscular flesh which has been bruised to render it tender. Laennec denominates this state *carnification*. There is now no trace of air cells; no air can be passed from the part, and it is but slightly humid.

The resolution of this state is slow, under the pressure of the pleuritic effusion. When it occurs, the affected part becomes less red, then changes into a pale violet, which latter becomes of a grayish colour; at the same time the vesicular texture of the lung reappears.

The resolution of peripneumonia under the influence of the pressure of fluid, in the stage of purulent infiltration, is very rare indeed. Laennec describes instances in which he had seen carnified portions of lung of a yellowish tint, in which the air cells were distinguishable, and appeared filled with semi-concreted pus.

Signs.—The complication of even a slight peripneumonia with an abundant pleuritic effusion, may generally be distinguished by the crepitating rhoncus, which usually occurs at the root of the lung, in the axilla, or a little below the clavicles.

This complication can hardly take place, except at the commencement of the disease, and when the effusion is not yet great; for when the lung is completely compressed, it is no longer susceptible of inflammation.

3. *Pleuritis and Peripneumonia of equal intensity.*

This conjunction is much less frequent than the two preceding cases. The pleurisy does not increase the danger of the peripneumonia; it even diminishes it, in moderating the inflammation by the compression of the effused fluid. On the other hand, the peripneumonia augments at first the danger of the pleurisy, which rarely threatens life at its acute period, and it renders the absorption of the fluid more rapid, and does not permit so great an accumulation of it as occurs in simple pleurisy; for this liquid is thrown out between two bodies, neither of which cedes to the

pressure exercised upon them—viz. the hardened lung on one side, and the firm thoracic parietes on the other. Laennec therefore infers that this form of pleuro-peripneumonia ought to be regarded as less dangerous than either simple pleurisy or peripneumonia.

Signs.—The re-union of the signs of pleurisy and peripneumonia renders these combinations easily determinable; many of their pathognomonic signs are even more permanent than in the simple, or uncombined affections; thus the rhoncus crepitans, and ægophony, often persist even to the period of convalescence. The latter sound is usually only apparent at the root of the lung, and in the vicinity of the inferior angle of the scapula; and from the presence of the large bronchial divisions, as well as from the density of the pulmonary tissue, it is rarely simple, but is generally accompanied by a loud and noisy bronchophony; it is in this case particularly that the united sounds imitate so perfectly the voice of *Punch*.

Treatment.—The treatment of pleuro-peripneumonia ought to be regulated according to the predominance of one or other of these diseases; it is therefore unnecessary, after what has already been said, to repeat what I have stated in speaking of the uncomplicated forms of the separate affections.

ACCIDENTAL PRODUCTIONS DEPOSITED IN THE PLEURA.

Laennec has divided these formations into three classes.

1. *Productions which develop themselves on the inner surface of the Pleura, ordinarily accompanied by liquid effusion.*

These are usually cancerous or tubercular deposits. The first generally offers the characters of medullary sarcoma, presenting masses of various sizes, but rarely, nevertheless, beyond that of an almond; they are strongly adherent to the pleura, which membrane is of an areolar redness around these deposits, for some distance; sometimes melanotic lines are seen to pass from the tumors to the surface of the pleura. The tumors are rarely numerous.

Tubercles are occasionally deposited in great numbers upon the surface of the membrane; they approximate closely, and are often united by a soft and semi-transparent false membrane, in which they seem at first imbedded. At a remoter period from their formation, this false membrane can no longer be found, because it is organized and united to the pleura; the tubercles are then very adherent, and appear implanted into the thickness of that membrane. Sometimes the tubercles are gray and semi-transparent, sometimes yellow

and opaque, but they have not been seen softened. The interstices between them are generally reddened. In this state the pleura has the aspect of certain miliary eruptions on the skin; and in the midst of the redness lines of melanotic matter may be seen. Although tubercles are commonly first deposited in a false membrane, yet they may occur in the pleura without any signs of previous inflammation.

Small, white, opaque, and flattened granulations, of a firm and fibrous texture, are occasionally seen on the surface of the pleura; the membrane is then thickened.

These two productions are more commonly observed upon the peritoneum than the pleura; they are accompanied by effusion, which is generally sanguineous. Cancerous productions sometimes form an exception to this rule. The signs of effusion are of course apparent, but there are none of the organic causes which have occasioned it.

2. *Solid Productions.*

The pleura, instead of secreting its serosity, sometimes deposits tubercular or cancerous matters in large quantities, which accumulate and gradually compress the lung against the vertebral column, and thus fill up one side of the chest: these cases are very rare. Boerhaave found a white matter filling up one side of the chest of a patient; Corvisart mentions a similar case; Recamier found an enormous tubercular mass occupying the cavity of the pleura; Cayol and Laennec had each observed analogous instances. Haller appears also to have met with a considerable mass of softened melanosis in the same situation.

3. *Accidental Productions developed between the adherent surface of the Pleura and the neighbouring parts.*

Medullary sarcoma and tubercles, imperfect or petrous ossific deposits, and large cartilaginous incrustations, have occasionally been found in this situation. Haller and Dupuytren have described large cysts, placed between the pleura and the intercostal muscles, filling almost entirely the pleuritic cavity, and compressing the lungs.

DIAPHRAGMATIC INTESTINAL HERNIA.

A wound, a rupture from a fall, or a mal-conformation of the diaphragm, may occasion an opening sufficiently large to admit a portion of the intestines, or even the stomach, into the cavity of the chest. Herniæ of this kind could only be distinguished by the absence of the respiratory murmur at the points of the chest corresponding to the position occupied by these viscera, and by the horborygmata which might be heard in the same situations.

The lungs have been seen forming hernia through the intercostal muscles.—Gratcloup mentions one produced by a violent cough; Boerhaave speaks of another, produced by the efforts of accouchement; Sabatier a third, which appeared after the cicatrization of a bayonet wound between the fifth and sixth ribs; Richter gives a fourth instance; and two cases have lately been observed at Paris.

The respiratory murmur would be most distinctly heard in tumors of this kind, by which their nature could easily be determined.

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

BY HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Continued from page 652.]

MORE unexceptionable instances of the effect of inflammation, the result of extension of disease, will be found in Mr. Swan's chapter upon ulceration of nerves. In the first case, that of William Sharpe, he suffered such violent pain in the thigh and leg, as far as the ankle, that he wished to have the limb amputated. The ulcer was upon the tibia, and the only nerve ulcerated was the dorsal branch of the peroneal; yet the pain was by no means confined to the parts upon which this nerve was distributed. All the other nerves of the leg were implicated: "the sciatic nerve was very much enlarged, but many of its branches more so in proportion," and "varicose veins were observed in several parts" of it. "Some of the nerves were unusually soft, and easily torn." "The branch of the anterior crural nerve, accompanying the saphena vein, was somewhat enlarged; about an inch and a half above the ulcer it was still larger, and it was nearly surrounded by the ulcer, and at the upper part of this was firmly united to the adjacent parts for an inch and a half." "The peroneal nerve was very much enlarged, and the anterior tibial and dorsal branch of the peroneal were nearly twice the size they are in a healthy limb." "The anterior tibial nerve was enlarged, and proceeded firmly united all the way to

surrounding parts." "The long cutaneous branch of the peroneal nerve was very much enlarged." "The posterior tibial, at the upper part, was larger than natural, but towards the bottom of the leg was still larger, and continued so until it had got beyond the inner ankle." Those who consider the extent to which the nerves of this limb were inflamed, will cease to wonder that the patient's sufferings were so excruciating as to make him wish to have the limb amputated before his surgeon was disposed to accede to his request; and the case is an admirable illustration of the extent to which inflammation occasionally extends in the course of the nerves, both upwards towards the sensorium, as well as in the direction of their remote distribution.

In the second case, one of fungous ulcer in the lower part, and chiefly on the outside, of the left leg, the patient had suffered excruciating pain, which darted down to each side of the ankle and top of the foot. The pain she experienced was continual, but became the most violent in the night, and generally about the time she was going to sleep. Mr. Swan introduces this case by stating, that "although the nerves were not exactly ulcerated, yet they were so connected with the diseased parts, and many branches from them were distributed in such a manner to the fungus, as to occasion the same symptoms." This is a virtual admission that the phenomena were those of inflammation, not the result of ulceration. The symptoms were common to both cases, and must have arisen from a cause common to both. But ulceration existed only in one, inflammation in both; and it is impossible, therefore, not to infer, that the pain this woman experienced was the consequence of inflammation, not of ulceration. Accordingly, upon dissection of the amputated limb, "the peroneal nerve was found much larger in the lower part of the ham than it was higher up. Its long cutaneous branch was blended with the posterior part of the fungus, and was then so much enlarged and confused as not to appear like nerve; but beyond the fungus had again its natural appearance. The anterior tibial, near the fungus, was "covered by a firm and very vascular membrane, from which it could hardly be separated. This was the case most of the way through the fungus, after which

it had a more natural appearance." "The dorsal branch of the peroneal nerve could, in the same manner, be traced to the fungus, when it exhibited nearly the same appearances as the anterior tibial. Just at the beginning of the fungus it gave off to its base many filaments, which were very much enlarged."

A third case is related by Mr. Swan, of a large ulcer on the left leg, with exuberant granulations, which bled profusely, attended with excruciating pain, which hardly ever allowed the patient to rest; and it was so bad at night as to oblige him to get out of bed. The pain came on with violent stabs, like spasms, which extended up the outside of the leg to the ham, and from thence to the back; and in these paroxysms the limb would frequently be moved involuntarily. The pain was almost entirely confined to the peroneal nerve, for when pressed in the ham, it produced or aggravated the violent pain. A portion of the peroneal nerve, near the outer hamstring, was removed by excision, when an artery bled freely, but ceased without the application of a ligature. "The pain in the ulcer ceased, and he had no feeling when the upper part of the foot was touched." But the day after the operation there was pain in the wound, and there was perfect sensation in the upper part of the foot. The discharge of pus and blood ceased after the operation, but "he never had any of the spasms in the limb, or any of the violent pain which followed the course of the sciatic nerve, and caused so much suffering;" "but he still at times suffered pain from the connexion of the saphenus nerve with the ulcer." In about six weeks after, amputation became necessary, in consequence of the extent of caries of the tibia, attended with diarrhoea and night sweats, under which his health appeared to decline. Upon examination of the limb, it appeared that the saphenus nerve "was very much enlarged, and was connected with the ulcer. The sciatic nerve was enlarged." "The peroneal nerve was also enlarged, and at the place where it had been divided was much thickened; and one new branch went from this part to the anterior tibial nerve. New branches went from the same portion of the divided nerve to the dorsal branch and the surrounding parts. Both the anterior tibial nerve and the dorsal

branch were larger than in their natural state." The state of the nerves thus discovered upon dissection explains satisfactorily the symptoms. Until the communication with the sciatic nerve was cut off by the division and excision of a portion of the peroneal, irritation, perhaps inflammation, crept upwards along that nerve, so as to affect even its motor branches; but upon its separation from the source of irritation, the evil consequences were intercepted. On the day succeeding the operation there was no pain in the ulcer, but there was "a little in the wound;" this continued on the following day; and on the third day after the excision of the nerve the ulcer is reported to have been again painful. This pain could hardly have resulted from the connexion of the saphenus nerve with the ulcer, since that nerve must have been equally affected on the day of the operation, and the two succeeding days; it was probably the result of inflammation having occurred at the upper extremity of the divided nerve; for the wound had been painful for two days, and even a fortnight, before the amputation of the limb. On pressing the part where the nerve was divided, the patient said he felt it quite down his leg. But as the continuity of the nerve was destroyed, the limb, as far as that nerve was concerned, was as if it had not existed; and the pain which returned in the ulcer was probably to be referred to the same principle as that in an amputated limb, in which Haller states that an individual can hardly divest his mind of the idea that he is bending the joints of the separated member. The question as to the existence of new branches, and of their influence in this case in conveying the nervous influence, rendered defective by the operation of dividing the peroneal nerve, I leave to those more versed in these matters than myself. Mr. Swan himself is not altogether confident in his own opinions upon the point, and his account, therefore, of such new nerves requires confirmation. Is it not possible, or even probable, that these supposed new branches may have been some of those minute filaments which, from their extreme tenuity in a natural state, escape the observation of the anatomist, but partaking of the inflammation of the trunks with which they communicate, may have become indurated and enlarged, and consequently capable of be-

ing traced? just as in some parts and surfaces of the body, there are vessels so small in their natural condition as not to admit the red particles of the blood, and are therefore imperceptible; and yet they become abundantly obvious when, from simple congestion, or from inflammation, red blood is forced into and distends them. This is, indeed, but a conjecture, or at best an argument from analogy; but no one has yet discovered the ultimate fibril of a nerve, or even traced it, excepting perhaps in the optic nerve, to that point where, divesting itself of its neurilematous investiture, it begins to dilate, as some suppose, into a pulpy expansion, to become the seat of sensation.

There is in the last edition of Sir Benjamin Brodie's work "On the Diseases of the Joints," an interesting case, in which the distention, or stretching, of some filaments of lumbar nerves by subjacent glands is supposed to have modified the symptoms of a diseased hip-joint. "One evening after the application of leeches he had a paroxysm of violent pain, attended with spasmodic action of the muscles of the thigh. The pain during this attack was so excruciating, that, to use his own expression, 'he wished for immediate death.' From this time, however, he was never wholly free from pain, and he was also liable to repeated attacks of more intense suffering, attended with violent spasms of the muscles of the thigh. The slightest motion of the limb induced one of these attacks of spasm, during which the thigh was jerked in a most remarkable manner." It is scarcely necessary, after what I have already advanced, to state that these are precisely the phenomena which arise from inflammation of nerves. The symptoms are to be referred principally to those branches of the anterior crural nerve which supply the great muscles of the thigh; for the thigh was apparently affected to the exclusion of the leg. There had been inflammation, with "a collection of thin pus amongst the muscles on the anterior part of the thigh, below the hip-joint, but communicating with it. The tumor thus formed was of the size of a large orange, and being situated under the femoral artery, the latter was thereby raised out of its natural situation. There were two enlarged lymphatic glands, each of the size of a walnut, immediately below the crural arch on the fore part of the joint,

and these lay in contact with, and immediately behind, two branches of the lumbar nerves, so as to keep the latter upon the stretch, like the strings passing over the bridge of a violin. This last-mentioned circumstance seemed to afford a reasonable explanation of the spasmodic affection to which the patient had been liable, and which probably had become relieved in consequence of some degree of diminution in the size of the glands after the escape of the abscess from the joint."

Several considerations lead me to doubt the accuracy of this explanation, which is not given with any great confidence by the author himself. He offers it only as probable and plausible, not as conclusively established. It may be objected, first, that it is no unfrequent occurrence for the whole of the glands to which allusion has been made to be immensely enlarged, and of a stony hardness, from cancerous ulceration of the os uteri and upper part of the vagina. They may be seen as well as felt, and often implicate the whole chain of lumbar glands also, and yet it has never chanced to me in any one of these cases, which my connexion with the Middlesex Hospital has given me repeated opportunities of examining, to witness similar extraordinary jerkings of the limb, though I have not unfrequently found the cutaneous branches of the upper part of the thigh implicated, so as to produce pains of neuralgic character; and not uncommonly have I observed, in similar cases, considerable numbness, with imperfect movement of the thigh. 2dly, If the pain and convulsive movements arose from any influence upon these nerves, it must have been because they constituted part of those bundles which go to the formation of the anterior crural nerve, all the branches of which should have been similarly affected. The leg below the knee would hardly have escaped. But 3dly, The nerves which passed over the glands situated near the joint, were more probably mere cutaneous branches, and neuralgia without muscular spasm would have occurred if these had partaken of the inflammatory disease of the neighbourhood; or if simply stretched by elevation, diminished sensibility would have been the more probable result. 4thly, There was much suppurative inflammation, of an unhealthy character, amongst the muscles which the branches

of the anterior crural nerve supply with nervous energy; these, surrounded by parts undergoing inflammation, would probably partake of that morbid condition; and this is rendered more probable by the observations of Sir Charles Bell and Mr. Swan, both of whom have seen nerves contiguous to disease of joints, or of other organs, becoming inflamed, and producing the symptoms and changes of texture consequent upon inflammation. "It was but the other evening that a gentleman complained to me of a pain and numbness of the back of the thumb and fore-finger; this I found referable to a disease of the elbow-joint, and an affection of the muscular spiral nerve. I visited a woman with a disease of the womb, who complained of an unusual pain and frequent spasms of the leg. I imagined that the disease had involved the sacro-ischiatic nerve, and *found it so on dissection*.*" "The nerves contiguous to a diseased joint are apt to become enlarged. In one case of scrofulous disease of the elbow-joint much pain had been experienced. The ulnar nerve was very much thickened and enlarged as it passed behind the internal condyle of the arm-bone; the median nerve was also enlarged, but not in the same degree†." Since, then, in Sir Benjamin Brodie's case there was disease of the joint, around which nerves are apt to become inflamed; since the motor filaments must have been surrounded in their course by the collection of thin pus amongst the muscles affected; and since the symptoms were those of inflamed nerve, I think it more probable, upon the whole, that the pain and jerkings of the limb were rather from inflammation than simple stretching; and it appears to me a valuable illustration of the extension of an inflammatory affection from surrounding parts to a nerve in their vicinity.

But this view of the case by no means diminishes its interest. It equally "shews to what extent the symptoms may be modified and aggravated by an accidental circumstance;" the consequences, whether the result of stretching or of inflammation, being any thing but trivial.

Another curious instance of the extension of inflammation from contiguous parts to a particular nerve, will be

found in the Transactions of the Medical Society of London, by the late Mr. Norris, surgeon to the Charter-house,—the subject of which was his apoplexy, as it must be mine, for giving the most characteristic details in Latin, rather than in the vernacular tongue. The nerve which appears to have been affected was the internal pudic, and the symptoms which presented themselves those of ungovernable satyriasis. This vigorous gentleman, *sixty years of age*, "*nunquam meminit se in venere propensorem fuisse, nedum insana et insatiabili libidine permotum ante hos duos menses, quando se diro hoc et terribino correptum esse morbo sentit; ejus vis tanta est et tam effrenata ut expleri nequeat; et ad coitum cum uxore se singula nocte quindecies saltem, imo vices nonnunquam impellat.*" As might be expected, the evils of such a state were not confined to the patient himself; Mr. Norris therefore begged to be allowed "*cum uxore colloqui.*" Imo inquit, *id ipsa summopere vult quippe admodum invalida tuique indiga consilii.* Eo visum et reperiō feminam matronali pudicitia et gravitate decoram quæ omnia dudum a marito narrata amplissimo testimonio comprobavit, adjecitque se propter noctes continuo insomnes et inquietas multa lassitudine, et propter vim sibi toties oblatam pudenda sibi timore et dolore affligi. Cum de constanti in coitu immisione seminis rogarem, fidem fecit, virum omnia vere dixisse; nunquam enim aliter ab illo rem actam fuisse. Quibus verbis ei facilius et libentius credidi quod mulierem bis nuptam, et ex utroque marito bis matrem experientia satis hæc edocuerat*." The cause of these extraordinary symptoms was a tumor from a blow upon the perineum, which increasing, and at length becoming softer, was opened by incision, and gave vent to an abundant discharge of a glutinous and sanious character, a short time after which the symptoms vanished, and the wound healed kindly. This is, indeed, a rare sequence of inflammation and abscess of the perineum; and the peculiar results appear to me to be explicable upon no other supposition than that the internal pudic nerve, which ministers to an office of great animal gratification, and which supplies

* Operative Surgery, vol. ii. p. 330.

† Swan, p. 65.

* Trans. of the Med. Soc. of London, vol. i. part i. page 171.

certain erector muscles and other contiguous sensitive parts, had become implicated in the surrounding inflammation, and produced, in the language of modern physiologists and pathologists, an exaltation or exaggeration of function.

Some, perhaps, may fancy in these instances that the mere acrid products of inflammation, like certain chemical agents, may have irritated the nerve by contact; as in the numerous experiments with concentrated mineral acids, or, according to Haller, as in the mere application of a cold sponge. An observation, however, of Bichat, upon this point, may be taken as at least an approximation to evidence that this is not sufficient. After stating that sensibility depends rather upon the medullary fibre than upon the neurilema, whose office it is to protect the medullary matter, he adds, "hence it is that simple contact without compression is very little painful; and that a nerve may almost with impunity be bathed in a purulent ichorous fluid, and even in the sanies of cancer."

Amongst other causes of inflammation of a nerve, pressure ought not to be excluded. Numerous instances are upon record in which such connexion has been traced; and hence many who have discovered tumors situated in the course of nerves, attended with suffering, have adopted the conclusion, that compression of a healthy nerve will occasion pain. The recorded cases, however, when minutely examined and faithfully related, do not appear to warrant this inference; for in the majority of such instances, subsequent dissection has shewn even extensive disorganization of the nerve itself. Of this Morgagni has related two very interesting instances. In one, that of a man fifty years of age, an aneurism first made its appearance in the groin, and increasing gradually, became attended with considerable pain and œdema. During the last month, the pain had been excruciating, not only in the tumor, but often below the inner ankle, the rest of the foot having lost all sense and motion. It was found, on examining the body, that the aneurism, extending to the great sciatic nerve, had so eroded it that very few (*vix paucæ*) fibres remained to connect the upper with the lower part. Morgagni gives an accurate explanation of the symptoms, founded on dissection. After the distended vessel, he says, had given way, and formed a spurious aneu-

rism, the clots pressing upon the veins impeded the return of blood, and œdema was the consequence. These also forcibly separating the muscular fibres and their nervous filaments from each other, occasioned a pain, which was, however, much more bearable than that which subsequently occurred when the nerve *began* to be eroded. At length, when the nerve which communicated the faculties of sense and motion to the foot was almost entirely eroded (*exesus*), both these faculties were lost, excepting under the inner ankle, which part derives its nerves not only from the posterior crural, but also from that branch of the anterior crural nerve which accompanies the saphena vein. Hence, Morgagni adds, an aneurism may destroy life not only by bursting, but also by the agonizing sufferings (*per acerbissimos cruciatus*) which it may induce.

The other case was one of popliteal aneurism, of the size at least of a small melon, which produced most excruciating suffering in the limb. The patient died of sphacelus, followed by hæmorrhage. Along the whole trunk of the aneurism was a cavity full of grumous blood and matter, the nerve and vein being completely eroded, as were also the condyles of the femur and the head of the fibula.

A similar instance occurred to Guatani of popliteal aneurism attended with violent pain, in which the nerve had been much changed in its course and character, and was probably glued to the surface of the tumor by an inflammatory process; and in the valuable paper upon malignant tumors by Mr. Travers, is a case of tumor, situated in the ham, and producing very severe suffering, which the author was disposed to ascribe to "the obvious circumstance of pressure;" but the details of which case force conviction upon my mind that the nerves had become inflamed.

Occasionally the symptoms mark the existence of inflammation of nerves; and yet we can trace none of the causes which I have enumerated, or any other, to account for its occurrence, and we are then driven to the conclusion that it is an idiopathic disease. M. Descot represents this as an extremely rare disease, but still its existence has been very satisfactorily ascertained. The more superficial nerves of the extremities are the most common seat of the

disease, which would seem to afford countenance to the opinion that the principal cause is exposure to cold. Hence it is by no means uncommon in the sciatic nerve, in which, in the opinion of M. Descot, a great many cases of ischias have their seat. "Dans beaucoup de cas de sciaticque, je crois que le nerf sciaticque est le siège de la maladie; la douleur suit, en général, si exactement le trajet du nerf, et les parties voisines sont tellement libres de toute apparence pathologique, que je crois que le nerf seul est le siège de la douleur; et l'affection, ce me semble, doit naître d'une action inflammatoire dans le néurilème, laquelle se termine souvent par l'épanchement d'un fluide séreux*."

In the absence of all evidence of the existence of any local cause, it may be safely inferred that one of the cases related by Mr. Earle was of this kind. This patient laboured under the symptoms of inflamed ulnar nerve, the whole of which, in its course from the elbow downwards, was morbidly sensible when touched: "the mere drawing on of a glove would sometimes cause so much pain as to make her scream and fall to the ground." The pain at times occurred spontaneously, without any apparent exciting cause. The integuments on the inside of the forearm near the elbow were hotter and fuller than natural. The symptoms were removed by excision of a portion, equal to rather more than an inch, of the nerve, when it was found upon examination that "the neurilema covering the nerve appeared thicker and firmer than natural." These appearances were incontestibly the consequence of inflammation, no cause for which could be ascertained, for "she was unable to account for the origin of the complaint, and said that it had been gradually increasing for some months."

In the instance also quoted by Dr. Cooke from a manuscript communication to him by Sir Charles Bell, inflammation had occurred spontaneously in the ulnar and fibular nerves, and the pain, which was of a most agonizing kind, had confined the patient for two years, and "had quite subdued a powerful frame." The existence of inflammation was proved by the tender state of these nerves, which throughout their course were acutely sensible to the slightest pressure, by the periodical and

alternate accessions of pain, and by the effect of remedies; for the disease yielded to measures the principal of which consisted in repeated purging, and the application of leeches along the course of the nerves.

Tumors occasionally form within the substance of nerves, and produce, generally, well-marked symptoms of excitement. These tumors vary in situation, in size, in form, and in texture. They may exist in nerves in the interior of the cavities of the body, or in those of the extremities—the latter, however, being by far the most frequent; and in both they occasion the phenomena of excitement—convulsive movement, if a motor nerve; severe neuralgia, if a nerve of sensation; the combination of the two if a symmetrical or compound nerve, before it has exhausted its muscular filaments. A striking example of the effect of such tumor imbedded in an internal and simple motor nerve will be found in a case which occurred to M. Berard, aîné. The phrenic nerve of the right side appeared interrupted by a tubercle as large as a pea, scirrhous and blackish, and had produced asthma*,—obviously implying a convulsive action of the diaphragm. Instances of similar tumors in the nerves of the extremities are by no means uncommon; and upon this branch of his subject M. Descot has shown great industry, research, and judgment, and has at the same time done ample justice to the British records of medicine and of surgery, from which he has derived a large proportion of his illustrations.

These tumors commonly form upon sentient filaments of cutaneous nerves before they terminate in the cutaneous tissue for the purpose of conveying impressions from the surface, and are consequently generally found in the upper and lower extremities. M. Marjolin, however, communicated a case to Descot, in which they appeared at all events very near to the sentient extremities of the scrotal nerves. There were in the cellular tissue of the scrotum "many small, lenticular, smooth, moveable, hard, and insulated bodies, compression of which between the fingers produced pains like those which the patient habitually experienced†." A

* Descot, p. 200.

trifling incision upon each enabled M. Marjolin to remove them all; they weighed a few grains each, and were of a fibro-cartilaginous texture. The sufferings of the patient ceased altogether from the period of the operation.

They are sometimes very small, as in the disease so accurately described by Mr. Wood under the denomination of painful subcutaneous tubercle, of which he has recorded five instances occurring within his observation, and others communicated to him by his professional friends, amounting altogether to eight cases, all of which yielded to extirpation of the tumor*. The disease, however, had been noticed by others before his time, and amongst them by Cheselden†, Camper‡, Portal§, Bisset||, and Pearson¶.

Mr. Wood has offered no explanation of the pathological nature of this disease, but Mr. Windsor has supplied the deficiency by tracing the filament of a nerve into the substance of the tubercle**. Mr. John Pearson also saw at the upper extremity of a slough, which he had produced by an escharotic applied for the purpose of extirpating the tubercle, the ragged extremity of a nerve, as well as the saphena vein; thus proving incontestibly that the nerve is at least essentially implicated, and is probably the matrix of the tumor.

These small tumors are generally found in cutaneous branches; and the excruciating pains of neuralgia are the common, if not the invariable, consequence. In some, with this violent pain have been combined muscular spasms of the limb, and even sometimes general epileptic convulsions; but I know of no instance in which paralysis was observed.

tremens, a case very illustrative of its specific power in that affection having recently occurred to me, I transcribe it for your pages, leaving it to your option to insert or reject it.—I am, Sir,

Your obedient servant,
J. C. BADELEY, M.D.

Chelmsford, Jan. 30, 1835.

Mr. A.—, ætat. 45, a farmer of property and respectability in this neighbourhood, in the habit of unrestrained conviviality, and for the last few days preceding his attack more intemperate than usual, evinced, on Saturday, the 28th ult., symptoms of delirium: he awoke in the night with the apprehension that his stacks were on fire, got up, dressed himself, and went into his farmyard under that delusion, which was not removed by visiting them. He remained in that false conviction the whole of Sunday, riding about to procure men to extinguish the flames, talking very incoherently, and evincing great general excitement; got no sleep on the Sunday night, and his friends being alarmed at his condition, sent for Mr. Barlow, of Writtle. The impression of fire was still so strong on his mind, that he insisted on Mr. Barlow's accompanying him to see the blaze, and took him into the yard; and it was in vain that Mr. Barlow attempted to convince him to the contrary. At this time there was a general tremor of the whole system; great anxiety; pulse very quick; tongue clean; restlessness, and general apprehension. Mr. Barlow immediately gave him two grains of opium, and ordered that dose to be repeated every three hours, till sleep should be induced. After the fourth dose he slept for two hours, after which he awoke with great oppression of breath, and severe pain in the head. Mr. Barlow reached him at two in the morning, and found him as wild as ever: skin dry; pulse very full; tongue furred, and considerable thirst. Mr. Barlow bled him, and after losing ʒxij. the pulse fell, and he expressed great relief. He then gave him two grains of opium, ordering it to be repeated every six hours, and ʒss. of Battley's liquor opii sedativus every three hours after each pill. Mr. A. continued these pills and draughts regularly till the Tuesday night, but refused to keep his bed, and continued as wild, and as full of strange fancies, as before.

OPIUM IN DELIRIUM TREMENS.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH no medical practitioner can doubt the efficacy of opium in delirium

** Edin. Med. and Phys. Journ. vol. xvii. p. 262.

After taking five doses he was, however, put to bed, and fell asleep for three hours; he then awoke as agitated as ever, and under apprehension that he was going to be murdered. Mr. Barlow now gave him a pill, containing one and a half grain of the muriate of morphia; no sleep followed, but he was drowsy, and more tranquil. In three hours another pill, containing one and a half grain of the muriate of morphia, was given, after which he dozed a little; but at 8 A.M. started up, dressed, and ran across the fields for nearly a mile and a half, leaping hedges and ditches, and crying murder! It appears that he had made his will on Thursday night, under the impression that his life was in danger, and had actually taken his pocket-book from his desk, with a considerable sum of money in it, which he said was to bribe the murderers to spare his life in case they caught him. As the disease continued unabated on Wednesday, January 1st, I was requested to visit him immediately. He met me on my entering the house; appeared much agitated, and very apprehensive of murderers; told me that he saw them lurking about his premises, that his stacks were still on fire, and other such nonsense. I found him tremulous; pulse frequent; tongue white, dry, and coated; pupils of the eye contracted; skin rather relaxed; he had scarcely made any water, and his bowels had not been relieved since the Sunday. I gave him a large table spoonful of castor oil immediately, and ordered it to be repeated in three hours if necessary. As soon as the bowels had acted, I prescribed a pill, containing four grains of opium, to be taken, and this dose to be repeated every three hours till sleep followed. On Thursday I found that he had taken eight grains of opium, and 3iss. of liq. opii sedativus, since my visit; he slept none after the first pill, but fell asleep for four hours soon after taking the second, and awoke tolerably sensible. At eight this morning he still rather apprehended murder, but got up, ate some breakfast, and became more composed; his tongue was much cleaner; pulse very weak; bowels open; water scanty; but he still looked wild, though he talked rationally. I ordered the following draught:—

R Ammoniac Carbon. gr. v.; Liqueoris

Opii Sedativ. ℥v.; Sp. Juniperi, ʒj.; Mist. Camphoræ, ʒxj. M. ft. haustus 4ta quaque hora sumend. et rep. Pil. Opii, gr. iv. si rediret Delirium.

Friday.—Had slept tolerably, but now appeared a little more wild; said he would go to a relation's, a few miles off: his friends had no control over him. I immediately gave him (11 A.M.) two grains of opium, and ordered it to be repeated if necessary: he was quieter, but being still rather wild, the other pill was taken at three, after which he ate some beef, and drank some gin and water.

R Hydrarg. Submur. gr. iij.; Opii, gr. ij. Fiat Pilula hora. 10 P.M. sumenda.

Rep. Haust. jamjam prescript. 4ta quaque hora.

Saturday.—Much better; took the calomel and opium pill, after which he slept till three this morning; took a draught, and slept again till five; awoke sensible, and soon fell asleep again till nine this morning, when he awoke quite calm and rational, took another draught, after which he rose, breakfasted, and went out. He now appears much as usual, but his tongue is white; bowels confined; stomach feels uncomfortable, together with nausea; pulse 64; says his head feels light.

R Infusi. Sennæ, ʒivss.; Tinct. Jalapæ, ʒj.; Syr. Zingib. ʒij. M. sumat Coeh. iij. statim, et rep. 3ta quaque hora donec responderit alons.

Perstet in usu haust. ut antea et sumat. Opii, gr. ij. si rediret Delirium.

Sunday.—His bowels had been relieved; had passed a quiet night; all his delusion at an end, and felt much as usual, excepting being a little weak. I ordered a few draughts, with ammonia and bitter infusion, omitting the opiate; under which treatment he entirely recovered, and has had no relapse.

The delusion returning after he awoke from two or three hours' sleep, is probably owing to its not being of sufficient duration to renovate the nervous system; for when it continues uninterrupted for twelve or fourteen hours, the patient generally awakes unconscious of what has occurred.

TWO CASES OF PERITONITIS ;

WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

I FORWARD you the accompanying cases ; if you deem them of sufficient interest for publication, you will oblige me by their insertion in the *Medical Gazette*.

I am, sir,

Your obedient servant,

JOHN BADHAM, M.D.

Workshop, Notts,
Feb. 4, 1835.

CASE I.—Ann Frost, aged seven, a child who had previously enjoyed good health, was suddenly seized, on the 2d of January, and four days prior to my seeing her, with violent fixed pain in the abdomen, great tenderness on pressure, and considerable tension of the belly, with frequent vomitings, quick small pulse, and, in a word, all the symptoms of acute peritoneal inflammation. When called in by my friend Mr. Beadsale, I found the patient very restless ; indeed, she had been remarkably so from the commencement of her attack: the tongue, which was dry, presented a broad chocolate-coloured stripe down its centre ; the other physical symptoms (which so frequently happen in this disease) were only moderate: though the pulse beat 120 in the minute, the abdomen continued exquisitely intolerant of pressure, as it was before recourse had been had to those active means opposed by Mr. B. to remove it. The breathing, though thoracic in its character, seemed (probably from sympathy merely), hurried and uneasy ; perpetual retchings, with ineffectual attempts at vomiting, were very prominent ; and among the most distressing of the symptoms presented to us, the urine was scanty, without being very high coloured. The sensorium was not in the least implicated. Frequent picking of the nose constituted in this, as in the succeeding case, a characteristic peculiarity. Lastly, there was a clanging harsh cough, without expectoration. The stethoscopic indications were such as one would have expected—viz. puerile respiration ; and in one or two places the rales sibilants or sonores were heard. I gave an unfavourable prognosis as to the issue of

the case, which seemed already beyond the control of medicine ; however, as general blood-letting seemed out of the question, I ordered leeches to the abdomen, and the bleeding to be encouraged if practicable, and prescribed calomel every four hours, once in combination with opium. One or two doses of castor oil were likewise given, and which the stomach at last retained. The bowels were obstinately bound from the beginning, and were not satisfactorily cleared throughout the disease. The abdomen was blistered, and then treated with warm poultices and fomentations over the seat of pain, &c. ; but notwithstanding all that could be done, the child was evidently sinking: the disease had taken so firm a hold, that it appeared only to relax its grasp as the power of manifesting suffering was by degrees withdrawn from its victim, who lingered out a few hours, to die (apparently from extreme exhaustion), on the sixth day after the attack, or on the second of my attendance.

Section cadaveris.—The autopsy took place twenty-four hours after death. The first thing observed on making an incision and laying open the abdominal parietes, was a quantity of pus of that kind which issues from the cellular membrane in phlegmon—thick, matured, and pure, but neither sanguinolent nor containing any shreds of membrane—in quantity sufficient to bathe all the abdominal viscera, particularly such of them as lay to the right side of the body. Our first care was to examine very attentively the condition of the peritoncum, which, after a most careful survey, we were surprised to find perfectly healthy. There was, indeed, one small cake of coagulated lymph thrown out on the convex surface of the liver, of the size of a crown piece ; but excepting this, there was not so much as the slightest adhesion between any of the contiguous portions of its surface. We next turned our attention to the state of the intestines, and here again we found nothing to explain the effusion. Externally the bowels presented a pale appearance (the peritoncum throughout presented the same exsanguine condition) ; and on slitting them up, so as to expose the mucous membrane, it was found scarcely more coloured than the serous membrane which invested them. It was neither hardened, thickened, softened, or ulcerated, nor in any other

way changed in structure, or unlike in appearance to its natural and healthy structure. The bladder was empty, but healthy; and the parenchymatous organs, severally examined, offered no trace of disease. The lungs presented nothing worthy of remark. The gall-bladder was distended with bile. The head was not examined.

CASE II.—Three days only elapsed when my advice was again requested to attend another member of the same family, a younger brother of the deceased. This child, who was six years old, and had, to the moment of his attack, been in rude health, was seized on a sudden, while at play, with sickness and a violent pain in his belly. The parents instantly took the alarm, and sent for medical aid. I saw him a few hours afterwards; the pulse was then considerably quickened, but slight heat of skin or febrile excitement; the tongue was moist, and covered with a creamy coat; the eye was bright and watery; the tenderness of the abdomen exquisite; there was incessant picking of the nose; no cough; but all other symptoms were precisely of a kind with the last. This case was likewise treated *more majorum* with bleeding, mercury, saline and other medicines, as particular symptoms seemed to point out the expediency of their exhibition. The medicines were retained generally; and on the morning of the 9th of January, the third from the attack, the urgency of the symptoms had all abated, and I began to entertain hopes of a favourable issue to the case. On the morning of the 10th this pleasant state of things continued; a blister which I had ordered to the abdomen had risen well, and the pulse had lost its thrill and become soft; the bowels were several times relieved, and the urine was more free. The day passed flatteringly, but in the middle of the night (I had given him a powder of hydr. c. creta, with pulvis ipecacuan. co. at bed time), he became alarmingly worse; and when I saw him next morning, the hand of death was upon him. The features had collapsed; the eyes were fixed; tongue dry; abdominal tenderness nearly gone. He appeared now to suffer very little, and died without a struggle on the morning of the 11th.

Sectio cadaveris. — The inspection took place eight hours after death. The peritoneum, throughout the whole of its

extent, presented not a vestige of disease. On slitting up the intestines, the mucous membrane was found as healthy as the serous; there was, indeed, a slight red arborescence in one or two portions of the canal, chiefly in the jejunum; but this appearance was not more than might fairly be ascribed to the stimulating effects of aperient medicines so largely exhibited; for, as I have remarked in the former case, the bowels were very torpid in their action, and depraved in the quality of the secretions, being likened to tar. The parenchymatous organs, as in the last case, were all healthy; there were slight adhesions between the pleura of the right lung and the pleura costalis; the right lung itself was slightly congested, but it freely crepitated between the fingers; the left lung and its enveloping membranes quite healthy. There was no other trace of disease. The head was not examined.

REMARKS.—The above cases are interesting in several points of view; and when duly weighed, afford to the intelligent pathologist some very interesting materials for his speculations. There is one circumstance, however, to which at present I would particularly direct the reader's attention;—I mean the striking similarity of symptoms in the two cases, with the remarkable discrepancy of appearances revealed to us after death. From such apparent clashing of evidence, what are we entitled to conclude? Assuming that there had been an inflammation in the neighbourhood of the peritoneum in either case (for what else but an inflammation could have produced the symptoms?) is it to be believed that it should have conducted to such a diversity of result—in the one case to a large effusion of pus, in the other to no effusion of any sort? When two young subjects of similar predispositions, and so far of similar idiosyncrasies, are both attacked with acute inflammation, when the seat of the inflammation is the same, when the symptoms are not different, and when we observe the same tendencies, followed by the same fatal termination, can we suppose the different appearances revealed after such terminations are severally ascribable to some difference in the kind of inflammation set up? In short, are these different kinds of inflammation? Is there not something almost contradictory in the very terms of this ques-

tion? All disease is action; and how can an action be one and many at the same time? Can unity be divided into multiplicity? If the pus really were the product of pure inflammatory action in the first case, and not rather, as my brother, Dr. David Badham, supposes, of an engrafted morbid action on natural active inflammation, why was it not produced in like manner in the second? Was the inflammation not high enough? It destroyed life. Was it too high? Then why did it not end in gangrene, or some other change of structure? Was it modified by tissue? The affected tissues were the same. By difference of cause? The same general cause produced both diseases. By difference of constitution, then? As far as we can see, the constitution of the parties was very similar. Inflammation may end in death (it did so here), as it might have ended in resolution; but can it properly be said ever to terminate in any morbid secretion or organic change? I leave the question to the consideration of the intelligent reader: it is sufficient to have suggested it here. Some have denied that serous membranes can inflame; they suppose the inflammation to be round and about, but not in, the substance of these membranes. This is a speculation which, from the absence of all those phenomena so constantly attendant upon, if not immediately associated with, inflammation, may be not irrationally entertained in the present case.

DIAGNOSIS BY AUSCULTATION IN SURGICAL CASES.

To the Editor of the Medical Gazette.

SIR,

THAT a gentleman of such reputation as a surgeon and physiologist as Sir Charles Bell, with whom the discovery of truth, for the sake of truth alone, should naturally be the actuating principle—that one who ranks so high among the scientific and philosophic of his liberal profession, should allow himself to give utterance to such expressions as are attributed to him in your journal of the 17th instant, concerning the value of auscultation and percussion, is to be

regretted. As it was before a body of students, a large proportion of whom would most probably be unable from inexperience to form an opinion for themselves on this important subject, and to whom, consequently, the *dictum* of so renowned a preceptor would be law itself, renders it a subject of especial regret.

The case was one of aneurism of the arch of the aorta—the nature of which was only discovered on the post-mortem examination. Because, it seems, the physical indications of aneurism were not in this case detected, it is made a peg on which to hang a sweeping charge against auscultation, with reference not merely to this class of diseases, but those in general to which it is applied; and we are told that “this would imply (*i. e.* the evidence of this case, and the candid admission of all stethoscopists, of the comparative difficulty of detecting aneurisms, particularly thoracic,) that the stethoscope discovers slight effects of disease, but not material or important changes.” If this be logic, we are no logicians; if it is science, science with us is at a discount; if it be philosophy, alas! we were deceived; in the vanity of our nature we imagined ourselves philosophers.

What the learned physiologist may consider the minor lesions, or “unimportant changes,” I cannot pretend accurately to understand; but if they comprehend such trifling cases as pneumonia in its different stages—pleurisy, acute and chronic—empyema—bronchitis in its various phases—œdema, emphysema, or phthisis, any or all of which we will pledge our stethoscopic character to point out and discriminate to the satisfaction even of his sceptical incredulity; or if it please him to comprehend in this definition the various affections of which the heart is so frequently the seat, and which this mode of exploration alone has enabled us to detect, and thus explain the causes of many deaths that formerly were the perplexity of the best informed practitioner; finally, if Sir Charles has reference to its adoption in obstetric practice, where it has already proved so eminently serviceable in the hands of the credulous Parisian and Dublin practitioners; if these be the cases of unimportant changes for which this mode is only fitted to be employed, I fear we

poor witless stethoscopists will scarcely be able to surmount the charge of fond credulity.

If it will add any strength to Sir Charles's opposition, I shall inform him that, in your journal within the last month, there have been two cases, both, if I mistake not—one certainly—of chronic pleurisy, in the large hospitals, in which the patients were allowed to die, the doctors being in a state of happy ignorance of their complaints, solely, as the reporter justly observes, from omitting percussion and auscultation. At such facts the learned gentleman will shrug his shoulders and look incredulous.

For a teacher in any, particularly a metropolitan, school of medicine, it is surely incumbent to have studied and be conversant with the subjects on which he sends forth his opinions to a class of students. Now Sir Charles is a surgeon, and as such, unless in the matter of fractures (in which, by the way, we would take the liberty of recommending a trial of this outcast instrument), is much less required to cultivate this physical means of diagnosis than he whose study is medicine. Nor was Sir Charles a very young man when Laennec gave to the world the brilliant result of his labours; and if a vulgar adage be true, this would be no slight ground for supposition that Sir Charles would not be particularly zealous in the cultivation of new habits.

From these considerations I would unwillingly incur the charge of presumption, in inquiring if Sir Charles be practically acquainted with what he has thus publicly anathematized. His reference to the candid avowals of others, and the tenor of his address, would lead me, *prima facie*, to conclude that he himself was not possessed of this practical knowledge, but has recommended to others his own self-satisfied condition of happy ignorance; for, doubtless,

"If ignorance is bliss,
'Tis folly to be wise."

Having already adverted to a few of the many *unimportant* diseases in which the stethoscope is more pre-eminently useful—all, of course, included in the general denunciation of Sir Charles Bell—to enter a little more particularly into the merits of the case under considera-

tion may not be altogether uninteresting. "The *whiz* of the blood," says Sir Charles, "through the narrow opening" (*i. e.* the comparatively contracted portion, in the normal condition of the artery, leading to the distended aneurismal tumor), "is a phenomenon so striking, as should instantly declare to the auscultator's ear the nature and position of the disease, or stamp his pretensions as the veriest quackery, equal in all its dimensions," I can conceive the learned physiologist continuing, "to its younger handmaid of homœopathic celebrity." In this observation, it is tacitly assumed that, in aneurism, this *whiz* has a constant existence; that, consequently, the stethoscope should in all cases detect, elucidate the nature of the obscure affection, or be admitted a mere pleasing toy—a very good thing with which to look wise, and laugh at a credulous public. Any student who has seen half a dozen cases of thoracic aneurism could have informed Sir Charles that this *bruit*, or *whiz*, was as frequently absent as present; that, in the same case, it will be present to-day, absent to-morrow. Now in this case we have admitted the perfect stethoscopic attainments of the physicians to the Middlesex Hospital, so far as was necessary for the detection of this phenomenon; (but that by withholding this assent, we might not have been doing great violence to the merits of these gentlemen is not improbable, from the fact, that not long since, in a case of pneumonia of some standing, in one of the large hospitals, the physician, who considers himself, and I believe really is, one of the initiated in the arcanæ of stethoscopic exploration, told the class that the *râle* had disappeared, when such was not the fact,—shewing the liability to be deceived without the utmost caution; but to return;) either this *whiz* had or had not existence in the present case; if the former, we are necessarily compelled to retract our homage to the merits of the learned doctors, and attribute to their ignorance the failure in discovering the nature of the disease; a circumstance not at all in the scale of probabilities, since we have already said that the veriest tyro—even Sir Charles himself, had he adopted the means—could not have avoided detecting so abnormal a phenomenon. If, the more probable case, this sound was not present—and, be it remembered, it is its

erroneously-assumed universal presence in aneurism that Sir Charles has taken as the basis of his attack, if such it can seriously be styled—neither the stethoscope, nor the acoustic organs of the gentlemen examiners, all men in the possession of their senses, will, I doubt not, agree in saying, were in fault for not detecting it.

Thus Sir Charles Bell's unqualified denunciation is contracted into a condemnation for not discovering that which had not existence, or must have been heard; and thence concludes that the sense of hearing, for which auscultation is another name, is a valueless possession. Let any one read his observations referred to, and this logical Scylla and Charybdis cannot fail to present itself.

That the diagnosis of aneurism is still more obscure than that of most other affections of which physical diagnosis professes to treat, is a matter of notoriety. That, when its especial pathognomonic phenomena do present themselves—for instance, this *bruit* or whiz, one amongst many others—it renders equally certain either an aneurism of the vessel, or a condition analogous to it, the persistence or decline of which, without the supervention of other morbid phenomena, will serve to distinguish, is also well known. Thus, pressure even, as of the instrument on the abdominal aorta, or any tumor, as an enlarged or tumified liver, exerting the same pressure, will temporarily produce the same phenomenon, and to the incautious practitioner may be a source of error. In certain conditions of an aneurismal tumor it will be present, when, from some modifying circumstance, which, like too many other medical facts, is yet, I believe, veiled in obscurity, the following day may find it absent, as occurred not long since in a patient of Dr. Bright's, in Guy's Hospital, whom I accidentally saw.

When the portion forming the aneurism is not filled up by coagula to a dimension equal to the calibre of the normal condition of the artery, but presents a space into which the blood is driven through a contracted opening, and thus thrown into sonorous vibrations, there is sufficient reason for the presence of an unnatural sound, which Sir Charles calls the "whiz;" but if this space in the aneurismal sac be filled up by successive

layers of coagulum, so that, although the sac may continue enlarging externally, there is an uniform calibre presented to the current of blood, I cannot see any cause for the production of this sound; and if such condition could exist, it is most probable the phenomenon would be wanting.

As the disease in the present case appears to have occurred in the posterior portion of the aorta, it is most probable that, from a want of suspicion of its nature, the examination of the physician was confined to the anterior portions of the chest, in which case all of the auxiliary means of diagnosis, in the absence of the *bruit*—as the modification of the respiratory murmur, the dulness on percussion, great impetus in the portion of the artery, decreasing as the heart is approached, &c.—would be entirely overlooked, and a case set down to the debtor side of the stethoscope, instead of the physician.

Without offering these remarks as more than mere probabilities, to explain some circumstances in this and similar cases, some such circumstances might surely have occurred to Sir Charles, in arrest of his ill-considered judgment.

It is said, that had not Mr. Canning attracted attention by the outpouring of his brilliant eloquence to an attack of some less distinguished member, the country would have known nothing of it; and so it might be in the present case; and really, had this puerile attack been the only one of the kind sent forth, or rather, did we not daily meet, in the medical periodicals and otherwise, scoffs and ridicule towards a branch of science its calumniators do not even pretend to understand—will not take the trouble to learn, yet dare to traduce—this should most probably receive its merit in silent derision; but they have issued from so many quarters possessed of official influence, that it would well become some more able and powerful advocate to expose the presumptuous arrogance with which ignorance would assail the temple of knowledge.

I am, sir,
Your obedient servant,
AUSCULTATOR.

London, Jan. 26, 1835.

THE PROSPECTS OF REFORM IN THE COLLEGE OF PHYSICIANS.

"WHICH SHALL WE DO—REPAIR OR REBUILD?"

To the Editor of the Medical Gazette.

SIR,

THE Fellows, it seems, are fully convinced at last that something must be done. The purport of Sir Robert Peel's address could not be mistaken; the admissions of several of the Fellows before Mr. Warburton, cannot be forgotten. The facts established by several Licentiate witnesses cannot be evaded or denied; and it is obvious that, judging from present appearances, the next assault on ancient privileges and institutions is likely to be not only more fierce but also more effective than the former: for, in the first place, several conservative members of the last Committee (the eminent Baronet, for example) will, it may be feared, have many to them much more important interests to defend; and secondly, Mr. Warburton, and almost every other member of that Committee, was wholly indifferent and impartial, compared with the honourable member for Finsbury, who, I presume, will, as matter of course, be included in the next; and thirdly, the published evidence, the examination already made of the Annals, &c. will enable the chairman (Mr. Warburton, I presume) to open at once on all the weak points of existing arrangements, a fire of queries which, I apprehend, he will find the more conservative reformers ill able to answer.

Under these circumstances it no doubt behoves the Fellows to set their house in order; and it is especially desirable that those of them who hold office, and exercise influence in the College councils, should, with all convenient expedition, propose and urge changes of a large and liberal character. The *official* differs from the *private* Fellow in authority, and therefore likewise in responsibility. The reputation of every society takes its colour very much from the conduct of men in office. I, therefore, as one humble friend of the venerable institution in Pall-Mall East, sincerely wish and hope that the authorities of that accomplished body may translate in the right sense the

signs of the times; the bolder taking counsel of prudence, the more timid of fear, and all co-operating in adequate reforms. Such are the earnest wishes of every sincere friend of the College, who is at the same time no hollow admirer and unwilling professor of our noble art. No man, anxious for the honour of British medicine, would unnecessarily subject to a second parliamentary visitation an Institution aged and decayed, indeed, but easily rendered habitable *suâ sponte*, and independently of extra-professional aid. Yet the inevitable result of delay in the prosecution of reforms sufficient to satisfy the majority of eminent Licentiates, will be to expose the influential Fellows at least to a second dose, much worse, probably, than the former, because administered partly, if not principally, by a person who will hardly be suspected of any wish to spare the feelings of the patient. I allude, of course, to the representative of Finsbury. Nor are other reasons besides those of a purely selfish kind wanting. Are the Fellows of one mind, and prepared to stand or fall together in defence of existing defects? Is there no division in the body? If all the seniors are, as is currently reported and generally believed, opposed to large reforms, are all the juniors so also? Mr. Warburton's committee-room was open to the whole town: what sort of evidence fell from Drs. Wilson, Elliotson, Billing, Burrows, and Clendinning; whose statements were made, for the most part, in my own hearing? Did they admit or deny the necessity for numerous and extensive reforms? Dr. Seymour was reported, in the Gazette, to have moved and carried the adjourning, *sine die*, the further consideration of the propositions of the College Reform Committee of last year. Well; did that acute and rather conservative witness deny the justice and necessity of change? Did he not, in some respects, outdo every other College reformer that I know of, except the last of the above-named, in proposing that the Licentiates should have a share in the business of election to the Fellowship? How few of the Fellows, whether senior or junior, denied the hardship of the dissenters' case, or denying it, were found able to assign any decent reason of justice or expediency in defence of their opinion? Did not several deponent Fellows ad-

mit that no sufficient ground existed for the exclusive privileges enjoyed by graduates of the English Universities above those of other schools? Has not the superior moral feeling attributed to Anglican Doctors by several Fellows before the committee, been at least doubted of by others, who seemed to consider the *Permissi* of their acquaintance not less virtuously sensitive than the *Socii*, both classes being, in fact, by all parties admitted as distinguished by correctness of conduct and integrity of principle? Justice, then, and prudence, the House of Commons, the periodical press, the Licentiates, and a portion of the Fellowship, are on the side of concession, and call for ample changes. Reform, therefore, is inevitable; but though sure to come, we may doubt whether it will be spontaneously effected. To mend an institution is often more difficult than to erect one. Personal feelings, associations, and relations, and selfish interests, and corporate biases and usages, are formidable obstacles in the path of the renovator, with which the original builder had nothing to do. College reform must embrace two classes of regulations:—1, such as are permanent, or intended for the future government of the body; 2, such as are merely occasional. Under each head will be found questions calculated to kindle disputes and awaken dormant animosities: for example, with respect to the future. Is the body of physicians to consist of two parts quite distinct, though nominally united?—the one subject to the other;—the one enjoying toleration, the other privilege;—the governing body rendered by self-election and secrecy of proceeding wholly independent of, and irresponsible to the governed? And if the exclusive oligarchical principle is to be impaired, to what extent is such impairment to extend? Will the Censor board-room remain closed, or be opened to the profession? Will the Fourth Estate be allowed to notice the proceedings of the *comitia majora*, or will any change creating responsibility be admitted? Will the elective franchise and eligibility be extended to all Licentiates without any distinction? and if not, on what principle is this distribution to be restricted or regulated? So much for the questions of permanent regulation;—then, as to the purely occasional measures. What are to be the terms of compromise with

the present Licentiates? are some few to be selected by the Fellows for incorporation? or are all of a certain standing to be admitted at once? On what footing are those not admitted to stand? as *alieni homines*, as the existing *Permissi*, or in the enjoyment of a greater or less extent of the privileges of the present Fellows—viz. having the use of the library, reading-room, &c. &c.; having the right of voting for candidates for vacancies in the governing body, to which they themselves should be eligible, &c. &c. These and similar questions present themselves the instant the mind is turned towards practical reform. How can gentlemen long accustomed to the easy responsibility of a secret self-elective system be expected to consent that their proceedings should be made public? Some may see the propriety of such publicity, and even wish for the salutary innovation; but what can be expected of the majority? With masses of men, prejudice and habit are as uniform in their operation as gravity: will, then, a majority of the Fellows consent to divide the elective power with other Licentiates? The interests of the public and profession require such an extension; but will the exclusives grant it? And as to terms of compromise with the sufferers by past misrule, will the Fellows insist on selecting, and the Licentiates submit to such picking and choosing? And how are the apprehensions of the Fellows with respect to their future relative influence and responsibility to be allayed by such as would advocate so large an admission of *Permissi* as would probably satisfy the excluded body? such as would, for example, at once double the number of resident Fellows? How are the Fellows to be reconciled to the risk of being *swamped*? So much for those two classes of difficulties.

Then there are interior reforms in the College very much wanted, some of which have been glanced at by several witnesses before Mr. Warburton's committee. The powers, for example, of the anomalous body called Elects are scarcely compatible with good government; they are, it is well known, self-elected, which is of itself too bad; they license for England and Wales at their discretion, I imagine, without any responsibility to the College. Of them, and by them exclusively, is the President elected. Now the President is the head of the medical profession; but he

is more: not to speak of various small pieces of patronage within the College, he is, *ex officio*, a Trustee of the British Museum, a Trustee of the Hunterian Museum, a principal member of the Vaccine Board, and Physician in Ordinary to the King. The office, therefore, of President of the College of Physicians is one of some emolument, and great influence and dignity. Will, then, the physicians of London, or the major part of either section of them, be satisfied with the system that gives the exclusive rights of electing, and being elected, to that high office, to nine senior Fellows?

There are other defects in the organization of the College. The compilation, correction, and publication, of a codex; the inspection of the apothecaries' shops east of Temple Bar; the regulation of the practice of physicians in the metropolis, all devolve on them, and comprehend for the most part duties for which, if practicable at all, the College is very indifferently qualified. Waving debateable points, I ask, is it desirable that the College of Physicians should be empowered to prosecute and punish for unlicensed or unskilful practice? The Censors, like other Fellows, are practitioners; the College vends licenses. The Censors, therefore, are doubly liable to suspicion, whether as witnesses, or jurymen, or judges, in College prosecutions.

Again, let me ask is it *pro bono publico* that gentlemen practising physic only should have the superintendence of the practice of pharmacy, to the exclusion of surgeons, who are for the most part medical practitioners, and of chemists and druggists, whose profession is pharmacy? Again, is it *pro bono publico* that the practice of physic outside the London district should be wholly beyond the pale of collegiate authority? Regulation is salutary or hurtful. If the latter, why permit it in London? If the former, why limit it to the metropolis? Yet these defects it is not in the power of the College to remove; they are legalized.

On the whole, then, when I take into account the importance of the defects which it is beyond the powers of the College to remedy, and the imperfect acquaintance evinced by the Fellows, in their senatorial capacity, with the amount and nature of the grievances of the Licentiates, and the impossibility of their informing themselves sufficiently

without frequent and long conferences with the Licentiates, and their indisposition, to all appearance, to such a mode of ascertaining the true relative positions of the parties, and the shortness of the time between this and the meeting of Parliament, and the little likelihood there is of the friendly Tories being long at the helm; considering all these things, I confess I despair of the good cause of spontaneous reform.

I am, sir,
Your obedient servant,
CIVIS MEDICUS.

London, Feb. 10, 1835.

MEDICAL GAZETTE.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

REFORM PROCEEDINGS IN THE COLLEGE OF PHYSICIANS.

THE reform in the College of Physicians *progresses*—as the Americans say; not very rapidly indeed, but certainly at a better pace than the new Pharmacopœia. Monday and Friday last week, and Tuesday and Friday this week, have not seen the *Comitia majora extraordinaria* assembled for nothing at this busy season of the year. The excitement is great and critical; may it also prove salutary! We have no facts to make us despond, but, to say truth, our intelligent correspondent, CIVIS MEDICUS (see his letter) has rather alarmed us. We fear he knows more than he reveals, else we can scarcely understand why he should “despair of the good cause of spontaneous reform.” To us it seems that nothing is to be apprehended on this head, when we see the Tories founding their claim to public confidence, and basing their hopes of retaining place, on the extent and variety of the reforms which they propose. So long as the great political parties in the state are bent on the race of reformation, there appears to us little

danger of their failing to urge on all the corporate bodies to the full extent of what the public demand, or the several cases require. With respect to the College of Physicians, we are more disposed to marvel that they have done so much, than to be surprised that they have not done more. Have they not agreed to abolish *in toto* the orders of candidates and inceptor candidates? Have they not consented that a degree from either of the English Universities shall cease to be acknowledged as a passport to the Fellowship? Have they not determined that the alumni of Oxford and Cambridge shall take their place among the Licentiates, with the graduates of Edinburgh and Paris? Have they not thrown open their doors to all men who have received a certain specified education*, even though they may not have a medical degree? Have they not made every Licentiate of 30 years of age, and of four years' standing, eligible to the Fellowship? If they do all this—and we assert that they have agreed to do all this—surely it will be admitted by every candid person that a prodigious step has been made in forwarding the good cause. Indeed, we have no hesitation in saying, that if the above changes be carried into effect in a spirit as liberal as that which seems to have prompted them, there will remain little to desire; but we admit that much depends upon the manner in which the machinery is worked; and till we see how this is managed, we shall refrain from expressing unqualified approbation.

The plan at present is, to have a select committee, to whom certain powers are to be delegated, one-fourth of the number going out every year, but eligible to re-election. Much will depend on the duties imposed upon this com-

mittee, and on the manner in which they are performed. It may be very proper that this select body should recommend the persons to be chosen as Censors, and to hold other offices; but we do not approve of delegating to them exclusively the privilege of recommending Licentiates to be elevated to the Fellowship: the Licentiates ought themselves to have some voice in a matter in which they are so deeply interested. Why not allow them to send up two names for each Fellowship, the committee deciding between them? If the number admitted be not very large, there must be picking and choosing and favoritism. If the Licentiates themselves had a share in this, they could not reasonably complain; but if they have no share, they most certainly will complain. This—we mean the selection of those to be made Fellows—is the point of all others most likely to form a stumbling-block.

Again, the order of Licentiates ought at once to be recognised as *members* of the College, and have the right of admission to the library and museum. Indeed, their exclusion from these is quite preposterous and indefensible.

We wish the College had done away with the "Elects," which our correspondent very justly calls an "anomalous body;" but if they are to be retained, it appears to us that a regular succession of elective privilege might be established—thus: the Elects to choose the President (as now), the Fellows to choose the Elects, the Licentiates to choose the Fellows; that is, to send up two names for every one to be elected, as the Common Council send up two candidates for the Mayoralty, the selection resting with the Court of Aldermen.

We have given the latest information to be had on this subject, but shall probably have to recur to it again very soon, as it is evidently intended that something shall be done this time, and that too before the parliament meets.

* The precise curriculum has not yet been made out; but we understand that it will differ in some respects from that proposed in 1839.—*Ed. Gaz.*

CORONERS' INQUESTS.

CASE OF APPARENT DEATH.

CONSIDERING the number of inquests that are daily occurring, it is singular that they attract so little of the serious attention of practitioners. Perhaps the calculation which has been made is not very far from the truth—namely, that the number of judicial investigations taking place before coroners in the course of each year, throughout the country, does not fall far short of five thousand; and far the greater part of these require the assistance of medical witnesses. Even on Monday last, a single morning paper (the *Times*) contained an account of no less than *thirteen* inquests: two of them relating to cases of death from fracture of the skull; one a fall from a scaffold; two sudden deaths, from apoplexy supervening on drunkenness; one a case of hanging, in a supposed state of insanity; one death from burning—a red-hot iron having fallen out of a forge-fire on a person asleep and drunk; a case involving the question of child-murder; two cases of poisoning—one by prussic acid, the other by opium; and, finally, three cases of death by starvation and exposure to cold! Medical evidence was given in most of these cases.

But it is not our intention, at present, to dwell on the necessity of having proper professional evidence on such and the like occasions; nor need we repeat the remarks which we have heretofore frequently offered, on the wretched provision, or rather the absence of any regular provision, on the part of our government, for meeting the urgency of the want of medical assistance at inquests. We allude to the subject chiefly with a wish to point out the loose and incautious conduct which we have reason to think is but too often displayed by practitioners who have to deal with business of this na-

ture. In the example which we subjoin, the fault would seem principally to lie in the want of decision evinced by the medical man who had the treatment of the case. The question which required that decision, we admit, was one of more than ordinary difficulty; but what we are dissatisfied with, is the hastiness with which it was treated in the first instance, and then the facility, the almost infatuated acquiescence in an absurd proposal, with which it was afterwards met.

The case was one of apparent death. A young woman, aged 19, who had been confined three months previously, but was in good health and spirits up to the evening before her dissolution, was seized with illness, and soon fell into what those about her called "the agonies of death." A medical practitioner was sent for; he arrived in about twenty minutes (this was between 9 and 10 P.M.), and presently pronounced the patient dead, adding, that it was of no use to attempt any methods of restoring animation. However, on the following morning (twelve or fifteen hours after), the body being found still warm, he was called in once more, when he endeavoured to take blood from the arm, and ordered the deceased to be put into a warm bath. No benefit, of course, was derived from this proceeding.

It appeared by the statement of a woman who remained by the bed-side all night, that no motion had been observed in the body after "the agonies;" and it was suggested that the heat had been retained in the corpse by the several blankets which covered it. The cause of death could not be assigned. No morbid appearances were found in any of the cavities of the body. An inquest was held on the next day, when the jury, after a patient investigation of the circumstances, could not refrain from expressing their astonish-

ment at the proceedings of the medical attendant. After examining that gentleman, and hearing his defence—which amounted only to this, that he acted as he did on his second visit, merely *for the satisfaction of the friends*—the jury, we are told, had “a long discussion as to the propriety of censuring the conduct of the surgeon, but eventually the verdict was returned of ‘Died by the visitation of God’*.”

We give the facts just as we find them: we know nothing more of the case than what we read in the newspapers; and upon such grounds we own we are strongly inclined to think the surgeon was wrong in two ways;—1, in not adopting some active measure, when first called in, to resuscitate the patient: it was *then* that he should have attempted to *satisfy the friends*; and, 2, in acting as he did some fifteen hours afterwards—opening a vein and ordering a bath, at a time when, by his own admission, it was so perfectly hopeless. What a monstrous error of judgment, to dream of giving satisfaction to the friends by such a line of proceeding! surely any body with his ordinary wits about him would have perceived that it must have just the reverse effect, while it compromised most perilously his own reputation.

We abstain from further comment. We repeat, that in alluding to this and other similar cases, we are actuated by no other motive than that of warning medical men of the necessity of being particularly cautious in transactions like these, which bring them so prominently before the public.

HOMŒOPATHY.

A SET of obscure persons in Paris, professing to be the disciples of Hahnemann, lately petitioned the Minister of Public Instruction for leave to set up a Dispensary in the French metropolis.

The Minister referred the matter to the Academy of Medicine, who have, in consequence, been obliged to appoint a commission to inquire into the nature of homœopathy, and upon what ground the petitioners seek the attainment of their object. Some members of the Academy were for scouting the matter at once, but they were overruled; it being one of the blessings of a scientific institution thus under the immediate control of government, to be ever ready at the beck of the Minister to undertake the investigation of any monstrosity whatever submitted to them, whether Phrenology, Animal Magnetism, or the figments of Hahnemann.

DEATH OF M. DUPUYTREN.

THIS most illustrious surgeon expired on the morning of Sunday last. He had never perfectly recovered from the malady for which he had to visit Italy some months ago; and latterly he suffered from a disorder of the chest, which was rather overlooked till gone too far. He possessed the full use of his intellectual faculties up to nearly the last moment.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Diagnostic Symptom in Peritonitis.

A PAPER was read at the last meeting, by Dr. Bright, of Guy's Hospital, the chief object of which was to point out a symptom occasionally occurring in inflammatory attacks of the peritoneum, and of importance as diagnostic of particular changes in that membrane. He stated, that when adhesion had taken place between the peritoneum lining the parietes of the abdomen, and the peritoneum covering any portion of the included viscera, a peculiar sensation might be perceived by the physician who placed his hand over the part; which varied from “the crepitus yielded by emphysema, to the sensation produced by bending new leather in the hand.” Four cases were detailed in which this symptom had existed, and by it the existence of such adhesions had been detected during life; and the post-mortem examinations had proved the correctness of the diagnosis. Three of them were cases of ascites, two of which had survived the operation of paracentesis several years. One was a case of ovarian dropsy, in which the patient had

* *Times*, Feb. 4, 1835.

refused the relief which had been proposed by paracentesis.

Dr. Bright had seen other cases in which the same symptom had been observed, but the health of the patients having been re-established, the adhesion could only be matter of conjecture.

The paper afterwards proceeded to the description of several morbid changes occasionally observed in the peritoneum, which were illustrated by some cases and observations.

CLINICAL LECTURE

ON

SCROFULOUS DISEASES OF THE HIP,

Delivered at the Middlesex Hospital, November 29, 1834,

BY SIR CHARLES BELL.

I AM desirous of drawing your attention to-day to diseases of the hip, meaning the common scrofulous diseases of that joint.

When you see a child that is confined to bed with a great swelling of the hip, you often find that it has a pretty face; that is to say, a fair complexion, light hair, and blue eyes; and generally there is a peculiar character of mind as well as of body—a precocity of intellect; affording something like a reason for that greater affection on the part of the parents—a happy provision, at any rate, for a creature so miserable and helpless. The child passes many months, nay years, in this sad condition, and too often at last sinks under hectic, and suppuration around the hip; or if it survive, it rises only to move about on crutches, and is lame for life.

This disease makes its attack at all periods, from the earliest infancy to mature age. The cases about to be laid before you occurred from $4\frac{1}{2}$ to 30 years of age; and I have known it take place in a child at the breast; indeed, I have had reason to believe that the hip disease is occasionally consequent on violence done in delivery. You can imagine nothing more likely to sprain, and to give rise to disease of the hip, than the violence done to the infant in turning.

When an opportunity offers of examining the state of the parts, there is absorption of the cartilages, wasting of the firm ligaments, which are reduced to membranous shreds, and abscesses surround the joint. In a few words, this is the disease which I now desire you to

study, and with the advantage of seeing every variety.

In approaching such a subject, you must consider the structure of a joint, and especially the physiological character of the parts constituting it. You remember how the articular head of the bone is tipped with cartilage, and how the synovial membrane that forms the lining of the cavity, the stronger capsule, the accessory ligaments that are around it, the tendons that pass over the joint, the thecæ containing these tendons, the bursæ, and even the fasciæ, have all a peculiar character; that they are termed low in regard to vascular action, and are low in the scale of sensibility. But the application of the word *low* here is not right, because, instead of being an imperfection, it is a most admirable provision. That which we call insensibility is only the nice adjustment of the sensibility of the part to its functions; for were those parts which I have now enumerated more sensible, you would walk home with lameness, and suffer as though you had rheumatic inflammation of the joints. The apparent diminution of sensibility, therefore, is only the adaptation of it; there is sufficient sensibility to make it an appropriate guard against excessive motions of the joint, and yet to permit the natural use of the limb. In like manner, the vascularity of the joint is of a particular kind; but it is not therefore imperfect. But when we admit this fine adaptation, we can understand that with it a peculiar constitutional predisposition prevails.

All parts, then, so characterised, are the especial seats of scrofulous inflammation. There being a constitution prone to struma, those are the parts on which the constitutional predisposition falls; and it must be part of your study, in these local diseases, to ascertain what character of general disorder prevails. It may be that general disorder which you call bad health, and which to dwell upon would require hours of prelection; it may be, that there is strumous constitutional action concentrated and directed to the particular part; or it may be rheumatic inflammation, or gout, or syphilis. Surely it requires no argument to urge you to the belief, that to be a good and safe surgeon you require to be a physician. To-day, for example, there is a case sent into our wards from the physicians'; there is a large painful knee, stiff, and somewhat contracted. In what it differs from other cases we are warned by the place from which the young woman comes. Accordingly, she says she has been *cured* of pain in her shoulder, in her hip, in her elbow, by which at least we know in what condition is this more obstinate knee. In more sim-

ple cases, such as would be at once thrown over to the surgeon, you have all the varieties of disease to consider which may fall upon the great joints; in short, much of the practice of medicine must pass through your mind before you can be a safe surgeon, even in regard to disease of the hip-joint. How closely, then, is the study of the two departments connected.

The first case to be read will shew that an affection of the hip-joint is not a local disease, in the proper sense of the word; that it does not always arise from injury to that particular joint, but that you will find it intimately connected with the constitution.

“Elizabeth Cook, æt. 20, a little woman, with angular curvature of the spine, no doubt originating from caries of the bodies of the vertebræ, which has existed since she was three years old, was admitted for disease of the hip-joint. It is said to have been caused by a fall down stairs. Two years ago she was attacked with pain in the hip, and after it had existed for eleven months an abscess formed below the groin, and another behind the trochanter major: these burst, and have since continued to discharge matter, closing for a short time, and then again, with an accession of fever, bursting out. Two or three months ago she began to suffer pain in the left elbow, and soon afterwards abscesses formed around the joint; not, however, communicating with it. She complains a little of pain in the hip, but the disease of the elbow is the seat of her present misery, so as to prevent her sleeping, in spite of large doses of an opiate. She has been treated with quinine and steel. The elbow has been wrapped up very warmly in cotton wool; a bent splint has been constantly kept upon it, to prevent motion; and blisters have been occasionally applied. By this treatment the disease of the elbow has been much alleviated; but she is gradually becoming worse in constitution. There is now more discharge from the sinuses in the thigh; the appetite fails; she is subject to colliquative diarrhœa, which chalk, opium, and catechu, check only for a short time; she has a regular return of hectic fever every night.”

This case is illustrative of what I have been stating—indeed, of what you have seen. Here is disease of the spine, disease of the hip, and disease of the elbow. Wherever there is a slight injury, sprain, or sore, there the morbid action exhibits itself. Now, do you know, I believe this poor creature will weather it still. The period of constitutional disease will pass, but she will remain a maimed and contracted object.

I think I have observed, though we

should be slow of drawing such general conclusions, that these local diseases prevent worse; and that, of a consumptive family, she who has had diseased joints, or scrofulous glands, has escaped the more formidable attack on the lungs.

Directing our attention more particularly to the hip-joint, we become at once aware of the necessity of attending to the anatomy, because you must have seen that there are various diseases and accidents which you may mistake for scrofulous hip disease. There are various nervous affections which it is a serious evil to mistake; there are disorders in the abdomen and pelvis which produce pain in the loins and hips; a collection in the colon will produce pain in the hip, down the thigh, and in the groin; affection of the kidney, which will cause pain in the thigh and hip; and mere rheumatic affection of the muscles of the hip may be mistaken for a more serious disease of the joint; and the formidable affection of the ischiatic nerve may likewise be misunderstood. Now I hold, that in order properly to distinguish such cases from that which is our present subject, we must think of the anatomy. The grand features in the outline are these: you remember the acetabulum—that there is one cavity within another; and you remember what occupies the internal cavity—that there is a soft, fatty, vascular structure, and that this is especially the structure that will be influenced by the kind of deranged health we have spoken of. You will remember how possible it is to propel the head of the bone directly and perpendicularly into the joint, so as to hurt the soft part, and to give rise to just so much local injury as will direct the constitutional disposition; you will readily conceive also that on the fatty apparatus in the lesser cavity swelling, it becomes subject to the pressure and friction of the head of the femur, and that this is often the commencement of diseased hip, rather than the twist, or bruise, which first calls the attention of the patient. You especially remember the strength of the capsular ligament at the anterior part, where it is covered by the accessory ligament, which supports us whenever the line of gravity of the trunk is behind the centre of the joint; and you remember that there is a part of the capsule towards the inside which is very thin, and that this will be the part where there will be a communication between the external abscess and the internal suppuration of the joint, when the disease is far advanced. Then you will recollect the manner in which the psoas magnus and iliacus internus come down over part of the pelvis; how the latter runs over part of the joint, and how closely connected the ten-

dons of these muscles are with the accessory and capsular ligaments. Hence you are prepared to understand that in order to relieve the pain in all inflammations of the joint, there must be a relaxation of this muscle; and such relaxation implies a certain position of the person—whether standing upright or lying in bed. This is the reason that, in going round, I entreat the patient not to move; and, on laying down the bed-clothes, you may see by the posture of ease which he assumes what is the disease. You will remember the manner in which the glutei come down from the back of the pelvis and cover the hip, and what would be their action—that it would be to propel the head of the bone deep into the inflamed cavity, if that action were permitted. Therefore you will be sure to observe that position of the pelvis and thigh which tends to counteract this pressure, and throw the head of the femur out from the inflamed cavity. You will reflect also, that the state of total inactivity of those muscles causes them to waste; and hence the flatness of the diseased hip, in contrast with the roundness of the other. These considerations will be sufficient, being anatomists and surgeons, to enable you to distinguish the more serious and deep disease of the hip-joint from a casual affection of the surrounding parts or nerves—such as rheumatism or neuralgia; and also to distinguish the hip disease from psoas abscess. Again: you will find us, as we go round, having a certain difficulty in ascertaining whether there be disease in the hip, or whether there be suppuration coming down the tract of the psoas muscle to the groin.

Thus it is that we require data to reason upon and to direct our observations, so that we may comprehend the cause of the particular position of the patient—the indication from that position.

The next case is that of

“Mary Davies, *æt.* 8. Some weeks ago she fell down and bruised her hip. She is a scrofulous looking child, and the mother is very poor. The hip became inflamed; she was treated as an out-patient for a fortnight, but was getting worse instead of better, from the want of good diet and warm clothing. She was admitted into the house on the 18th November. She assumed the usual posture of a patient with inflamed hip, when in bed—*viz.* the knee bent, the thigh drawn up, the diseased hip raised, and the body twisted. At first leeches were applied; then a succession of anodyne fomentations, then a warm stimulating plaister over all the hip. She had proper nourishing milk diet, with tonics. Now she is better, and lies straight in bed.”

From this case you see the character of

the disease. You will find, in private practice, that the mother calls you to examine her child's hip. She will tell you that her boy can run about, but when he comes in from play, and gets cool, he becomes stiff and full of pain, and cries on motion; but on the morrow he is again active and running about, and when he is heated and excited he can walk and run very well, but still in the evening he comes home to his parents complaining of pain and stiffness; and this is the first thing that attracts their attention. By and by the pain and inflammation arise to that extent that the child must be confined, and now there is sympathy of the general system, and fever. This is the chronic disease; but do not let us forget, that instead of such a disease as we have seen in visiting the wards to-day, there are instances of acute inflammation of the hip running its course, and destroying the delicate subject of it, in three weeks. We sometimes see a delicate boy, or girl, with acute pain and high fever, and the twisting of the pelvis and the position of the limb very remarkable; the limb and body lying at right angles, and death ensuing from the acute and rapid attack. I have actually found, on dissection, the femur dislocated.

How are you to examine the child brought to you with the chronic disease of hip? You place him before you, and you find that upon throwing off the clothes, in the early stage, there is a fulness of the hip, and an apparent projection of the trochanter. You have just seen this appearance, and therefore I hope it will make a due and permanent impression upon you. But afterwards, at a second period, instead of fulness, which implies an active state of inflammation, there is a remarkable breadth and flatness. The meaning of this I have in part explained to be, that the muscles and fat, but especially the glutei muscles, begin to waste: when inflammation of the hip has continued for a long time there can be no action of the glutei, and the fulness which these three muscles produce on the hip is gone—they become wasted, and a certain flatness of the hip is the consequence; and thus we explain the flatness of the hip. With regard to the hip, and also to the corresponding joint of the upper extremity (the shoulder and deltoid), how often do we find surgeons, imperfectly educated, asking, “Is this dislocation or not?”—when there is nothing but flatness from wasting of the deltoid, by which the fulness of the shoulder is lost. Now what deceives him is the flatness of the shoulder from the wasting of the deltoid muscle; and then the jerking of the wasted head of the humerus in the socket, the projection

of the acromion, and the uncommon distinctness of the bones, from the wasting of the deltoid muscle, appears very like dislocation. See, then, how the circumstances that attend the disease which you have to examine, and upon which you have to reason, must always be considered with a reference to the anatomy.

Another point upon which you must be very careful, is that of distinguishing hip disease from the general wasting of the limb; for remember that there is a condition of the extremity which it is very difficult to comprehend, but which is also a very common occurrence. The limb ceases to grow, it is struck with an imperfection of a peculiar kind that impedes its growth, the development of the parts is retarded, and there is, with the smallness of the hip, an imperfection in the whole limb. Hence it comes, that being drawn to observe the limp in the gait, and then the peculiarity of the hip, you may do as I have known some before you—put issues in the hip. But what a lamentable thing to put an issue in the hip, and perhaps confine the boy to bed, when, after all, it is only an imperfection in the growth of the limb, where proper exercise and general health can alone give any hope of amendment!

I have said that you must be careful to distinguish hip disease from lumbar abscess. When there is disease in the course of the lumbar muscles, the patient, in standing, bends forward, so as to make the origin and insertion of the muscles approach. He cannot stand upright; the knee is bent; and so much does it look like disease of the hip, that you will have to go into a course of inquiry before you can say whether it be that or commencing psoas abscess.

I particularly beg your attention to what you have seen, for it is much better to see than to hear; and what I have now to deliver, such attention would render almost superfluous. You have seen how the child lies in bed—that the body is bent towards the thigh, or the thigh raised, which is the same thing; the object of this, as I have stated, is to prevent the pressure that would otherwise be made by the psoas and iliacus internus muscles upon the inflamed capsule: the diseased limb is thrown over the other in a very particular manner. My explanation of this is, that the other thigh being, as it were, a fulcrum, the diseased limb is thrown over, so that the weight of the lower part of the limb shall more than counterbalance the upper part, and therefore raise the head of the femur outwards from the acetabulum—not actually raising it, but still relieving it from pressing upon the inflamed acetabulum, and therefore relieving the pain.

But there is another very singular occurrence, which seems to be a contradiction, viz., that the limb is sometimes elongated and sometimes shortened; you must therefore always mark whether it be actually an elongation or shortening of the limb, or whether the alteration is in correspondence with the pitching of the pelvis,—which pitching varies in different cases. If the child be going about with disease in the right hip, and cannot stand upon it, or throw the weight of the body directly over it, but rests rather upon the other limb, and shoves the diseased limb forward, that side of the pelvis sinks; the spine then assumes a curve or inclination corresponding with the pitching of the pelvis; and when you lay the child down, the diseased leg appears the longest. But if the complaint be more violent, not so slow or chronic in its progress, and the child lie as the half dozen patients whom you have seen lie with disease of the hip—that is to say, with the hip raised and the limb thrown over—then the limb will appear shortened. Thus the best way is to look to the position of the heels or of the patella, and mark the obliquity of their position with reference to one another; and then see whether that of the superior anterior spinous processes of the ilia is in a corresponding line of obliquity.

But I will not lead you to the consideration of the cases of unmitigated suffering and death, without the consolation of believing that many of these cases, especially of children, with care, rest, warmth, and good food, recover. If this should be with actual ankylosis, a serious question of operation occurs, which we will wave at present. But often it happens that the patients recover and retain the use of the limb, only it is short, and the cartilage and the head of the femur misshapen.

I will give the following case, to mark the disease in its almost ultimate stage, in a person further advanced in life: she lies in Northumberland ward.

“Sarah Ann Hoffmeister, æt. 30, was admitted on the 2d November, with sinuses around the right hip. She had diseased hip when she was seven years old, and was for three years unable to walk without crutches. At the age of 11 she left off using crutches, the leg being strong and useful, though she walked with a halt. Two years ago she says she had fever and cold, and a swelling formed under the hip, and burst, and continued to discharge for 18 months. She was then beginning to get a little better, when one day, after a long drive, she felt something troublesome in the rectum, and a friend extracted a piece of bone through the anus. It is cancellous, about the size of a nut, but pre-

sents only a small portion of the external surface. About the time when this piece of bone came away, she perceived air in the abscess, which she imagined came from the bowels, and passed out at the sinus. There are three sinuses, which all appear to tend towards the trochanter major; the largest opens on the outside of the thigh, three inches below the trochanter. There is not much discharge from the sinuses, but she is subject to diarrhœa; and the matter discharged from the bowels is like chalk and water, mixed with fecal matter, and appears to contain a very large proportion of pus. Poulitice to the wound occasions pain, so that it is dressed with simple dressing; the tongue was spotted, and the stomach out of order. She took hydrarg. creta and aromatics for a day or two, and cinchona, gentian, and spirit ammon. aromatics, &c. She was better for a few days, but the purging soon returned, which was stopped for a time with chalk, catechu, and aromatics. It is necessary to court her appetite.

"Nov. 20th.—She has continued to be purged five or six times in the twenty-four hours, and sometimes oftener, great part of the motions consisting of pus; and chalk and astringents only check it for a short time. She has found the flatus from the bowels passing more frequently through the sinuses of late; and for the last two days something like feculent matter has been observed upon the dressing, and the hip has become more painful.

"27th.—Since the last report she has been daily becoming weaker; she suffers more pain; she is worn out with diarrhœa and discharge, both external and internal, from the hip; and at each motion of the bowels a considerable quantity of feculent matter escapes by the sinus. She can take nothing now but a little wine and arrow-root, the stomach rejecting every thing else."

The reading of this case directs your attention to the pathology; and some of you may have seen the suite of preparations which were in my museum illustrative of this very stage. When the head of the femur itself had wasted, the sharp point bore through the acetabulum into the pelvis!

The first remark I make on the case is, that when the patient recovers from this horrid disease, there are always marks of the part being arrested in its motion; ligamentous connexion binds the trochanter to the pubis, or an exostosis extends from the top of the femur, and meets a corresponding process of the margin of the acetabulum; so that the motion of the joint is checked, or rather stopped, by anchylosis. Looking at this poor creature, one cannot

but suppose that the great excitement to the continuance of the disease is the motion of the diseased bones. You are aware, and it is particularly necessary that you should notice, in reference to this very complaint, that there is no motion of the body but what is attended with a corresponding change of position in the hip-joint. You cannot stretch out your arm but there is some new poising of the body, and which change is permitted by the trunk, in fact, the acetabulum, moving upon the head of the femur. Persons cannot change their position in bed without there being a change of position and relation between the head of the femur and the acetabulum; and hence it is, whether the patient be up or down, moving about, or lying in bed, there is incessant motion, and consequent upon it an uninterrupted irritation and excitement to inflammation in the hip-joint.

In other cases, we do not merely find that an exostosis has stopped the motion, or that a ligamentous connexion has been found tying the parts together, but we find an actual anchylosis, or joining of the head of the bone with the irregular surface of the acetabulum.

These are the circumstances observed on dissection, after a patient has recovered from an advanced state of the disease; but when they die under it, we find a very different condition of parts: the muscles over the hip are quite degenerated; not only have they decreased, as it were, by the process of wasting and inflammation, but having been totally without use, they have gone almost into shreds of cellular membrane, or a gelatinous matter occupies their substance. Then there are suppurations, or the remains of large abscesses, external to the capsule; and sometimes—nay, frequently—these abscesses communicate with, and have probably arisen from, suppuration within the joint. The head of the thigh bone is wasted by ulceration, the cavity of the acetabulum is shallow from absorption having taken place there, and sometimes it has almost disappeared. And I have just said that I have had preparations shewing the remaining head or cervix of the femur, projecting quite through the acetabulum, and resting on the rectum and bladder. Now that at once shews you what may have taken place in this unfortunate creature, since you see that she has been long subject to the disease, giving full time for this morbid condition to occur, and since you find that bone came by the rectum. But it has not the appearance of having passed by the stomach, or through a digestive process, nor of having stuck in the rectum after passing the œnal; on the contrary, it is a portion of the pubes or ischium.

But another circumstance certainly leaves no doubt of the extraordinary progress made in the disease: the flatus comes through the sinus; there is a communication, therefore, not only with the pelvis, but with the rectum, and flatus comes through this passage. There is an abscess, it may be, through the joint itself, and the feculent matter is discharged at the top of the thigh. These are the lamentable circumstances that attend the last stage of the disease.

Treatment.—Now what is to be done in these cases? Let us first contemplate the commencement of the disease in such young patients as we have seen. The indication here is to prescribe careful and good diet, not thoughtlessly ordering for an infant food appropriate only to an elderly person, but diet fit for a child; warmth, proper clothing, great attention to the discharges from the bowels, such occasional laxatives as will prevent accumulation, the warm salt bath, or warm hip bath, fomentations to the hip, warm plaisters over the hip, and perfect quiet. The child, which is described as now rolling freely in bed, was lame, and felt pain on every motion, when it came in; it has been treated in this way, and already you perceive the amendment. An issue may be placed on the hip, and warm poultices and fomentations over it.

In addition to the care of the diet, and of the state of the bowels, you add a tonic suited for a child; for example, soda, rhubarb and steel, the vinum ferri, the alkalies, as liquor potassæ and lime water, in good beef-tea, &c. You must watch and satisfy yourselves of the effects of iodine in those children who are taking it. Where there has been scrofulous cutaneous ulceration it appears to have a happy effect. It is to be regretted when you have to lower the action in these cases; but you must cup and apply leeches in the acute and violent inflammation of the hip joint. In all cases you watch the formation of abscesses, and open them early by puncture, or the matter will burrow extensively.

But what is to be said when your patient approaches to the state in which you find the parts in this elderly person? Such is the condition of the joint, that you cannot secure it against motion. You see that in one patient I have attempted to stiffen the elbow-joint. I did not then know what the bed clothes covered; I did not know that the patient was so far gone with disease of the spine and hip; my attention was drawn to disease of the elbow; and I endeavoured to keep it perfectly fixed, knowing that thereby the activity of the inflammation and the pain would subside. And, by the by, as I hope I am of some

use to my dressers, let me beg them to recollect that the connexion is that of reciprocal advantage; they should be to me eyes and ears, reminding me of all that is neglected. However, that poor creature, by our attention to the elbow, has certainly reaped advantage; and were the disease of this joint her only complaint, I think I would eventually have shewn you that there is a better and a milder cure than cutting out the joint;—an operation which should not be thought of unless there be caries of the extremities of the bones entirely into the joint. But we cannot fix the hip-joint; I have attempted to fix the thigh, but I did not find it practicable: the continual motion of the whole body upon the head of the thigh bone counteracts our little contrivances.

I am almost loath to present anything that has the character of being speculative, but you have sometimes seen a curious object in the streets, with his leg sticking out before him, and moving alertly on crutches; ankylosis, effecting a cure of the disease, having taken place in the hip. The question, then, is, whether the neck of the thigh-bone might not be here divided, and ligamentous union produced, so that the limb might at least hang from the body, and not always project in front of the person. The operation has been done, but it was not from its success that another suggested itself to me, but which I have never executed, viz., the division of the neck of the thigh-bone, so as to permit the head of the bone to lie quiet in the acetabulum. I am convinced that motion is the great source of irritation; and I do verily believe, that if we could divide the neck of the thigh-bone, and cause the limb to move upon the cervix instead of the head of the bone, the disease would subside. With respect to this patient, I fear we shall never have an opportunity of performing such an operation; indeed, she lies in a state of such suffering, that it would be cruel to examine her or even to move her. Yet I will be bold to say that the neck of the femur in this woman is as soft as a piece of bread the second day after baking; so completely has it been bereft of its natural play, and consequently of its solidity.

Although these are my last words upon this head, let them not be thought of the most consequence to you, but attend to the common cases—such as were described to you in the beginning of the lecture. Look at the marks and the symptoms of the disease—at the manner of ascertaining its particular nature, and treating it: for as these cases must come repeatedly before you in the course of practice, so I repeat my old saying—that therefore they are in-

finitely the most important points for you to consider.

The patient above alluded to, died exhausted. Both the femora were found ankylosed in the acetabula. The history gave no reason to believe that she had ever had inflammation of the left hip. Sir Charles Bell mentioned that he had seen both the hips and knees ankylosed merely by confinement, where no disease was suspected in those joints. Sinuses containing fecal matter surrounded the right hip joint: the principal one ran between the trochanter minor and os pubis, and under Poupart's ligament, and so communicated with an extensive chain of abscesses, filled with serofulous matter, in the psoas and iliacus internus muscles. These abscesses winding round, at length communicated with the rectum by a large funnel-shaped opening, opposite the middle of the sacrum. This led to the remark that the case originally had been psoas abscess, and gave another proof of the difficulty of distinguishing the disease of the hip, properly so called, from serofulous inflammations which affect the joint in a secondary way.

AUSTRIAN STATISTICS.

In the year 1833, the number of deaths in the Austrian monarchy was 655,731, being 76,917 fewer than in the preceding year; the deaths from cholera, however, in the latter year may account for the difference. The number of births was 815,293. Among the deaths were—by suicide, 721; hydrophobia, 35; casualties, 5003; murdered, 422 (in the preceding year, 466); executed, 36 (in the preceding year, 53). There were 450 persons who were above 100 years of age. The population of Austria, including Lombardy, Venice, Dalmatia, the Tyrol, &c. is at present reckoned at about 31 millions.—*Frankfort Paper.*

Delivered at the London Hospital,
By THOS. DAVIES, M.D.

LECTURE XXI.
DISEASES OF THE HEART.

THEORY OF THE SIGNS OF DISEASES OF
THE HEART.

THE diseases of the heart, like those of the lungs, were involved in great obscurity from the earliest period of medical history to the present century. It is true, more had been effected towards the description of the morbid changes of the heart than of those of the pulmonary organ, by the successive labours of Lancisi, Morgagni, and, above all, of Senae; but whilst these authors pretty tolerably described the organic changes which took place in this important viscus, they overlooked almost entirely the physical causes which commonly produce them. Since the time of these illustrious anatomists, the morbid anatomy of the heart has been so accurately described, that perhaps there is nothing left undone. We owe this perfection to the works of Corvisart, Burus, Bertin and Kreysig, and Laennec.

But although the lesions of the tissues composing the cardiac organ were earlier understood than those of the lungs, yet their signs were, if possible, still more obscure than those of the latter viscus. It may be said that there were then no local signs, and that the functional and general symptoms also were extremely uncertain: thus palpitations, or irregularities of the pulse may occur, either with or without a change of the structure of the heart, and

dyspnoea being a common sign of the affections of both the thoracic viscera, is insufficient alone to demonstrate which of them is diseased. The great discovery of Laennec has, however, so completely unveiled all obscurity relative to the signs of cardiac diseases, that we are now enabled to distinguish even which particular cavity or valve of the organ is affected.

In prosecuting this subject, we shall first treat of the theory of the local signs of the diseases of the heart; and, secondly, of the diseases of that organ, of the pericardium, and of the large blood-vessels.

Before we consider the theory of the signs, it will be necessary to describe the situation of the different parts of the heart in relation to the parietes of the chest.

Laennec divided the precordial region into two parts; the right corresponding to the inferior third of the sternum, and to the right side of the heart; and the left comprising the space between the cartilages of the fourth and the seventh sternal ribs, having beneath it the left side of the organ.

I have followed the example given by Dr. Hope, of passing needles into the chest, for the purpose of ascertaining the relative positions of the thoracic parietes to the different cavities and valves of the heart, and to the large blood-vessels. Placing a subject upon its back, I dissected the skin from the anterior part of the chest, and drilled a hole through the centre of each bone of the sternum and passed long knitting needles through them as perpendicularly as possible to the vertebral column, and fixed them there. The intercostal and pectoral muscles were then removed, so that the anterior surfaces of the lungs and the pericardium could be seen. The sternum was carefully removed, leaving the needles transfixing the soft parts beneath it. The centre of the first bone was seen to correspond to the lower edge of the left subclavian vein, and to the arch of the aorta crossing the

trachea. The centre of the second bone corresponded to the right side of the ascending aorta, and to the upper edge of the appendix of the right auricle. The third needle passed into the right side of the right auricle, and the fourth into the right ventricle. Another needle penetrating the chest at the upper edge of the cartilage of the fifth rib, close to its costal extremity, entered into the septum of the ventricle; the point of the heart was about an inch and a half below this, and inclined to the left side.

The pulmonary semilunar valves corresponded to a spot a little below the centre of the third bone of the sternum, the aortic valves were a few lines below and behind the pulmonary, and the mitral were still more deeply seated, and a little lower also than the aortic. The origins of the pulmonary artery and aorta are slightly below, and to the left of, the centre of the third bone. The pulmonary artery passes upwards, touching the sternum, inclines to the left, and may be found between the second and third ribs, close to the sternum: the aorta ascends to the first bone, crosses it, and then forms the arch.

One third of the heart, consisting of the upper part of the right ventricle, and of the whole of the right auricle, is situated immediately beneath the sternum, and the rest, being the remainder of the right ventricle, the left ventricle, and auricle, to the left of that bone.

Nearly the whole of the anterior surface of the heart is formed by the right auricle and ventricle, a small portion only of the left ventricle and its point, and the appendix of the left auricle, forming a part of that surface. The left auricle and the greater portion of the left ventricle form the posterior surface.

The pericardium invests the heart from the diaphragm to the commencement of the arch of the aorta.

Percussion.

The heart being a solid body, at least in relation to percussion, ought to give a dull sound upon striking the parietes of the chest covering it; but perhaps from its being imbedded, as it were, in the lungs, and from its being partially also covered by them, the sound is not so fleshy as that produced by striking over the liver, or the pulmonary substance, consolidated by hepatization, or compressed by a fluid. The sound on percussion is something intermediate between that produced at the upper part of the sternum and the muscular parts of the body. The sounds also are still duller and more uncertain when the parietes of the chest are charged with fat, or are infiltrated with serum.

All lesions, however, which by their

action distend the pericardium, increase the dulness of the sound upon percussion, as hypertrophy and dilatation of the heart, the dilatation of the auricles or ventricles, hydro-pericarditis, accumulations of blood in the pericardium, &c.

Auscultation.

There are four points of view in which the heart may be examined with reference to auscultation.

1. *The extent to which the beatings of the heart are heard upon the thoracic parietes.*

2. *The impulse or shock communicated to the ear of the observer, by the movements of the heart.*

3. *The rhythm of the movements of the heart.*

4. *The nature of the sounds produced by the heart's action.*

1. *Extent of Pulsation.*—When the ear or the stethoscope is applied to the precordial region, the beatings of the heart are usually heard most distinctly all over it. There are but few exceptions to this rule. It sometimes, however, occurs, that in individuals who are very fat, or whose thoracic parietes are infiltrated with serosity, that these beatings are confined to a space not greater than the circumference of the stethoscope, or the sounds of them may even be almost entirely lost. If extensive catarrh be united to the above-described conditions, the deep sonorous wheezing tends still farther to mask the cardiac sounds. In all ordinary cases, the pulsations are perfectly evident over the space corresponding to the inferior half of the sternum, and to the cartilages of from the fourth to the seventh ribs. The movements of the right side of the organ are heard in the former region; those of the left, in the latter. If the sternum be short, they can also be distinguished in the epigastrium.

If the heart be heard beating only at the points I have just described, it may be considered to be of good proportions.

When the heart increases in its volume, the sounds of its movements are heard, with equal, or nearly equal, intensity, to an extent over the surface of the chest proportionate to that increase: thus, if it be slightly enlarged, its pulsations are distinguishable on the left side of the chest from the axilla to the region corresponding to the stomach; if larger, its sounds may be heard to the same extent on the right side; if the organ be of very large proportions, then its beatings are audible on the left side of the spine, and, finally, though rarely, on the right.

When, also, the heart is of its normal size, or nearly so, the extent of its pulsations may be modified by the thickness of

its parietes: thus, if they be very thin, the sounds are more extensively heard than in their natural state; if they be thick or hypertrophied, the pulsations are often concentrated in a small space. When, however, the cavities of the organ are dilated, and their walls are thickened, then the heart is occasionally enlarged to an enormous volume, and its beatings may be heard all over the chest.

The following observations may be made upon this subject:—1. That the extent of the pulsations of the heart is increased whenever its volume increases, especially if the augmentation of the size of the organ depends upon the enlargement of its cavities, combined with hypertrophy of their parietes. 2. That although the heart be of its natural size, or nearly so, if its parietes be thin the sounds of its beatings will extend beyond the precordial region; this probably depends upon the increased *loudness* of the sound, which we shall hereafter describe to exist, under these circumstances. 3. That in concentric hypertrophy of the heart, where its walls are thickened, and the capacities of its ventricles proportionately diminished, the pulsations are not heard, or at least but extremely slightly, beyond the cardiac region; and sometimes even they are not distinguishable, except upon a spot equal in surface to a square inch.

Are there any exceptions to the rule, that the extent of the pulsations of the heart is proportionate to its volume? There are several, and it is of the greatest importance to understand them, as I find that, practically, constant errors are made upon this subject.

In the first place, any cause which renders the lung solid, will occasion it to be a better conductor of sounds of the heart, and consequently increase the extent of the surface of the chest over which they may be heard; as hepatization, or even the firm parietes of a tubercular excavation. Fluids contained in the pleuritic cavities will produce the same effect. The extent of the sounds is greater in persons having narrow and contracted chests; the heart then, although perhaps of its natural size, has not sufficient space to perform its movements freely, and therefore is too large for the diminished capacity of the part in which it is placed. The hearts of children are also larger proportionately than those of adults, so that their pulsations can be distinctly heard all over the thorax; and, finally, the extent of the pulsations is always increased by any cause tending to accelerate the movements of the organ; as nervous emotions, fevers, &c.

To determine the volume of the heart, attention then should be paid to the configuration of the chest, to the age of the

patient, to any alarm he may feel from the mode of your examination, and to febrile action augmenting the frequency of the pulse. Even then do not hurry to a conclusion, but make repeated and daily examinations before you form a diagnosis.

2. *Impulsion*.—By *impulsion* or *shock* is meant the sensation of elevation communicated to the ear of the observer, in consequence of the heart striking the parietes of the chest with a certain force.

The stethoscope renders this elevation much more evident than the application of the hand; the shock often cannot even be distinguished by the sense of touch. Sometimes, too, in those persons who are agitated at the moment of examination, a considerable impulsion will be given to the hand, which the stethoscope shews to consist of but little real increased force of the action of the heart. Care must be taken not to mistake the impulsions of the heart's movements for the short and rapid inspirations which occasionally take place in dyspnoea. A very slight attention will render such an error impossible.

This proposition may be advanced relative to the force of the heart's action;—that the intensity of its impulse, or shock, is in a direct ratio to the thickness of its parietes, and in an inverse ratio to the extent of its pulsations.

In the natural state of the heart, its impulse is but slight, and in persons of a certain degree of obesity it is not to be distinguished; but if the organ be slightly thickened, and its movements quickened by nervous agitation, running, palpitations, or febrile action, then its impulsions become exceedingly evident: the shocks are still greater, if the hypertrophy be considerable; they then distinctly elevate the head of the observer when applied to the chest. If the hypertrophy be extreme, the impulsion is affected in a progressive manner: the heart at first seems to swell, is applied upon a point only to the corresponding surface of the chest, then upon its whole surface; finally, it gives its shock, and instantly recedes, to recommence the same series of movements: to this recession, described by Laennec, Dr. Hope gives the name of *back-stroke*. The impulsion is felt during the contraction of the ventricles.

The force of the impulsion is always proportionate to the thickness of the parietes of the heart: if the hypertrophy be great, the shock is great also; if the walls of the heart be thin, no impulsion whatever can be distinguished.

When the heart is in a state of simple or concentric hypertrophy, its impulse is felt in the precordial region only, and sometimes even in a small part of it; if, however, the hypertrophy be eccentric, or combined with dilatation, the heart then

acquires the largest possible proportions, and the shock of its pulsations may be felt all over the chest. It is in the latter case that the impulsions are so great as to communicate their vibrations to the person of the patient, and even to the bed on which he is placed.

All causes by which debility may be produced diminish the impulsion of the heart's movements—as repeated bleedings, continued diarrhoea, low diet, digitalis, &c. Even in very marked hypertrophy of the organ, a severe dyspnoea may produce the same effect, particularly when the difficulty of breathing arises from pneumonia, pleurisy, œdema of the lungs, a paroxysm of asthma, or the congestions which form during the agonies of death. Nothing, therefore, should be concluded from an examination under such circumstances.

3. *Rhythm of the beatings of the heart.*—By rhythm is meant the order of succession in which the contractions and dilations of the heart occur, and the relative time occupied in effecting each movement.

It is perhaps impossible to determine the size of the heart, compared to the rest of the body: usually, Laennec asserts, it is a little less, or equal, or it slightly exceeds, that of the closed hand of the subject. The parietes of the left ventricle are almost double the thickness of those of the right, and their tissue is firmer and more compact than that of the rest of the muscles of the body. The walls of the left ventricle should not depress upon being cut into. The right ventricle is somewhat larger than the left, its earneæ columnæ are more voluminous, and a section of the parietes of the cavity causes them to fall inwards upon it.

If the finger be placed upon the radial artery, and the stethoscope be applied at the same time to the region of the heart, the following phenomena may be readily distinguished, if the organ be in good proportions.

The instant the artery strikes the finger, a slight elevation is communicated to the ear through the stethoscope, by a movement of the heart; this is accompanied by a dull sound. The isochronism of the movement and sound, with the elevation of the artery, shews distinctly that the phenomena are due to the contraction of the ventricles, since the arteries cannot be elevated except by the ventricular systole.

Immediately after this ventricular movement and sound, a louder noise is heard, the duration of which is considerably less than of that just described; it is unaccompanied by any sensation of impulsion or shock, and is similar to those produced by the clacking of a valve, the

smacking of a small whip, or the lapping of a dog. This sound Laennec attributed to the contraction of the auricles; we shall presently examine the correctness of this opinion.

Directly following the second sound, there is a period of repose, the duration of which is equal, or nearly so, to the second sound itself. At the termination of this repose of the movements of the heart, the ventricular contractions recommence.

According to Laennec, the rhythm, or relative proportion of time, occupied by the beatings of the different parts of the heart, and the period of repose, is as follows; and for the purpose of elucidating this subject, let us suppose that the successive movements and repose occur in one second—that time would be thus divided:

The impulse and first sound, caused by the ventricular contraction, half a second.

The second or louder sound, caused by the auricular contractions, quarter of a second.

The period of repose, quarter of a second.

Such are the succession of phenomena which may be distinguished by auscultation. The cause of one of the sounds is, however, still a subject of dispute. Laennec asserted, that the feeling of slight impulse, accompanied by the first, or dull sound, was caused by the contraction of the ventricles: this is accorded to him; for the simultaneous elevation of the arterial pulse incontestably proves it. He ascribes the second, or clicking sound, to the contraction of the auricles: this is denied by Dr. Hope; and I think he has succeeded in establishing his refutation, and in proving its real cause.

Dr. Hope examined the movements of the heart in several living animals, of various sizes, after depriving them of sensation, and keeping up respiration by artificial means. He saw, upon opening the pericardium of the ass, that the auricles first contracted by a vermicular and slight action, which was continued to the parietes of the ventricles; that when that movement arrived at the ventricles, they instantly contracted, and propelled the blood into their emerging vessels; the point of the heart then striking the parietes of the chest. Dr. Hope, at the moment of the ventricular contraction, applied the stethoscope to the naked surface of the ventricles, and distinctly felt the impulsion of their movement, and heard the first sound, and found that they accorded, or nearly so, with the elevation of the arteries; proving that the first sound, the impulsion, and the arterial pulsation, depended upon the contraction of the ventricles. The moment the ventricles ceased to contract, they receded from the parietes of the chest, and

became dilated and swollen. The stethoscope, according to Dr. Hope and numerous assistants, then communicated the second sound,—proving, if the facts were well observed, that it did not depend upon the auricular contraction, but upon the ventricular dilatation. It was then observed that the heart remained for a short time in a state of repose, during the latter part of which the auricle again commenced its vermicular contraction, which was immediately again followed by that of the ventricles, &c.

The time occupied by these states will now be as follows:—The ventricular contraction, half a second; the ventricular dilatation, a quarter of a second; the period of repose, a quarter of a second, the latter part of that period being interrupted by a certain quantity of blood entering into the ventricles, in consequence of the contraction of the auricles.

Such are the leading points of Dr. Hope's theory of the movements of the heart; for a more complete account, I recommend to you the perusal of his excellent work.

Impressed with the importance of this theory, especially in a pathological point of view, I repeatedly attempted to verify these experiments. I perfectly satisfied myself that the contraction of the ventricles coincided with the first sound, the impulsion or shock, and the elevation of the pulse; but I confess I could not as satisfactorily ascertain that the dilatation of the ventricles occasioned the second: I much doubt even whether I heard the sound at all, but it was evident that the successive movements of the heart were performed in accordance with Dr. Hope's description; and it was clear also that the contractions of the auricles were too slight to produce that sound. Although, therefore, I could not succeed in observing all that Dr. Hope describes, yet I fully believe his explanation to be the most rational. This theory singularly corroborates the description of the symptoms of the diseases of the heart given by Laennec, since it not only does not invalidate a single sign, but confirms and explains them all.

The rhythm of these movements is modified by disease; thus, if the ventricles be in a state of moderate hypertrophy, their contractions are less sonorous, and are of longer duration than usual, the period of repose being still well marked. If, however, the hypertrophy be considerable, the ventricles occupy a still longer time in contracting; these contractions are at first obscure, deep-seated, but augment gradually, elevate the ear, and terminate in a shock, unattended by any noise, or if any, it is a slight murmur, like that of respiration; the second sound is then of short duration, and nearly inaudible—sometimes

it cannot be heard: the period of repose is then lost. In extreme cases of hypertrophy, no sound whatever is heard, except, perhaps, the slight murmur before described; but the ventricular contractions are manifested by a strong rolling movement, as if a large mass of solid flesh were irregularly and tumultuously revolving within the cavity of the chest. The second sound in this case is heard with great difficulty; now and then, however, two or three ventricular dilatations succeed each other rapidly and convulsively.

When the parietes of the ventricles are thin, the interval of repose is lost; the sounds of their contractions are louder than natural, and approximate in character to that of their dilatations; so that these movements often cannot be distinguished. The shock of the ventricle is also diminished—indeed, it may be said not to exist. If to these signs be superadded an increased extent of pulsation over the parietes of the chest, it may then be inferred that the walls of the ventricles are not only thin, but that their cavities are enlarged.

4. *Of the sounds produced by the movements of the Heart.*

The sounds produced by the movements of the heart cannot be heard by the patient himself, except he be suffering from febrile action or nervous palpitation, or in the case of these sounds being heard at a certain distance from the chest.

If the stethoscope be applied to the precordial region, two distinct sounds may be heard in the natural state; the one clear, short, like the clicking of a small valve, and corresponding to the dilatation of the ventricle; the other dull, longer in duration, coinciding with the beating of the pulse and with the sensation of impulsion previously described, and indicating the contraction of the ventricle.

The sounds heard in the right precordial region are produced by the right ventricle; those in the left, by the left ventricle. In the natural state, the sounds of both ventricles are similar; in their diseased state, they are often very dissimilar.

These sounds are the only phenomena which the beatings of the heart present, when they are heard on any other point of the chest than in the precordial region; for the shock or impulsion is generally confined to the latter space alone, except in cases of hypertrophy with dilatation of the ventricles.

The sounds produced by the beatings of the heart are always the loudest when the parietes of the ventricles are thin, and the impulsion feeble. When the ventricles are in a state of moderate hypertrophy, their contractions produce a dull sound

like an inspiratory murmur, and the clicking noise of their dilatations is less than natural. If the hypertrophy be extreme, the sound of the ventricular contraction is lost; a shock only is felt, and the dilatation is also to be distinguished with difficulty.

When the parietes of the ventricles are thin, the sounds of these contractions are clear and loud, and similar to that of their diastole. If their cavities be also dilated, the sounds become still more similar and equal in intensity; so that finally they cannot be distinguished from each other.

In the natural state, these noises are always most evident in the precordial region, becoming feebler at the remoter parts of the chest. In some diseased states of the heart they may be louder at other parts; as we shall hereafter describe.

It frequently happens, that in cases of hypertrophy, when nothing is felt in the precordial region but a noiseless impulse, and where the sound of the diastole of the ventricle can scarcely be heard, that the latter can be distinguished under the clavicles and even on the back; and in almost all slight cases, it is more evident in these situations than in the precordial regions, especially in persons possessing thin and narrow chests.

Of certain anormal sounds produced by the action of the heart and arteries.

Bruit de soufflet.—The heart, either in the systole or diastole of its cavities, and the arteries in their diastole only, occasionally produce a peculiar sound, often exactly similar to that of the blowing of a bellows, from which analogy Laennec has denominated it "*bruit de soufflet*." There are certain modifications of this sound; hence he divided them into three species.

1. *Bruit de soufflet*, properly so called.
2. *Bruit de scie ou de râpe*.
3. *Bruit de soufflet musical ou sibilant*.

1. *Bruit de soufflet*, properly so called. Laennec has most singularly stated that the bellows sound occurs only during the diastole of the heart and arteries; when, in fact, it occurs frequently during the systole of the ventricles. This sound, although precisely analogous to that produced by blowing a bellows, yet sometimes changes in its character both in the heart and arteries: it then becomes similar to the continued murmur of the sea heard at a distance, or to that caused by holding a large univalve convoluted shell to the ear. This latter sound is sometimes heard in the carotid and subclavian arteries on one side, while the ordinary *bruit de soufflet* occurs in those of the opposite side. It is isochronous with the arterial diastole, and most frequently exactly circumscribed by the

caliber of the artery or ventricle producing it; sometimes it is, however, more diffused.

Bruit de scie ou de râpe.—This sound is much rougher, and, as its name indicates, is like those caused by the sawing, rasping, or filing of wood, when heard at a distance.

Bruit de soufflet musical ou sibilant.—The musical or sibilating bellows-sound is, according to my experience, very rare: many of you have heard it very distinctly lately, in a lad in this hospital. This sound is generally preceded by the ordinary *bruit de soufflet*; it was so in the case I have just alluded to. Its characters vary: it is sometimes like that caused by the wind blowing through a key-hole, or to the resonance of a metallic cord which vibrates a long time after it has been touched.

These sounds, although not very intense, are yet perfectly appreciable; sometimes they consist of two or three notes: the instance I have mentioned consisted of two only.

The musical or sibilating bellows-sound is very rarely produced by the heart, and never in a very distinct manner.

The *bruit de soufflet* may exist in the heart and arteries with or without an increase of the force of their impulse.

The *bruit de soufflet* may manifest itself at once in the cavities of the heart, and to a great extent of the arteries. Nothing is more uncertain than its duration, for it may be heard in the left carotid and not in the right, on one day—it may be reversed, or altogether absent, on the following—and so of the rest of the arteries. The musical sound continued in the right inguinal artery of the boy I have mentioned many days after it had disappeared from the carotids.

Proximate causes of the sounds produced by the movements of the heart and arteries.

It is not my intention to enter here into any elaborate detail of the various opinions entertained of the efficient causes of the sounds produced by the movements of the heart and arteries, because the time permitted me in delivering this portion of the course is not more than sufficient even to state all the facts, without entering into hypothetical speculations, and because also these speculations are of minor importance, compared to a perfect knowledge of the facts themselves; yet it may be necessary to say a few words upon this subject, although I shall be as brief as possible.

What are the efficient causes of the sounds produced by the movements of the heart in its natural state; and what are the causes of the anormal sounds denominated *bruit de soufflet*?

In relation to the first question, there are two sounds to explain: the first dull,

and corresponding to the contraction of the ventricles; the second louder, and synchronous with the dilatation of the same cavities.

There are two elements which enter into the consideration of these questions; which are, that these sounds can only be produced by the action of the solid structure of the heart, or by the blood entering into its cavities; or perhaps by the united movements of one and the other.

I believe that the first sound is caused by the point of the heart striking against the ribs. One, however, has thought that it was produced by the rushing of the blood into the ventricles during their dilatation; a second supposed that it was during that dilatation that the point of the heart arose to strike the ribs; a third, that the closing of the mitral and triuspid valves, during the contraction of the ventricles, was a sufficient cause to produce the sound; a fourth, that it was effected by the rushing of blood into the arteries; a fifth, that it was to be accounted for by the collision of the particles of the blood itself in the ventricles, and, finally, that the contraction of the muscular fibres is the cause.

I believe, also, with Dr. Hope, that the second sound is caused by the ventricular dilatation; at least it is certainly coincident with it. Laennec supposed it to be formed by the auricular systole: we have, however, sufficiently discussed that question, and it is unnecessary to revert to it. But as there have been a variety of opinions as to the proximate cause of the first sound, so have there been also of the second: thus it has been supposed to be caused by the contraction of the ventricles; by the flapping of the mitral and triuspid valves against the sides of their corresponding ventricles; by the striking of the blood against the parietes of the pulmonary artery and aorta; by the movement of the base of the heart against the chest; by the action of the arterial blood in closing the semilunar valves; by the impulse given by the blood in dilating the ventricles during the contraction of the auricles; and lastly, by the mere muscular action of the parietes of the ventricles in their dilatation.

Such, gentlemen, is a summary of the opinions entertained upon this subject. I can here enter into no further details, but refer you to the appendix of Dr. Williams's work upon Diseases of the Lungs and Pleura. Recollect, however, that these facts are proved:—that the impulse of the heart, the first sound, and the pulsation of the arteries, occur at the same moment, and therefore must be caused by the ventricular contraction; also, that the second sound, and a part of the time between two

successive elevations of the pulse, are isochronous with the period of the dilatation of the ventricles, and that that sound is caused, in all probability, by the ventricular diastole.

The abnormal sound denominated "*bruit de soufflet*," is equally difficult of explanation. When, however, it, or any of its modifications, exist, either in the heart or arteries, it may always be inferred that there is a mechanical obstruction to the current of the blood, or that these organs are under the influence of some peculiar and inexplicable state of the nervous system. If the sound be caused by mechanical obstruction, it is permanent, since the cause is so; but if it be the consequence of nervous disorder, it disappears with the affection that has caused, or, at least, is concomitant with it.

The efficient cause of the *bruit de soufflet* must be sought for in the parietes of the heart and arteries, or in the blood flowing within them. Laennec, after adverting to Wollaston and Erman's discoveries of the sounds produced by muscular movements, some of which are precisely similar to the *bruit de soufflet*, attributes the bellows sound to a vibratory action of the heart and arteries. Dr. Hope, and others, believe the sound to be caused by the movements of the blood; but in the latter case, it is impossible to explain why it should occur in one carotid, and not in the other; or in the subclavian, and not in the carotids; or in the inguinal artery, and not in the subclavian; or that in different days, or in different parts of the same day, it should so frequently change its situation. We cannot suppose that the blood changes its qualities so rapidly, or that it should differ so materially in vessels of similar caliber and distance from the heart, as to produce the sound in one carotid artery, for instance, and not in the other.

Fremissement Cataire.

Laennec gives the following description of this sensation, which is occasionally detected by the application of the hand upon the heart and arteries.

The *fremissement cataire* is almost exactly similar to the tremulous sensation produced in passing the hand upon the skin of a cat while she is purring; it may also be assimilated to the feeling caused by gently rubbing a hard brush over the palm of the hand covered by a glove. This tremor is commonly felt over the precordial region, or a part of it; or over the whole surface of the chest; and frequently, also, in the course of the larger arteries.

The arterial purring tremor is usually similar to that already described, and is exactly bounded by the caliber of the ar-

tery. It is felt by a slight pressure upon the vessel; but if the force be increased, the trembling diminishes: in this case it is saccaded, and not continuous. Sometimes, and especially in the carotids, the purring extends beyond the diameter of the artery, and is superficial, continuous, and not saccaded. The vessels in which the *fremissement cataire* is commonly found, are the carotids, subclavians, brachials, and inguinals. Laennec observes that it is rare in the ascending aorta, but I certainly have not found it so; it is, however, infrequent in the abdominal aorta, and it can only be felt there by considerable pressure. The purring is but little sensible in the smaller arteries; yet when it exists in the heart, or a great blood-vessel, or even when the bruit de soufflet is formed in them without the *fremissement cataire*, the pulse often presents a slight tremor corresponding to the arterial diastole.

The *fremissement cataire* of the heart and arteries is constantly accompanied by the bruit de soufflet, and appears to be caused by it. According to my experience, the intensity of the trembling is always proportionate to the loudness of the bellows-sound. Laennec, however, asserts that it is not always so, and consequently infers that the two phenomena are not determined by the same cause. I cannot help believing, after several years' observation, that, considering that these sensations are always perfectly synchronous, and that the force of the *fremissement cataire* is always in a direct ratio to the loudness and roughness of the bruit de soufflet; that it is, in fact, but one phenomenon, rendered evident to the tact by the vibrations communicated to the hand and to the ear, by the sounds they occasion.

The two sensations, then, have, I presume, identical causes; they may arise from organic obstruction to the circulation, or from nervous agitation. In the latter case, the purring is as uncertain as to its seat and duration, as the bruit de soufflet. If the cause be organic, like that sound it is always present in the same situation.

Of the Beatings of the Heart heard at some distance from the Chest.

It requires the application of the ear, or the stethoscope, to the surface of the chest, to hear the sounds produced by the pulsations of the heart. It very rarely occurs that these movements can be heard at a distance from the thorax. It sometimes, however, happens that these noises may be distinguished at a certain distance from the body. I have heard them two or three times, and in one instance at five or six yards from the patient.

I have also occasionally heard the bruit de soufflet at a distance from the indivi-

dual; and have little doubt that, if this sound were constantly attended to in this point of view, it might frequently be heard when intense.

The cause of this phenomenon is extremely obscure. Laennec believed it depended upon the presence of air in the pericardium, or that air might even be formed in the cavities of the heart during the agonies of death, so as to occasion this sound. I mention it as a singular circumstance, that, in the cases of the beatings of the heart heard at a distance by myself, they occurred in females who were at that period under the influence of the catamenial discharge. I perceive, however, no connexion of cause and effect between these two events.

Laennec mentions another cause of this phenomenon, which is doubly interesting, on account of the fact itself, and on the probability of his having noticed it on his death-bed. It is the last page of his work, which I shall transcribe entire.

"At the moment they brought me the last proof of my work, indisposed for some days, I have observed in myself the phenomenon of the noise of the heart, sensible also to those around me; and I was enabled to distinguish an evident cause, altogether physical, and which, being of the same nature as that we have already spoken of, ought certainly to be much more frequent.

"I had just been bled in the foot, and placed myself in bed, where I rested a few minutes in a sitting posture, the back but slightly supported, and the head upright; finding myself very easy in this position. Suddenly I felt the contractions of my heart (a very rare circumstance with me), and I heard them also very distinctly. These contractions were regular, not unusual in their force, but had the frequency which a slight degree of fever occasioned. It seemed to me that, at each contraction, the heart slightly repelled a veil moderately tightened. I examined the region of the stomach, which I found very distended by gas, and strongly resonant by the slightest percussion. A person placed his head about six inches from my chest, and heard distinctly the beatings of my heart. From thence I began to think, that a certain degree of flatulent distention of the stomach, from its lying in such close contact with the diaphragm, might produce the phenomenon of which I speak. An instant after, I doubted no more, for an eructation of gas occasioned it to disappear."

[Under the head of Observations on Empyema, in the Table of Operations, in last lecture, for "of the third I have no account," read "of the fourth I have no account."]

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

BY HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and
the General Lying-in Hospitals.

[Continued from page 685.]

TUMORS of greater magnitude imbedded in the substance of nerves are less frequent than the smaller, and are to be found commonly in the larger and deeper-seated trunks. These, like the smaller tubercles, are commonly attended with neuralgic affections in the distribution of the diseased nerve. In some of the cases there is also muscular spasm combined with intense suffering; but upon other occasions it is absent; and even sometimes the muscles are paralysed, or at least have defective power. Cheselden mentions a case of this kind, but his history is imperfect. It was situated in the centre of the cubital nerve, and occasioned a great numbness in all the parts that nerve leads to, and excessive pain upon the least touch or motion. The pain ceased with the operation, but the numbness increased a little. The operation here mentioned, as explained by the engraving, consisted in the removal of the tumor, together with a portion of the nerve at each of its extremities*. The filaments of the nerve ran over the surface of the tumor, and were separated from each other. In this case the ordinary function of the nerve was essentially impaired, the few undiseased filaments upon the surface bestowing a small proportion of sensibility only in the parts supplied by the nerve, the total division and removal of which could only "increase the numbness a little." The pain, therefore, produced by touch or motion was probably produced in the diseased portion, but, as in stumps, referred to a distant part; just as in Mr. Earle's case, wherein he supposed the axillary plexus of nerves to have been lacerated or crushed as they pass under the clavicle, the violent pain referred to the extremities of his fingers, which was occasionally produced in the "useless and paralysed limb" by any attempt to move it, and at times when perfectly quiet, was probably "excited where the nerves were injured under the

clavicle, and the percipient mind referred it to the extremities, as is frequently the case after amputation*."

Sir Everard Home also has detailed two instances of this painful disease. Both were attended with excessive sensibility in the tumor, pressure upon which produced not only great suffering in the part compressed, but pains also in the distribution of the diseased nerves. The first of these two cases was cured by excision of the tumor, together with an adjacent portion of healthy nerve; the other, in which the operator contented himself with disengaging the tumor from the interior of the nerve, terminated unfavourably. "*In consequence of having been inflamed, the cavity was lined with coagulable lymph, and almost filled with coagulated blood, as suppuration had not completely taken place.*" That, however, there was more than a mere tendency to the formation of matter, is to be inferred from the general practical conclusion, which Sir Everard himself draws from the two cases, that "the taking away three inches of a nerve is productive of less violent effects than are occasioned by inflammation and suppuration in the substance of a nerve for an equal extent†."

In the operative surgery of Sir Charles Bell‡ is related another interesting example of the same disease from mechanical injury of the popliteal nerve. This man appears to have died, worn out by the mere severity of pain. The peroneal nerve had escaped both the effect of the injury and the contamination of disease; its function was therefore perfect, excepting when from change of posture, as in sitting, it became subject to compression from the contiguous tumor. Then the parts supplied by the latter nerve lost their sensibility; and the case possesses an extraordinary interest, as presenting us with a striking illustration of the difference between morbid excitement in a diseased nerve, and paralysis from pressure in one that is healthy. The tumor in the popliteal nerve produced such agonizing pains in the parts upon which that nerve is distributed, as to destroy the patient; but when, in bending the leg, the peroneal nerve, which was *un-*

diseased, became compressed between the tumor upon one side, the inner hamstring upon the other, the tendinous fascia immediately above, and the condyle of the femur below, the parts supplied by this nerve were immediately deprived of their nervous energy.

A gentleman, whose leg had been amputated in 1819, to free him from an exquisitely painful tumor of the thigh, consulted Mr. Lawrence, in 1828, on account of a tumor in the fore-arm, as large as a walnut, situated over the course of the ulnar nerve, and causing severe pain, with indescribable sensations, like electric shocks, upwards and downwards in the direction of that nerve. The disease was removed in February, 1829. "It was situated between the flexor carpi ulnaris and the bone, and the nerve adhered so closely to it, that a portion was removed with it. The part healed favourably, and remains well*." A similar tumor afterwards formed in the flesh of his stump; this was as large as a goose's egg, and produced most severe shooting pains in the part, with repeated recurrence of electric dartings from the stump into the body. The growth appeared to be prolonged to the tuber ischii, and was removed up to the bone. Mr. Lawrence has given no other account of these tumors, than that they were not malignant, although they were originally suspected to be so. But from their situation, character, and symptoms, it appears difficult to dissociate them from the tumors I have been noticing either imbedded in, or intimately connected with, and perhaps morbid growths of, the nerves affected. The resemblance between this case and that related by Sir E. Home is most striking, the only difference being in the nerve affected. In the former, the ulnar nerve was affected; in the latter, the musculo-cutaneous. Both were attended with severe darting pains in the course of the nerve: in the former, the nerve adhered so closely to the tumor, that in the removal of the latter a portion of the nerve was removed with it; "in the latter, the tumor terminated at its upper and lower ends in a strong white cord, which proved to be the musculo-cutaneous nerve," which led to the removal of a portion of the nerve. There is also

another curious analogy to be observed between the case of Mr. Lawrence and the second of Sir Everard Home: this consisted in the proneness to the formation of similar tumors (nevromes) in other nerves. They are commonly imbedded in the substance of the nerve, but the direction of their growth may be influenced by external causes. If they grow towards the interior, fibres of the nerve will be found upon the surface of the tumor, as in Cheselden's case; if meeting with little resistance in the growth outwards, the nerve will appear behind, but attached to the tumor, as in Mr. Lawrence's case, and in one of those described by Sir Everard Home; but more commonly they are in the centre of the nerve, and a few scattered nervous fibrils may commonly be traced all around them. They are said to be encysted; and from the facility with which, in Sir Everard Home's case, they were detached by the finger from the thin membrane, probably composed of neurilemma, which surrounded them, the opinion appears not without foundation, and is much confirmed by the observations of Cheselden, Marshall Hall, Windsor, Descot, De la Roche et Petit, Radel, Alexandre, Misd, Jolly, and Andral. M. Andral believes the larger tumors to be seated within the enveloping membranes of the nerves; sometimes to be a mere deposit betwixt the fibres of the nerves which are extended over the tumor like ribands, whilst others are consisting of many cysts, containing a jelly-like fluid; and others again of a single and larger cyst, of a fibrous or cartilaginous texture, containing matters of different character*. The smaller subcutaneous tubercles he pronounces not to be formed in the substance of the nerve, though some of the nervous filaments may be attached to them; and in this opinion he is supported by Dupuytren and Jaumes. I have, however, upon the whole, more confidence in the perspicuous statement of Camper, who had seen many cases in women, with whom all are agreed that it is more common than in the opposite sex, and who adds, "in viris plus semel ea (in nervis tubercula parva et dura) vidi: albicant intus, cartilaginee duritie sunt residua et intra nervorum tunicas sedem

* Med.-Chir. Trans. vol. xvii. p. 33. The paper was read Nov. 8, 1831.

* Précis d'Anatomie Pathologique, vol. ii. p. 838.

habent;" and this confidence is much increased by the simple annunciation, by Mr. Windsor, of the facts, that in the course of the operation for the removal of such tumor, "a filament of a nerve was observed going to the part," the removal of which was immediately followed by numbness; and that "the little tumor, along with the nerve which penetrated it," was preserved and shewn to his friends Dr. Hull and Mr. Wilford*.

The size of the subcutaneous tubercle varies from that of a pin's head up to that of a horse bean, or almond deprived of its shell, and has been compared to a pin's head, a split pea, a flattened pea, coffee bean, a horse bean, and an almond. The larger tumors differ in bulk from that of a hazel-nut up to that of a small melon, which was the size of one removed with impunity, and indeed success, by M. Dubois†.

The smaller tumors are commonly whitish and pearly, and, according to Andral, fibro-cellular, or fibro-cartilaginous. In texture, they are described by the majority of writers as very hard, like cartilage‡, containing, in some instances, gritty or earthy particles§; and by some French writers, as resembling in character true carcinomatous scirrhus||, and as having such an intimate alliance with that disease, as to lead M. Bejin, in his article Cancer, in the "Dictionnaire de Medecine et Chirurgie Pratiques," to designate the disease "cancer des nerfs." But this is an objectionable application of the term cancer; for although it has been asserted that the tumor has assumed the character of a "degeneration squirreux," yet no instance, as far as I know, has been seen on record in which it went on to the production of cancerous ulceration.

The larger tumors are rarely so firm in structure, or so distinctly fibrous in texture. These often consist of numerous cysts, sometimes containing materials of varied degrees of consistence; in some instances like transparent jelly¶ —in others, encephaloid** — in others again, of a syrup-like consistence, in-

terspersed with fibrous striae*. But the most accurate description of these larger tumors is given by Sir Everard Home, who, speaking of the first which he extirpated, says, "it had the appearance of serpentine nervous fibres running in the course of the nerve; these were separated from each other, and the intestines filled up with the substance of the tumor; but that part of the tumor which was exterior to these fibres had something of a radiated structure†." The second tumor, which he removed from its matrix in the centre of the nerve, was of a yellowish-white colour; "when cut through, it was found to consist of a whitish firm substance, in the centre of which there was a very obscure fibrous texture, and towards the outer surface the texture was indistinctly radiated." A second tumor, much smaller than the one removed, in the same subject, was exactly similar to that from the arm of the first of these cases, except that the nervous fibres in the centre were rather more distinctly seen, the spiral direction of the fibres ‡ being readily distinguished by the naked eye; "in other respects it was exactly the same. The want of distinctness in those of the larger tumor may therefore be reasonably supposed to be the effect of the increase of size, by which they were rendered obscure§." Another great master of description has given us an account of the structure of a tumor which he removed:—"It was of firm texture, but not so hard as scirrhus; the swelling was covered with a thin white capsule, and was homogeneous; in compactness, toughness, and colour, it approached to the character of scirrhus||:" and this account, in combination with the symptoms, like electric shocks, and with the attachment of the tumor to a nerve, a portion of which it was necessary to remove together with the tumor, is calculated to remove all doubts as to its seat and nature, and identifies it with the disease the pathological character of which I have been noticing.

Whether these tumors are to be considered as inflammatory products, has not been ascertained, and is of little

moment. If not the result of inflammatory, or of increased, at least they are the consequence of morbid action of the arteries of supply. That, however, they are occasionally attended with inflammation of the contiguous portion of the nerve, is matter of observation, the nerve having in some rare instances been found of three times its average dimensions; and in the case operated upon by Sir E. Home, the vessel of the interior of the nerve, from its enlargement, bleeding so profusely as to require the application of a ligature to restrain it.

Another question suggests itself upon this subject, which it may be equally difficult to answer;—this relates to the precise mode in which these tumors occasion the sufferings, which, as far as I have been able to collect, are their invariable result. M. Descot is of opinion that they act by keeping up a state of chronic inflammation of the nerve. No decisive evidence, however, has been adduced of this; it is stated merely as a matter of suspicion or belief, but without investigation and without proof: still it is far from improbable, though they may act also as mechanical irritants, to which their hard texture, often described as gritty, or gristly, or like grains of sand or cartilage, blunting a knife with which the attempt is made to cut through them, would naturally contribute; thus resembling in their influence the experiments of pathologists upon nerves with the point of a needle, a forceps, or a probe. Some, again, may think that they act by distention of the fibrils of the nerve; but the effect of such distention has been far from satisfactorily proved, and appears to be in great measure negatived by the observations and experiments to which I have before adverted.

But the decision of these points is of comparatively trifling moment. It is enough that these tumors, whether in the form of painful subcutaneous tubercle or the larger tumors in the trunks of nerves, produce, in point of fact, the phenomena of an "exaltation of function," rather than those of paralysis; or if this be not universally true, the exceptions are so rare, that they may be said, according to the old grammatical rule, to prove and establish, rather than to overturn, the general principle. "Exceptio probat regulam."

Such are the principal pathological conditions of a nerve upon which its excitement, productive of the consequence of a morbid excess and irregular distribution of nervous energy, have been found most frequently to depend. But occasionally none of these causes can be traced, and pathologists are then driven to adopt the alternative conclusion, that the symptoms result from mere functional derangement. This inference, however, involves a negative proposition, which, like other negatives, it may be difficult or impossible to prove, and which, in some instances, subsequent dissection has shewn to be an assumption contrary to fact. An exciting cause cognizable to the senses has been sometimes detected after death, where there had been no previous suspicion of its existence, either at the very roots of the nerves in the brain, or in the spinal marrow, or somewhere in the course of the nerve, or in the part itself which is the seat of the painful affection. An instructive example has been recorded by M. Serres*, of the most severe neuralgia arising from disease of the root of the fifth pair. It was examined in the presence of some of the most enlightened of the profession in Paris; but as it has been quoted at large by almost all subsequent writers upon this subject, it is unnecessary to give the details†. In the case of a late estimable physician, who was among the brightest ornaments of our profession, no suspicion, I believe, was entertained during his life, or at least until a very advanced period of his malady, that the *tic douloureux* under which he laboured so long, and so severely, as to make him an object of commiseration to all his friends, was more than neuralgia, a mere functional derangement, as distinguished from neuritis or other structural diseases; yet, after death, in the head, and consequently at the very origin of the nerves, there was found a spiculum of bone, which had proved a source of mechanical irritation, analogous in its effect to the successive and frequent excitement of a nerve by a needle or a forceps, the movement of the brain in the alternate actions of respiration, bringing, as it were, the nerve to the pointed instrument, instead of the

* Archives de Médecine, vol. v.

† Descot, Swan, Bell, Andral, Bégin.

experimental physiologist bringing his instrument of torture to the nerve. In some of the instances of *le douloureux* related by Sir Henry Hallford, the nerves, before their exit from the cranium, were incased in canals undergoing inflammatory action, the dura mater being in that excited state which led to large deposits of osseous matter, so as to form, in the forcible language of the eloquent President of the College, a complete "rock work."

In an instance of neuralgia of the posterior branch of the second cervical nerve, recorded in the admirable work of M. Ollivier, upon the Diseases of the Spinal Marrow, whilst paralysis had been produced by disease of the spine, the cause of the neuralgic affection was discovered after death in inflammation of that nerve *as it proceeded from the vertebral canal*; thus beautifully illustrating the important distinction between the effects of inflammation on the one hand, and of simple pressure upon the other*.

That the cause of neuralgia may exist at a considerable distance both from the ultimate distribution of the nerve affected and the seat of pain, and yet remote from its origin either in the brain or spinal marrow, is also a point well ascertained, and of which endless examples might be produced. I shall, however, content myself with once more referring to the cases recorded by Mr. Earle, Sir Charles Bell, and Mr. Denmark, as affording ample and conclusive testimony of the fact.

Lastly, the cause may act upon the seat of pain itself. It may not, indeed, be appreciable to the unaided senses, and yet we may be justified in inferring it from the nature of the producing cause, as in the instance of neuralgia from the prick of a gooseberry thorn, related by Mr. Wardrop; or a piece of angular porcelain imbedded in the lip, recorded by Mr. Jeffries; or a sharp point of a nail, by Mr. Swan; or decayed teeth, which become sharp, extraneous, and irritating bodies, as in the cases mentioned by Mr. Mitchell and Mr. Swan.

Still it is but candid to admit, in the absence of all proof to the contrary, that there have been cases, and those perhaps

numerous, of most severe neuralgia, and perhaps local convulsive movement, wherein no perceptible morbid change, either of vascularity or of texture, could be traced in any portion of the nerve from which the parts affected derive their nervous energy. But the investigation of these cases of mere functional derangement presents to our view a field of inquiry so fertile in speculation and controversy, and so little promising in the prospect it affords of useful information, and, above all, is so little connected with the province to which I have restricted myself, that it offers little temptation to win me from the more immediate objects of my pursuit. I forbear, for these reasons, to do more than allude to this very extensive subject, and to tender my concession of a general principle, which, as must ever be the case with negative propositions, it may be more than difficult to prove; "for that sort of negative evidence in these cases is not quite satisfactory, because, in order to say that there was no state of disease in the nerves, it would be necessary to follow up the nervous filaments through their bony canals, and that would require a very long dissection. I believe that hardly any case has been examined in that way*." Besides, even where the examination has been so conducted, it may be with a nerve as it is with the brain; its "minute and subtle structure opposes an obstacle which must, on many occasions, be nearly insurmountable. Many changes may have taken place in so delicate an organ, unfitting it for the due and perfect performance of its functions, which changes may yet not be manifest to the senses. Morbid conditions of parts often exist without being discoverable by the eye or the touch of the practitioner. The change from healthy to diseased action, and still more from health to visible alteration of structure, is often by slow and imperceptible degrees†"

INHALATION IN CHEST DISEASES; WITH CASES.

To the Editor of the Medical Gazette.

SIR,

If you should consider the following cases and observations to be of sufficient importance, I shall be much obliged by the favour of their early insertion in your journal.—I am, sir,

Your obedient servant,

CHARLES SCUDAMORE.

Wimpole-Street, Feb. 9, 1835.

Deeply impressed as I am, by continued experience, of the very important advantages to be derived from inhalation of certain medicated vapours in the treatment of chronic bronchitis, of some conditions of asthma, and even of that most formidable of disorders, tubercular phthisis pulmonalis, I owe it, as I conceive, no less to medical science than to humanity, to persist steadily in using my humble but sincere exertions to advocate the practice, and to be its defender, if defence it may require, through good and evil report.

I cannot help suspecting that objections are frequently raised against the inhaling treatment by those who have never made any trial of it, and who have no better grounds for their opposition than some theoretical notion, or, what is less worthy, some prejudice—some objection to any innovation, as it is called, on the accustomed method of practice. And let me ask any candid person who reflects for one moment on the subject, what are the almost invariable results which flow from the ordinary proceedings of the physician with consumptive patients? Change of climate is for the most part the proposed remedy; and, with a few happy exceptions, does it not generally happen that a foreign grave receives the destined victim of the disease? If a distant removal from home be inconvenient from circumstances, or for any reason objected to, some routine treatment is tried at home; as, probably, the employment of *dry* emetics, upon empirical principles, rather than upon any theory with which I am acquainted; of digitalis, with the intention of retarding the circulation; of a milk and vegetable, or very slender diet, with the same view; of small bleedings, and the appli-

cation of leeches and blisters to the chest, on the idea of a chronic inflammation of the lungs. But with how little success these or any of the usual methods are employed, the Bills of Mortality, and the history of consumption, afford too melancholy an example. It must therefore be admitted on all hands, that a new treatment of pulmonary consumption is called for; and that any one who quits the beaten path in which failure has always marked his steps, does not enter upon a new one with the hope of better success, as a wanton adventurer merely pursuing novelty and change.

Some persons appear to call in question the propriety of employing any active agent to be administered by inhalation, asserting that the danger of producing injurious irritation to the air-passages and the lungs is more certain than the chance of removing the tubercular disease. The fact, however, is, that in no form of pulmonary complaints does inhalation relieve with so much promptitude and certainty as in chronic irritation of the bronchial mucous membrane; and with regard to the tubercular part of the disease, I am willing to rest the whole proof of my recommendation upon actual experience, of many years' standing, which has yielded me a larger share of success than I ever expected to obtain.

It unfortunately happens, that in a large proportion of consumptive cases there is too great an extent of organic disease to be reached by any treatment; in many instances also the disease has from neglect acquired so much inveteracy as to be incurable. It does, indeed, too commonly happen that no attention is paid to the first inroads of the disease, which makes progress with sure but insidious march; and when, at last, an anxious appeal is made for medical assistance, the lungs may have undergone such extensive disorganization as to allow of no other possible relief than some mitigation of the symptoms.

Failure of success on such occasions ought not to impair the credit of the mode of treatment which I am advocating; but I am too well aware that this serious disadvantage to the *good character* of inhalation is always more or less incurred when the case ends fatally, notwithstanding that only slight, if any, hopes of success might have been held out to the friends of the patient; for

with regard to the patient himself, we must sustain his mind by kind encouragement: the despondency of the invalid would greatly diminish our power of affording relief.

In conclusion, I have to express, as my most frequent cause of regret, the delay of the patient to make a timely application for the material benefits to be afforded by inhalation; for although there is a satisfaction in mitigating sufferings, the task is a melancholy one of watching the progress of a disease which has become incurable. I cannot help stating my belief, that a considerable cause of the supine indifference amongst invalids towards this new method of practice is to be ascribed to the medical profession itself: there appears to be a reluctance amongst medical men to inquire into any real merits of this plan of treatment, which is rather more troublesome in its details than the prescribing of the more usual forms of medicine.

For the better comprehension of my statements in the following cases, I take the liberty of referring the reader to the second edition of my work*, in which I have fully detailed my principles and method of treatment.

CASE I.—J. A., *æt.* 47, a superintendent of a gas district, tall, and well proportioned, of delicate constitution. His father, and mother, and uncle, had died from consumption. He consulted me in January 1834. He was very thin, and stated "that he had lost almost all his flesh and strength, and feared he was past help." He had been ill with cough and shortness of breath since the beginning of December, having caught cold from continued exposure to a N.E. wind. I found his pulse from 96 to 106, and feeble; the respiration was distressingly hurried by slight exertion; the animal heat was 101°. By auscultation, great obstruction to the breathing was manifested, and the sound on percussion was dull; these indications being most remarkable on the right side. The sputum was greenish in colour, viscid, and ragged, and, examined by the optical experiment, did not present the prismatic colours; the tongue was morbidly red; the appetite impaired; the bowels

prone to diarrhoea, and occasionally painful, as if from colic. He had sometimes two hectic paroxysms in the day, and always one; night perspiration was more or less abundant, and he never obtained comfortable sleep.

I directed the inhalation of a solution of iodine and hydriodate of potash, with the addition of a saturated tincture of conium (for the formula, see my second edition, and *Medical Gazette*, vol. viii. p. 157) three times a-day; the internal use of sarsaparilla and alkali twice in the day; and at night, the acetate of morphia, with diluted sulphuric acid, water, and syrup of tolu. The chest was washed night and morning with the lotion of purified pyroligneous acid, *eau de Cologne* and water, used just tepid, followed by the use of the flesh-brush. The diet was nourishing and supporting.

The means of treatment agreed; but as I was convinced that the lungs were obstructed by tubercles which would soften, I viewed this as a case which, in the most favourable event that could happen, would become much aggravated in its symptoms before any convalescence could take place; in other words, he would get worse before he could get better.

From taking cold again, he lost his smell and taste, and suffered much pain in the right side of the chest from a subacute attack of pleurisy, which was removed by blistering; and till this relief was obtained, the inhaling had been suspended. He described that he felt very sensible relief from the inhalations; and that not only was his chest comfortably relieved, but his appetite, he thought, was always improved after the process. The intestinal canal continued to be frequently irritable, and also painful. He received relief for this state of complaint from a mixture of infusion of catechu with mucilage, tincture of kino, compound chalk powder, and Ford's laudanum (a saturated tincture of opium with the addition of spices). He took occasionally at bed-time, when there was evidence of vitiated biliary secretion, small doses of the hydr. c. cret. joined with pulv. ipecac. comp.

A journal of this case would occupy too much space; I shall content myself, therefore, with a brief general statement. At the middle of March it was evident, both from the general signs and the local indications, that the expected softening process in the tubercles was ad-

* "Cases, illustrating and confirming the remedial power of the Inhalation of Iodine and Conium in Tubercular Phthisis, and various disordered states of the Lungs and Air-passages."

vanced. He was thinner and weaker, and his ankles were swollen towards night; the expectoration was increased in quantity, was more or less puriform, and often coloured with blood; the night sweats were usually profuse. In the right axilla I detected by the stethoscope a resonance approaching to pectoriloquism. The sound on the right side was dull to a great extent, and the breathing very imperfect. For the most part he maintained a tolerable appetite, but his appearance was altogether so unpromising, that I almost despaired of any success.

He persevered with unabated confidence in the inhaling. I changed the iodine for chlorine for a short time; but of his own accord he returned to the use of the iodine, judging from his own feelings that it was by far the most useful. When the bowels became settled I gave him the *mistura ferri composita*, and changed it at the end of a fortnight for the mixture of *sarsaparilla* with alkali, occasionally interposing a dose of quinine, according to circumstances. I directed some porter and a little sherry, with as substantial and nutritious food as his digestive powers would allow.

At the end of another fortnight, pectoriloquism in the right axilla was unequivocal; the expectoration was abundant; and the sputum examined by the optical means gave prismatic colours. The respiration was become less restrained; there was an abatement of the hectic fever in the day; and the night perspirations were much diminished.

From this period he improved, steadily pursuing all the means of treatment. I saw him at the end of November, when his appearance was so changed that I scarcely recognised him as the same individual when he first consulted me, so wonderfully was he recovered in flesh and strength, with his spirits quite regained. His pulse was 76 to 80; the animal heat 98°. At that time he returned to his regular employment, in which he has continued without interruption, and I have the satisfaction of learning that he remains in the enjoyment of comfortable health.

CASE II.—A gentleman, aged 26, of the middle height, muscular, of the mixed temperament, well formed in the chest, usually enjoying good health, with the exception of a liability to take cold and have a catarrhal cough in the

winter season, caught cold from exposure for some hours on horseback to a north-east wind, in March, 1834. Inflammatory symptoms, with pleuritic pain, occurred, for which general and local bleeding was used, with blistering, and an antiphlogistic treatment.

I saw him first in the beginning of June, and received the following account of his case from Dr. Skrimshire, of Peterborough, in Northamptonshire. "This patient is the subject of recent, but rapid, tubercular phthisis." Then, detailing the treatment which had been used, he adds, "I have not, however, at any time reduced the rapidity of pulse, or the urgency of the cough, for more than a day or two. The wasting has been progressive and rapid; and the expectoration, though never profuse, has for the last three weeks or a month been puriform."

I found the sound dull on percussion over a considerable extent of the left side; the respiration imperfect; and near the axilla the indication of pectoriloquism was sufficient to render it probable that a small cavity existed at the upper part of the lung. The signs on the right side were good. His breathing was more hurried on slight exertion; the cough was harassing; the morning expectoration was considerable, creamy, of disagreeable odour, and gave prismatic colours. He was suffering from slight pleurisy of the left side. He could not sleep without having the head and chest raised, nor lie well on either side. He had been more sensible of daily hectic fever and night perspirations a month before, than at the period of my visit. The pulse ranged from 112 to 120; the animal heat was 101°. He had greatly lost flesh and strength, and his pale and hollow cheeks proclaimed at once the severe character of his disease. It was encouraging that his appetite was for the most part good, and that the digestive functions were not much disturbed; but the urine deposited lateritious sediment very abundantly.

So soon as I had removed the pleuritic pain by local treatment, I directed the inhalation of iodine with conium, and treated him altogether on the principles which I have described in the statement of my other cases.

The patient improved from the first day, and derived the most sensible relief from the inhalation, which, according to his feelings, moderated the cough,

facilitated his expectorating, amended the character of the sputum, and very remarkably rendered his respiration more comfortable.

At the end of July his recovery was so advanced, that he had materially gained flesh and strength, and was almost free from cough, breathing comfortably. The pulse was regularly under 80, and the animal heat was reduced to 97°.

I have seen this gentleman lately, and have the satisfaction of adding that he finds himself quite well; his pulse 68. In the autumn he took a journey to Paris, and now he is engaged in active business.

CASE III.—A young gentleman, aged 22, tall, slight, with circular chest, of the nervous temperament, while labouring under great mental excitement, which was quickly followed by inflammation of the membranes of the brain, exposed himself in a state of delirium to the cold night air, when without clothes. Bronchitis in the acute form ensued. He lost blood by the arm and by leeches, and blisters were applied. It was observed that the severe symptoms affecting both the head and the chest alternated remarkably, so that at times one disease appeared to supersede the other. This happened, however, only during the height of the illness. When I first visited the patient, I found him extremely emaciated; he was pallid and exhausted, and his whole appearance that of a person in the last stage of a dangerous disease. He was scarcely equal to the least conversation; and if any exciting topic was touched upon, he became delirious. The eyes were blood-shot; he could not bear light or noise; said that his nights were almost sleepless, and when he did sleep his dreams were most distressing. Both the upper and lower extremities were affected at night, and sometimes in the day, with violent jactitations. He described that his brain often seemed to be "on fire," and that it was his greatest comfort to have his shaved head washed with the coldest water. He felt his chest bound as if with cords; the breathing was uneasy; cough was frequent, and often exhausting, from its severity and long continuance; the expectoration was in very large quantity, of highly puriform appearance, much coloured with blood,

and of offensive odour. The pulse ranged from 120 to 130, and under excitement it ran on to 140, or upwards; the animal heat was 102°. Hectic fever was urgent, as shewn by the deep rose-red of his cheek, the brilliancy of his eye, and general heat of surface, succeeding to fits of chilliness; and on most nights the perspiration was excessive. The urine was of a dark colour, and deposited lateritious sediment in the greatest abundance. On the right side, over the upper part, the sound was dull. The voice gave much resonance to the ear with the stethoscope, near the axilla. It seemed very probable that some ulceration had taken place. His powers were so much prostrated, and his nervous system so exquisitely sensitive, that I could not consider him equal to the task of inhaling. I directed a blister to the chest, and the following mixture:—

R Potassæ Bicarbon. gr. viij.; Succ Lemon. ʒij.; Mist. Amygd. ʒiv.; Syrupi Tolutani. ʒij.; Acidi Hydrocyan. ℥x.; Gutt. Nigr. gtt. xv.; Potassæ Nitrat. ʒij. M.

Of this two table-spoonfuls were taken every four hours. He derived great relief from this medicine; but his sleep being still deficient, I prescribed a small dose of the morphia syrup at night, and its effects were most satisfactory.

He gradually improved in the state of the nervous system, but as the brain acquired a more healthy condition, the pulmonary symptoms became more urgent. The cough sometimes continued for an hour without ceasing; and the expectoration, which was uniformly more or less coloured, was in quantity upwards of a pint in each twenty-four hours.

I was resolved not to delay longer the trial of inhalation, and began with a small proportion of the iodine solution joined with the saturated tincture of opium. At first he experienced great giddiness and sickness, and could only inhale for five minutes. He was in so weak and nervous a state (scarcely able to raise himself in bed) that he was timid, and alarmed at the idea of the new treatment. With better courage, however, he resumed it on the following day; and I was highly gratified to hear him, in a short time, express in glowing terms the delightful relief which he experienced from inhaling, which he

said not only relieved his cough and breathing, but, "calmed him all over." After the first day of inhaling, the jactitations of the limbs were abated; after the third day they ceased altogether. Many of the symptoms remained urgent for a week;—the quick pulse; the breathing easily hurried; the cough much excited by any continuance of conversation; hectic fevers at mid-day severe; perspiration at night excessive. But some appetite returned. The nerves were in a more tranquil state, and much sleep was procured every night. Some decoction of bark was added to the mixture. The bowels required regulation, and a pill with pilul. aloës c. myrrh. et pulv. Jacob. answered perfectly. In other cases I have mentioned the remarkable reduction in quantity, and alteration in quality, speedily produced in the sputum by the influence of the iodine inhalation; but I never witnessed this effect more strikingly produced than in the present instance: within three days the quantity was lessened by one half, and it was much less coloured. At the end of a week it did not amount to more than four ounces, and in another space of ten days it was reduced to an ounce, with here and there only slight streaks of blood.

From this period he steadily improved, gaining appetite, strength, and flesh. When in a state of perfect quietude the pulse did not exceed 80; the animal heat lessened to 98°. His spirits, which were naturally buoyant, revived, and he became confident of recovery. For many weeks, however, his condition appeared doubtful; for cough with coloured expectoration continued troublesome; night sweats were occasionally profuse, and after sitting up some hours, the ankles become much swollen. He continued to inhale with regularity and with unabated satisfaction. He used eau de Cologne, &c. for the chest, and the flesh brush, with sensible benefit. He took sulphate of quinine with sulphuric acid, &c. two or three times a day, and the morphine syrup at night. His diet was of the most restorative kinds.

I have now to conclude with stating that this patient has perfectly recovered his health, and is indeed considered by his friends to look stouter and more healthy than before his illness. He was visited once during my attendance by Dr. Watson; and frequently by Mr. Vickers, of Baker Street.

CASE IV.—A gentleman, aged 24, of circular chest, of the mixed temperament, after wearing in his cheeks a colour like hectic flush, of a very consumptive family, was attacked with troublesome cough about four years ago. The expectoration was occasionally coloured with blood, and he found for the first time that his breathing became distressingly hurried by slight exertion. He had lost flesh and strength within a short period, and was much alarmed, as were also his friends, with the dread of pulmonary consumption, from which a brother and sister had died. The indications afforded by auscultation rendered it almost certain that his lungs were tuberculated, although not *en masse*. He inhaled iodine and conium with the greatest advantage; but being of an active disposition, and disliking confinement within doors, he went to Madeira, where he passed the winter and spring two years in succession. The last winter he passed at Lisbon. During his residence at that place, he caught cold, which was followed by cough, attended with coloured expectoration (which he spoke of as spitting of blood) every day for a month. He sent to London for an inhaler, the mixture of iodine, tincture of conium, and the internal medicines which I had prescribed for him on a former occasion.

He did not receive the articles till the expiration of a month.

A medical friend in attendance upon him, used his strongest persuasions to dissuade him from inhaling, under the circumstance of a troublesome cough attended with coloured sputum, assuring him that in all probability a dangerous hæmorrhage from the lungs would follow. He however, fortified by his former experience, was resolved to adopt the treatment; and accordingly he inhaled the iodine with conium. He informs me that after the space of three days, the blood entirely disappeared from the expectoration; the cough was satisfactorily relieved; and in a short time he recovered his health.

CASE V.—A young woman of delicate frame, and rather narrow chest, in the year 1825 suffered from cough and difficulty of breathing, for which she was bled twice from the arm, and blistered repeatedly.

In 1827 blisters were used; and she took digitalis with some relief of the

shortness of her breath, but with injury to her stomach and nerves.

During the two following winters, blisters were applied.

In 1830 I was consulted, when she was suffering from very troublesome cough, short breathing, a sense of tightness and of soreness in the chest, without any fever. Her breathing was like that of an asthmatic person, and always became distressed under the least exposure to a foggy atmosphere. She was getting thin and weak, and she had also a consumptive look.

I directed the inhalation of iodine and conium, in conjunction with the washing and friction of the chest; and no other treatment was employed. Suffice it to say, that she recovered in the most favourable manner.

Captain Kater, in whose service the patient lived, informs me that since the period of my attendance she has but rarely been affected with her complaint; and has, on each occasion, obtained relief in a few days, from having recourse to the inhalation.

I could multiply examples equally in favour of the value of inhalation of iodine and conium with those which I have stated, but I fear to trespass further on your pages, and hope that I have offered proofs sufficient.

I will take the opportunity of mentioning that the patients, whose cases of confirmed tubercular phthisis with ulcerated cavities, are detailed in the additional part of my second edition, at p. 138, c. i.; p. 184, c. ix.; p. 194, c. xi.; all continue to enjoy their recovered health, bearing the most happy testimony* to the benefits derived by them from inhalation, and the collateral treatment.

It is my earnest recommendation to the profession to give a fair trial to the practice, and to use due *perseverance*, without which success must not be expected. I have not allowed myself to lose hope from the slow progress of amendment, or even from the contrary, from those occasional relapses which are incidental to the disease. I am certain that the plan of inhalation, &c. is often abandoned much too hastily, and for very insufficient reasons.

In conclusion I will again observe, that no one should allow himself to think

* The several patients who have recovered have expressed their desire that I should refer to them any consumptive invalids, or their friends, who might wish to be assured of the advantages of the inhaling treatment.

slightly of the method of treatment because in many cases it will not prevail over the inveteracy of the disease. No human means can succeed in the worst cases of pulmonary consumption; but it is my sincere conviction that the best chance is given to the patient by the combined means which I have endeavoured fully to describe in my little volume; and it is not immaterial to add, that the remedies, in my experience, have never failed to render the comfort of largely mitigating the symptoms, even when the amount of disease has been too great to admit of cure.

A FEW OBSERVATIONS

ON THE

PARALYSIS PRODUCED BY LEAD;

With Cases.

By H. M. HUGHES, M.D.

SINCE the publication of the admirable essays of Sir George Baker, in the first volumes of the Medical Transactions, little or no doubt has existed among the generality of the profession that colica pictonum, with its attendant or subsequent paralysis, usually, if not universally, arises from the operation of lead. But how this effect is produced—upon what part the mineral primarily acts—whether its influence is exerted upon the cerebro-spinal axis, upon the nerves of the parts implicated in the disease, or upon the capillary portion of the vascular system—still remains a matter of doubt, and affords, therefore, room both for discussion and investigation. It is not with the idea of deciding this question that I have entered upon the present observations, but rather with the desire of adding a mite to the collection of recorded facts, upon which that degree of certainty attainable in medicine must be ultimately founded; and by relating some witnessed by myself, and collecting a few of a similar character observed by others, to make some deductions by which, though not sufficiently distinct and certain, numerous or extensive, to account for all the phenomena of the diseases produced by lead, we may, I think, arrive at conclusions nearly approximating to the truth.

Of the comparatively few cases of colica pictonum examined after death,

there appears a large majority in which scarcely any morbid appearances have been discovered in the intestinal canal. By some authors the colon is represented as firmly contracted; by others it is said to have been of smaller calibre than usual, but easily distensible by air or water gently propelled into it; and by others it is stated to have been found either natural, or actually distended. Some morbid anatomists, again, have reported the ganglia of the sympathetic to be enlarged and red; while others look for, and fancy they find, marks of irritation in the spinal marrow or its membranes.

In the only case that I recollect myself to have seen, and which, though it may be thought by some to militate against some of my opinions, I am bound in justice to mention, there was a gangrenous condition of the mucous membrane of the colon, *apparently* connected with an extremely rigid contraction of the muscular coat; but whether as cause or effect may admit of doubt; and as nothing analogous is usually discovered, no argument can be fairly derived from it.

Such being the general and almost universal absence of marks of disease, pathologists have been led to consider this affection as one of the nerves, and thence of the muscular coat of the intestinal canal, and, in connexion with the symptoms during life—the protracted constipation, the small, round, hardened feces, and the remittent pains—have generally, at least of late years, thought that the disease consisted in a paralytic condition of some part of the intestinal tube, and that the spasmodic pains (if spasm be really the source of the pains, which may, I think, admit of doubt,) were merely the consequence of such local paralysis. With this view accord the varying situation of the pain, affecting at one time the scrobiculus cordis, at others the loins, back, abdominal muscles, &c.; the different conditions of the abdomen itself—sometimes, perhaps generally, being flat or depressed towards the spine, but at others natural, or even distended, and the state of the circulation, it being often, if not generally, not only unexcited, but even slower than in health. But perhaps the greatest confirmation of this opinion is derived from the observation of the local effects of lead upon the external parts of the body, which, as the real object of

this paper, after a few words on the general action of the mineral, I shall proceed more particularly to examine.

Lead, when administered in small quantities, has usually been regarded as a sedative and astringent. This view appears to derive support from, or rather was, perhaps, originally founded upon, its remarkable influence in allaying pain when externally applied, and its surprising effect in restraining hæmorrhage when administered internally, together with its peculiarity in producing palsy, and the state of the general circulation in persons suffering from its deleterious consequences. A recent writer considers that it cannot act as a sedative upon the nerves, because spasms are among its frequent injurious results, and appears to think it probable that it primarily influences the capillary system. In answer to this I think it only necessary to observe, that it frequently acts as a medicine upon the system at large, without the production of any thing *like* spasm; that, when the spasmodic pains do occur, they appear to arise from, or to be intimately connected with, its specific operation on particular parts; and that a local sedative is by no means inconsistent with spasm in other distant or contiguous portions of the body; that, indeed, if by its sedative influence it temporarily enervates, or destroys, the function of an organ, as it is supposed in colica pictorum, this effect is not only possible, but highly probable, as evinced by spasm and convulsions, from torpor of the bowels, in children, &c. &c. As to the part primarily affected by it, I may add, that, from the more recent experiments, particularly those of Dr. Addison and Mr. Morgan, it seems at least probable that all poisons, whatever may be their remote effect, act *through* the nerves to which they are applied; that, though the paralysis from lead is generally gradual in its approach, it not unfrequently comes on quite suddenly, which I conceive to be inconsistent with the supposed affection of the capillaries, but perfectly compatible with, and customary in, that of the nerves; and that the muscles of the persons and of the parts suffering from this palsy, are at least at the period of, or soon after, their attack, firm and large—much firmer and much larger than those of many individuals suffering from long-standing chronic disease, in whom all the motions of the limbs are perfect. On this account,

I believe that the wasting of the muscles in the limbs of persons who have long laboured under this species of palsy, is attributable simply, as in other cases, to want of use, and that it does not arise, as supposed by John Hunter, from the action of lead upon the muscular fibre. Indeed, it may be doubted whether lead is absorbed in general, as it appears, in some cases at least, to exert its influence upon parts of the body, under circumstances in which absorption is, to say the least, highly improbable. I am aware that it is stated by some one, I believe Gmelin, that the mineral has been detected in the fluids of the body, but under what circumstances, or by whom discovered, does not appear. On the other hand, numerous experiments have been *ineffectually* made by several authors and analysts to detect it in the blood, secretions, excretions, muscles, &c. The fact may be therefore considered as still in some degree doubtful. But is it quite certain that the pain in colica pictionum is of the character generally supposed? It is decidedly not usually of an inflammatory nature; but is it therefore, and because remittent, necessarily spasmodic? Tic douloureux and neuralgic affections generally prove the contrary. I have been led to doubt the correctness of the general opinion on this subject, for the following reasons:—

1st, The pain in this species of colic is sometimes not only confined to a particular part, as the umbilicus and the scrobiculus cordis, but is also of a continued character.

2d, When it in some degree remits (for it is, I believe, never truly intermittent, as in pure spasmodic colic), the paroxysms are of much longer duration than in those affections in which muscular contraction is the source of pain.

3d, The pains of the external parts, with which those of the abdomen alternate (though sometimes they *may* be), frequently are not of a spasmodic character.

4th, When purgative medicines begin to act in colica pictionum, the patient experiences griping pains, which, as stated by Dr. Warren, though I must confess the assertion has been only once verified by my own inquiry, are of quite a different character, and easily distinguishable by the sufferer, from those of the disease itself.

5th, When the hands, or other exter-

nal parts, are primarily affected, though severe pains are felt in the back, shoulders, and upper arms, they are not mentioned as of a spasmodic origin, but are usually described as “pains of the joints,” or rheumatism.

6th, The abdomen is in general either *uniformly* flat, and depressed towards the spine, in a natural state, or *uniformly* distended; and not, as in diseases of a truly spasmodic nature, at one part rigid and flat, or contracted, and at another uneven, nodulated, and inflated; we feel not at this part the firmly contracted muscle, and at that find it lax, or stretched with a flatulent knuckle of intestine.

I by no means think that spasm is never produced by the operation of lead; I do not even say that the pain of colica pictionum is not attributable to it, and to it alone; but I do consider that, for the reasons above stated, this supposed fact is open to considerable doubt. I will on this part of my subject only add, that by no medicine is peculiarity of constitution more clearly evinced than by this mineral. Thus, on the one hand, some men may, and do, work in lead for their whole life*, or for many years, without experiencing any injurious results; while, on the other, palsy of the face, as related by Dr. Cooke, and constipation and colicky pains, as recorded by Dr. Percival, have been produced by sleeping for a few nights in a recently painted room. I lately heard of a lady complaining of severe pains of the abdomen, with protracted constipation, for which her physician was unable to account, until, on a succeeding visit, it was mentioned that she had, for a few nights, slept in a room which had been fresh painted. From such and similar facts it may be doubted whether cleanliness and care, however they may *decrease* the frequency of its attacks, will ever be sufficient entirely to *prevent* the occurrence of colica pictionum.

I now proceed to the local effects of the mineral. That some substances act simply upon the nerves of the part to which they are applied, without any visible organic change, will, I conceive, be doubted by few, after a due consideration of the observations of Brodie, on the effects of monkshood when chewed;

* I have just seen a man who was a painter for forty years, without ever being affected with either colic or paralysis.

of Monroe and Philip, on those of opium when applied to the leg of a frog, or the intestine of a rabbit; of Dr. Addison and Mr. Morgan, on the ticinas, when similarly employed, &c. &c.

When my attention was first directed to the diseases produced by lead, I was induced from some circumstances to suppose, that local paralysis, whether of the bowel or of the limb, was always the *direct result* of the topical application of the poison to the nerves of the part with which it came in contact, and that the general, or constitutional symptoms, were merely the consequence of the decreased nervous energy of the affected portion of the body. Reflection and further observation, however, have caused me very considerably to modify this opinion; for seeing that colica pictorum has been the consequence of saturnine lotions, and other external applications, and that paralysis of the limbs occasionally results from drinking wines and cyder adulterated with the metal and its oxides, and that water holding in solution the same substances has sometimes produced similar effects, it is, I think, impossible to deny that lead, however administered, if in small and long-continued doses, has a decided and particular action on the muscular coat of the intestinal tube, as well as a marked tendency to produce a paralytic weakness in the voluntary muscles, to which those of the wrist and hand may perhaps be justly considered especially obnoxious. Notwithstanding this, I am still disposed to believe that paralysis, whether internal or external, is occasionally the effect of the local application of the poison upon the *nerves* of the part paralysed, and is really and truly a *local complaint*. Nor can I by any means assent to the opinion of a celebrated modern surgeon, that paralysis from this metal may be known by its existing *only in the upper extremities*; inasmuch as its influence, whether sedative or otherwise, is frequently experienced in other, and sometimes, indeed, in almost all parts of the muscular system; and I am inclined to think that the hands are affected so much more frequently than other parts, principally on account of their constant or frequent contact with the mineral.

I am aware that it may be urged, and very fairly urged, against this local influence, that the poison is applied to the fingers, hands, wrists, &c., and that the

paralysed moving power is situated in the arm. But we constantly see, and feel, that though an impression is made upon the nerves of one part, the effect produced is exhibited in another; a fact that has been observed by, and familiar to, physiologists for years, or perhaps ages, though lately a *new name* has been assigned it, and the “reflex function” has been attributed to the medulla oblongata. How this is effected, it would not be consistent with the object of this paper to pretend to determine; suffice it to say, that the usual explanation, or that of continuity by nervous communication through the brain or spinal marrow (to which the celebrated experimentalist, whose paper is referred to above, adds the particular function of the medulla oblongata), appears at least probable; but however it may be explained, the fact is certain. In common palsy we also find that some parts retain their muscular power, but lose their sensibility, while with others the converse of this is observed,—facts which admit, I think, in the present state of our knowledge, no completely satisfactory or certain explanation.

Seeing, then, that lead appears to act solely upon the motor nerves, that those of sensation are seldom or never affected by it, and that it cannot come in immediate contact with the former, which are distributed to the muscles, and are, from observation, supposed to run through their whole course in filaments distinct from the latter, is it not natural to suppose—is it not consistent with observed facts—is it not analogical with other physiological and pathological phenomena, that the impression received by the extremities of the nerves of sensation should produce its effect upon those of voluntary motion, with which they are in immediate connexion? Nay, from the particular action, the known peculiarity of lead in this respect, is it not especially reasonable to believe that the influence received by the nerves of the part or parts to be moved should be felt in those of the moving powers? Such, whatever the explanation may be, I believe from observation to be the truth. To the two points mentioned above, viz. the occurrence of palsy in other parts of the muscular system, when coming in contact (through the nerves of sensation) with those alone, I shall at present confine my attention. First as to the constitutional effect:

Andenacus, as quoted by Sir George Baker, says, "Quod Paulus suo tempore, in morbo colico, commemorat, nos quoque nostra ætate frequenter vidimus,—nempe ex magno, diuturnoque, colico cruciatus, artuum resolutionem *præsertim* brachiorum, quamquam et *crurum imbecillitas* adfuerit." Citois, speaking of the wretched appearance of the sufferers from the malady he described, says, "Per vicos, veluti larvæ, aut, arte progredientes, statuas, pallidi, squallidi, macilenti, conspiciuntur, manibus ineurvis et suo pondere pendulis, ac *pedibus non suis, sed crurum musculis*, ad ridiculum, ni miserandum, compositis." Teller, referring to the effects produced by drinking wine adulterated with litharge, has these words: "Aliis miserrime patientibus, aut enervatis, clunibus, redditis, pendulis artibus, et *resolutis incedentibus*." Van Swieten, referring to colica pictorum, writes thus: "In this disease, after most tormenting pains in the belly, in several repeated paroxysms, a palsy follows, sometimes of the upper extremities, *sometimes of the lower*." Dr Heberden says, "The legs have been paralytic for a night, and I have remarked some, though not many cases, in which *they too*, as well as the arms, have been affected with a *lasting palsy*." Dr. Cook relates the case of a painter, of very dirty habits, who was suffering from paralysis of the *sphincter of the bladder, and the lower* as well as the upper extremities. There is upon record (but where, I cannot at present find) the case of a gentleman who was troubled with general palsy of the voluntary muscles, from drinking West India Madeira, of which he was very fond, and in all the bottles containing which were found shots. I also recollect reading a case in some periodical, where *general palsy of a temporary nature* followed the administration of lead for the cure of hydrophobia.

In addition to these testimonies, I may mention, that most of my professional friends whom I have asked, assure me that they have seen paralysis from lead affecting the lower extremities, as well, though certainly not so frequently, as the upper extremities; and that I have myself seen three* of a partial nature, one of which is at present

under my care. That comparatively so few occur except in the hands, is, I think, fairly attributable to the widely extended acquaintance with the injurious effects of the mineral when taken internally for a considerable time, and to these parts alone coming in frequent contact with, and being therefore especially exposed to, its local sedative operation; to exemplify which I shall now proceed.

[To be concluded in our next.]

LACERATION OF INTERNAL PARTS,

WITHOUT EXTERNAL LESION.

To the Editor of the Medical Gazette.

SIR,

THE cases of laceration of the transverse portion of the colon, and of lacerated liver without lesion of the external parts, recorded in your Journal of last Saturday, by M. Rognetta, remind me of an extraordinary case of the sort which came under my care at St. Bartholomew's, when I was a dresser, some years ago, at that hospital. The following notes of the case I made at the time of its occurrence.

John Turner, about nine years of age, was brought to St. Bartholomew's on the 25th of August, 1825, a cart-wheel having passed over his body. From the time he was brought to the hospital (about 8 P.M.) till his death (between five and six hours afterwards) he breathed with extreme difficulty, seemingly by the diaphragm and abdominal muscles alone; he was restless, his pulse small and feeble, and his limbs, I thought, were colder than the ordinary temperature of one's body. Between twenty and thirty leeches were applied to his chest. About half-past ten, the neck and left side of the thorax became emphysematous; but on the right side there was scarcely any emphysema. I put on the rib bandage, which at first afforded relief, but the emphysema increasing, and the patient complaining that the bandage was painful, I removed it. About one o'clock the difficulty of breathing had become so great that every inspiration seemed likely to be the patient's last. An opening was now made into the left cavity of the thorax, in the situation where the emphysema was first observed, and where it existed to the

* Since writing this, a woman has been admitted into Guy's Hospital with hemiplegia from this cause.

greatest extent. Immediately on the pleura (costalis) being divided, there followed a sound as of air rushing through the wound, and in about five minutes the patient died.

On examining the body after death, the left side of the thorax, which was supposed to have received the greatest injury, was found to have received the least: the lung of this side was considerably collapsed; in one or two points it was bruised, and its pleura seemed lacerated. On the right side there was one fractured rib (the second or third, fractured near its head); the lung was more collapsed than that of the left side, and there penetrated deep into its substance an extensive wound (about four inches in length, and above one in depth); its surfaces were in contact and adhering, probably only by coagulum. There was shed but a small quantity of blood (about six ounces) from this extensive laceration, which must have been enormous before the lung collapsed, inasmuch as the lung, in shrinking, must have caused a proportionate diminution in the length and depth of the wound. The integuments of the thorax were entire.

With regard to the rushing of air through the wound when the left cavity of the thorax was opened, it is doubtful whether air rushed into or rushed out of that cavity. The lung of that side was bruised, and seemed lacerated; if its surface was lacerated, air might have escaped into the cavity of the pleura; if air had escaped into that cavity, and if, at the time of its being opened, the patient had been in the act of expiration, then air must necessarily have been expelled from it; but if, on the contrary, the patient had been in the act of inspiration, then air must necessarily have rushed in. One cannot conclude that the latter happened, because the patient lived but about five minutes after the operation, as he was previously on the point of dying.

The extensive laceration of the right lung could not have been caused by the fractured ends of the rib, for the laceration was about the middle and in the outer side of the lung, whilst the broken ends of the bone were near the apex and at the back of the lung. It is probable that the whole of the bones and cartilages of the thorax yielded so far as to allow one of the ribs (and most likely that which was fractured, which, having

only its cartilaginous attachment to the sternum, would yield the most) to be pressed with such force against the lung as to make, blunt as it is, the wound I have described.

I have the honour to be, sir,

Your obedient servant,

WM. BEAUMONT.

2, Manchester-Street,
Manchester Square, Feb. 14, 1835.

CASE OF RUPTURE OF THE VISCERA,

WITHOUT EXTERNAL APPEARANCES.

To the Editor of the Medical Gazette.

SIR,

THE following notes of a case of rupture of the viscera, without external appearances, may be interesting to some of your readers, in connexion with those recorded in your last number.

I am, sir,

Your obedient servant,

JOHN ELWIN,

Late House Surgeon, Middlesex Hospital.

48, Poland-Street, Feb. 9, 1835.

Rupture of the Liver, Spleen, Kidney.

Eliza Fox, æt. 7, brought to the Middlesex Hospital about 9 o'clock, P.M. Features collapsed, surface cold, insensible, stertor; pulse not to be felt; pupils act, though sluggishly. There are no bruises to be observed; two slight scratches upon the face. The friends state that the child was knocked down an hour ago, in the Hampstead Road, by a cab, the wheel of which ran over its body.

It lived twenty-four hours. Two hours after admission it recovered from the state of insensibility, and some sickness came on. The countenance was pallid, and expressive of great mischief *somewhere*. Hands and feet cold, but the body sometimes would get hot and perspiring. Great jactitation and measiness. The child swallowed fluids, answered questions, and complained of no pain.

Postmortem examination.—No bruise observed in any part of the body.

Brain.—No unnatural appearances, excepting some effusion of blood, incon-

siderable in quantity, underneath the dura mater, at the base of the skull.

Thorax healthy.

Abdomen.—On opening this cavity there was found a large quantity of blood effused; in fact the intestines were found lying bathed in blood. The spleen was completely divided into two halves, which were lying separated from each other.

The right lobe of the liver was traversed by a fissure, which appeared upon examination to have been closed by coagulable lymph. When the sides were torn asunder there was found a large cavity, as large as the fist, containing dark clotted blood, mixed with the substance of the liver broken down, as if crushed or bruised. The left kidney was traversed by a similar fissure, and also bruised.

The peritoneal coat of the small intestines in several places was divided, as with a knife.

CONGENITAL DEFICIENCY OF THE IRIS.

To the Editor of the Medical Gazette.

SIR,

HAVING read in your last number an account of the absence of the iris, in the person of M. M., I beg to offer for your disposal the facts of a similar *lusus nature*, which has fallen under my own observation, in the case of Sarah Hill, a child four years old.

I shall endeavour to arrange the particulars of this interesting case in such a manner that they may be contrasted with those of M. M., so far as the one case relates to the other; but as, from the child's tender age, it is unable to reply to interrogatories, I am unavoidably obliged to omit some points altogether, and to depend upon the testimony of the mother for others.

Sarah Hill has always been in good health, and is stated to be particularly lively and even-tempered. On the outer and lower side of each eye may be seen a trace of a grayish membrane. The degree of convexity of the corneas appears natural, and of the ordinary size. Both eyes are in a constant state of vacillation, which the child is quite un-

able to control, and which is greatly increased by any sudden excitement. The singular appearance of the eyes attracting the mother's notice, she took the child, as soon as she was able after her confinement, to an eminent oculist, who gave it as his opinion that the child would never see. After the lapse of a few weeks, she was induced to apply to another of our first practitioners in that branch of surgery, who also expressed a similar opinion, but desired the mother to notice whether or not the child's eyes followed a candle carried about the room, as, if they did, he should consider the sight would improve. She tried this experiment, and found that the infant certainly noticed the lighted candle; and further, that it did not distress it when brought close to its eyes. While nursing it she frequently observed that *the child would keep its eyes fixed on the sun for several minutes together, without shewing any uneasiness.* This statement was also confirmed by the father.

When the child began to play about, it would frequently pick up pins in the street, and never exhibited any imperfection in its sight. Unlike the case of M. M., this child cannot see in an obseured light. The eyes appear to be strong and healthy, and have never been known to water more than naturally. This latter circumstance would lead me to consider, either that in the case of M. M. there is a considerable increase of irritability in the retina, or that, in Sarah Hill, the natural degree of excitability is as much diminished.

The shape of the child's head is rather unusual. The hair grows very low on the forehead, the upper surface of the head being flat, and its antero-posterior admeasurement being rather great. The parietal eminence of the left side is somewhat larger than that of the right. One of S. Hill's brothers fell a victim to hydrocephalus, and there appears a predisposition to this affection in the other branches of the family. May not the mobility of the eyes depend upon some internal disease?—I am, sir,

Your obedient servant,

F. W. WILLISFORD.

Sloane-Street, Feb. 10, 1835.

SODA IN TOOTH-ACHE, AND SOME FORMS OF NEURALGIA.

To the Editor of the Medical Gazette.

SIR,

HAVING seen in a recent number of the Medical Gazette some brief observations on the use of soda as a remedy in tooth-ache, I beg permission to add my testimony to the correctness of this fact.

In many cases of severe tooth-ache, the attack seems to depend upon a deranged state of the stomach, accompanied with copious formation of acid; and if this state be allowed to go on, the pain will not be confined to a single tooth, but extend to the whole side of the face, darting along the course of the pes anserinus, and having all the characters of *tic douloureux*.

I need scarcely observe, that no organ exerts such a powerful influence upon the whole system as the stomach. By its derangement a variety of sympathetic affections, almost infinite, are produced; and to this cause there can be little doubt that the different forms of neuralgia, among other complaints, frequently have their origin.

It is now four years ago, when suffering under an intense attack of *tic douloureux*, in which opium had been used internally and locally without the smallest relief, that my friend, Mr. H. Worship (now of Yarmouth, in Norfolk), suggested I should take a little sodic carb. in water. The effect was almost immediate; carbonic acid was eructated, and the pain quickly abated. For nearly two years after I continued liable to slight attacks, whenever by incautious eating or drinking I deranged the stomach; but matters were invariably set right by the use of the alkali.

Since this I have treated several cases of a similar sort upon the same principle, and with success. In all these there were evidently symptoms of gastric derangement, and when this was removed, the neuralgia disappeared also. In one case, which was very severe, the soda did not appear sufficient to restore the stomach to its healthy condition; and here a mild course of alteratives and tonics, in addition to the alkali, gave complete relief.

I think that if the subject be further investigated, it will be found that in some cases merely filling the decayed

tooth with sodic carb. will not succeed: indeed, in many cases it would be impossible, for, where the attack has been severest, the pain has been so diffused over the side of the face, that the patient has been unable to decide which tooth it was that ached. The varieties of tooth-ache have been but little attended to; and I am sure their investigation would lead to useful as well as curious results.

In offering these observations, I beg to assure you that I do so without the smallest wish to invalidate the originality of Mr. Gaskoin's remarks, to whom I am a perfect stranger; I do it simply to confirm a useful practical fact, which is well worthy the attention of the profession.—I am, sir,

Your obedient servant,

EDWARD RIGBY, M.D.

44, Parliament-Street,
Feb. 17, 1835.

FRACTURED SKULL—RUPTURE OF THE SPINOUS ARTERY—TREPHINE;

AND SUCCESSFUL TERMINATION.

To the Editor of the Medical Gazette.

SIR,

If you think the following detached case of sufficient interest for insertion in your journal, you will oblige me by introducing it. Individual cases of surgery do not present the same sort of interest to readers generally, unless attended with peculiar circumstances, as is attached to a well-arranged series of analogous cases. But when they involve the consideration of any principle in surgery, and tend to establish the propriety of any method of treatment, I conceive that they cannot be wholly unacceptable to a medical public.

The cases of injury to the head, in which the operation of trephine is applied, are comparatively rare in the present day. Two causes, of a totally opposite character, may be assigned for this:—1st, the lesion, in many instances, is of a character not of sufficient intensity to demand the operation, or the cases are of so severe a description that the operation cannot be performed even with the slightest prospect of success;

and hence some surgeons have fallen into the error of laying aside the operation altogether, and of treating cases upon what are called *common principles*—a practice directly opposite to that of the older surgeons, who are known to have resorted to the operation upon the most trifling occasions.

The following is that precise description of case in which this important operation can be employed with the best possible prospect of success; and it illustrates two points of great practical importance: 1st, it proves the advantage gained by the speedy removal of the compressing agent; 2dly, it shews the necessity of an extensive removal of bone, to give exit to the effused fluid.

October 22d.—Robert Dixon, æt. 20, was brought into the London Hospital, at 2 A.M., having received, in a drunken quarrel, a blow upon the head from a hand-spike. He was stunned by the blow, and taken up in a state of insensibility, in which condition he was admitted. The following was his state:—He lay upon his right side insensible; his pulse about 70 in the minute; skin warm; the pupils of his eyes, upon the application of the light of a candle, contracted freely for a short time, and then returned to their former state of partial dilatation,—that of the left side was rather more dilated than the right; great ecchymosis about the left eye. The examination of the scalp shewed a wound, of two or three inches, below the left parietal eminence; and a fracture of the parietal bone was readily perceived taking a semicircular course from behind forwards, as far as the frontal bone, but its termination I did not see. As the symptoms indicated compression of the brain, and as one portion of bone was driven beneath the other, and as the fracture, from its position, must of necessity have traversed the groove for lodging the spinous artery, I thought it advisable to remove a portion of bone with the trephine; I therefore performed the operation, including the edge of the fracture just within the crown of the instrument. A quantity of dark coagulum was found upon the dura mater. The extravasation appearing extensive, I removed in a similar manner a second portion with the trephine, and with Hey's saw three angular pieces were detached. The removed portions clearly exhibited the track of the spinous artery. Con-

siderable hæmorrhage took place from amidst the coagulum; and as the patient's pulse indicated great debility, a small dossil of lint was laid upon the part whence the hæmorrhage proceeded. The wound was dressed, and the man was ordered calomel, ℥j. to be taken early in the morning. Immediately after the operation the pulse increased in frequency, but was weaker, and the irides became more sensible to light.

23d.—Has passed a quiet night; became more sensible soon after the operation, and this morning he answers when spoken to; but his power of articulation being very imperfect, he makes a sign upon his pillow in answer to a question as to his age: complains of pain on the left side of the head; has vomited two or three times this morning; pulse calm, but weak; bowels relieved in the night; as he was unable to pass his water, it was drawn off by the catheter; the hæmorrhage continued for some time during the night, but has ceased.

Cold Lotion to the head, and Calomel, gr. ii. every four hours.

24th, 7 A.M.—Has passed a good night; still complains of pain on the left side of the head; pulse calm, and soft; bowels not relieved since.

20 Leeches to be applied to the head; a Cathartic Clyster immediately.

Passes his water himself.

25th, 7 A.M.—Is better this morning, and has passed a good night; answers more freely and distinctly, but still has difficulty in pronouncing; skin moist; pulse 80, and soft; bowels opened twice; complains still of his head, but it is less painful.

Continue the Calomel; 20 Leeches to the head.

26th.—In every respect better. The head has been dressed daily since the operation, and presents nothing peculiar in its aspect.

Continue Medicine.

27th.—Still improved in every respect; his mouth rather sore: the calomel is therefore to be taken only night and morning.

28th.—Has been disturbed the whole night by another patient, and is therefore not so well; complains of pain at the top of his head, and the wound, which previously had presented a

healthy aspect, now looks flabby and dry; pulse still calm; skin hot; bowels opened four times this morning.

Ordered 12 Leches to his head, and to take the Calomel only at night.

Nov. 3d.—Has continued to improve since, but is as yet unable to articulate distinctly. Leaves off his medicine.

5th.—Has had slight pain in his head; bowels rather confined; wound looks healthy, and is granulating well, the granulations rising from the surface of the dura mater.

27th.—No alteration but that indicating gradual improvement has taken place up to this period; he has to-day, however, a slight attack of jaundice.

Ordered Infus. Gentian, c. Magnes. Sulph. ter in die.

The jaundice soon subsided under this method of treatment, and the man has continued gradually to mend; the surface of the wound granulating, and the process of cicatrization proceeding in the most satisfactory manner. Two portions of bone have exfoliated, and have been removed; and the wound is now nearly healed. His articulation is natural.

I have omitted the mention of the diet of the patient, which at first consisted of the highest possible description of food, for which, after a certain period, a more nutritious one was substituted, and he now takes the ordinary diet of the hospital.

There is one point of some importance in this case to which I wish to allude;—it is this, the continued hæmorrhage from the spinous artery after the removal of the bone. I am by no means certain that the method pursued in this case, and which is generally recommended, is that which ought to be implicitly followed. Indeed, the surgeon will frequently find himself foiled in his attempt to arrest the hæmorrhage by the application of a dossil of lint; and I am well convinced that in a variety of cases this may be considered as rather a fortunate occurrence.

I have formed this opinion from the only two successful cases of the operation which I have witnessed;—I allude now to a case which occurred to the late Mr. Headington, and the one now under consideration; in both of which the bleeding continued after the operation, and

in the former instance almost to the complete exhaustion of the patient.

I am, sir,
Your obedient servant,
JOHN ADAMS.

MORALE OF MIXED PATIENTS IN HOSPITALS.

To the Editor of the Medical Gazette.

SIR,
I AM happy to find that M. Ferrus, in his "Rapport" upon the hospital system in this country, has laid so much stress upon the indiscriminate mixture of patients in our hospitals.

"Patients of different ages being found in the same wards,—this he conceives to be injurious to the *morale* of the inmates*." It seems somewhat strange that we, who pride ourselves upon our morality, should be set right on such a point by a foreigner. Now, sir, having heard the opinions of patients themselves upon this matter, there remains no doubt upon my mind, and there can be none in the minds of those who have thought upon the matter, that the system is decidedly wrong.

Young boys, just ripe for all kinds of mischief, but as yet unlearned in the more glaring vices of manhood, are admitted into a ward with adults in whom vices of the worst description are habitual. The poor children return to their parents, but, alas! the morality and the piety which was early instilled have given way to obscenity, to swearing, and other crimes equally detrimental; and so another member is sent forth to the community polluted and depraved, who, but for the example in the hospital, might have continued upright.

From such a system how can we expect morality; and how can we expect that sickness should be productive of those benefits which a wise Providence intended?

I hope earnestly that the subject will shortly be taken up by the governors of our hospitals, to whom there is entrusted a great responsibility.

I am, sir,
Your obedient servant,
PRO BONO PUBLICO.

ON INFANT MORTALITY IN
MANCHESTER,

AND SOME OTHER PARTS OF LANCASHIRE.

To the Editor of the Medical Gazette.

SIR,

I HAD read with very great interest Mr. Rickman's letters on infantile mortality, also your own valuable articles on the same topic, without the slightest thought of mingling in the discussion, until I noticed a remark in Mr. Rickman's last letter, in the No. of the Medical Gazette for February 7th, which induced me to think that I had it in my power to supply a few facts concerning the infantile mortality in Manchester, new perhaps to Mr. Rickman, who does not appear to be in possession of data in reference to this point. In the passage I allude to, that gentleman, after stating the mortality of infants at Leeds, Nottingham, Liverpool, and at several other large towns, proceeds thus:—"It is supposed that Manchester would exhibit a large proportion of infant mortality, but this cannot be ascertained, because more than half the number of burials take place where the ages of the dead are not recorded, and all the other burials would produce a fallacious result, because they consist of the more opulent classes of the community." Here I cannot help remarking that Mr. Rickman must be under a mistake when

he supposes that half the burials in Manchester take place where the ages of the dead are not recorded. All the registers belonging to the burial grounds of this establishment since 1812, contain the ages of the dead, according to Rose's act; and the ages are noted in the register of the cemetery for all denominations in Rusholme Road, now the most extensive burial ground in this quarter. If there be places here whose registers do not contain the ages of the buried, they are unknown to me, and I have for years paid some attention to this matter.

The following statement of the infant mortality of Manchester, at different ages under the tenth year, is free from the objection Mr. Rickman supposes would necessarily attach to such a statement—viz. that of representing the mortality in the opulent classes only. In 1826, I examined the list of interments at the Collegiate Church for eight years, from 1816 to 1823 inclusive; and also the lists of Rusholme Road cemetery for four years—from April 1821 to the same month in 1825. In the registers of neither place are the still-born entered. My researches were confined to these two burial grounds, believing that the results might be taken as a tolerably fair exhibition of the rate of mortality for the town at large; the poorest class burying at the collegiate church, and a class, all somewhat above the very lowest, at the general cemetery.

	Total Deaths in the Regis- ters, at all Ages.	Under 2 Years of Age.	Between 2 & 5.	Between 5 & 10.	Total under 10.
Collegiate Church ..	8656	40.40	14.78	4.17	59.65
Rusholme Cemetery	3559	40.06	12.43	3.82	56.31

It would appear that the infant mortality is greatest at the collegiate church. But this may depend, in some measure, on the table for the former place being made from an average of more years than that for the latter. In the first period—viz. under 2 years—there is little difference between the two in the amount; but in the second period, from the second to the fifth year, when the constitution is most strongly predisposed to the epidemic and contagious diseases of infancy, the difference is much greater—nearly $2\frac{1}{2}$ per cent.; and shews that in these circumstances

the children of the poorest class, as might be anticipated, are exposed to the greater risk of death.

Certainly these data corroborate Mr. Rickman's supposition, that "Manchester will exhibit a large proportion of infant mortality," since it appears, from the above facts, that more than 40 per cent. of the deaths at all ages occurs in the first two years of life; a percentage larger than in any other town, even than in Glasgow, and which is chiefly attributed to the high (in this respect unparalleled) proportion that the poor bear to the wealthy classes in the composition

of our population; as also to the enormous immigration of the Irish. But as this is a topic I have elsewhere enlarged on, I forbear extending my remarks*.

Eccles, near Manchester. This is a parish of considerable extent, in which there are many populous villages. In

the year 1821 it contained 4233 families, of which 3629 were employed in trade, manufactures, or handicraft. The following table gives the results, in reference to infantile mortality, for seven years—from 1818 to 1825 inclusive, excepting for 1823, which was accidentally omitted:—

Total Deaths in the Registers, at all Ages.	Under 2.	Between 2 & 5.	Between 5 & 10.	Total under 10.
3378	35.46	10.92	2.96	49.34

Lymm, a country parish, about 15 miles from Manchester, situated on the Duke of Bridgewater's canal, and containing a rather populous village. Most of the inhabitants, however, are em-

ployed in husbandry, and their amount, in 1821, was 2090. The following table is for nine years—from 1817 to 1825 inclusive.

Total Deaths in the Registers, at all Ages.	Under 2.	Between 2 & 5.	Between 5 & 10.	Total under 10.
333	31.52	4.80	3.90	40.22

Grappenhall, three miles south of Warrington. The number of families it contains I did not ascertain. The burials at the parish church are chiefly out

of the agricultural portion. From the parish register for eleven years (from 1815 to 1825 inclusive) I formed the following table:—

Total Deaths in the Registers, at all Ages.	Under 2.	Between 2 & 5.	Between 5 & 10.	Total under 10.
397	25.43	7.30	2.26	34.99

Winwick, situated three miles north of Warrington. Of the 3027 families which this parish contains, 2458 are employed in trade, manufactures, or handicraft. The annexed table is found-

ed on extracts, for nine years, from the register kept at Winwick church. It is, however, to be observed, that only a small portion of the inhabitants, and that the most *rural*, bury at the parish church.

Total Deaths in the Registers, at all Ages.	Under 2.	Between 2 & 5.	Between 5 & 10.	Total under 10.
1486	23.94	6.12	4.66	34.72

There are many considerations to be borne in mind, in estimating with due accuracy, from mortuary registers, the amount of infant mortality in any given

population. These I shall not enter upon, but merely call the reader's attention to the following obvious and simple conclusions:—

1st. From the above calculations it will be seen, that while, in a vast and populous town like Manchester (com-

* Observations on the Mortality, &c. of Children, 1827; and Observations on the Health of English Manufacturers. Ridgway.

posed chiefly of operatives), of every 100 deaths, above 40 occur at ages under the twenty-fourth month of life; in a village population, chiefly operative, as that of Eccles, the mortality of the same period falls to about 35 per cent.; in a still more rural condition of life, as at Lymm and Grappenhall, it farther falls to nearly 28; and in Winwick, in that portion which is strictly rural, the percentage of deaths under the twenty-fourth month is reduced to rather less than 24 per cent.

2dly. In the second period (*i. e.* from the beginning of the third to the end of the fifth year), the infant mortality becomes more nearly equalized in the different places. In Manchester it is about $13\frac{1}{2}$ per cent.; in Eccles, nearly 11 per cent.; in Lymm and Grappenhall, taken together, about 6 per cent.; and in Winwick also 6 per cent.

3dly. In the next period (*i. e.* from the fifth to the tenth year of life), the equalization of the mortality becomes remarkable. We now find the percentage of deaths, in this period, actually greater in the rural district of Winwick than in Manchester;—a circumstance easily accounted for, when we reflect, that, in such a town as Manchester, all the more feeble and sickly children are carried off in the first few years of existence, and only the more vigorous (speaking generally) attain their seventh or eighth year. Hence, as I have elsewhere remarked*, children in this great manufacturing community, who live to an age when they can be legally admitted into cotton factories, *possess, for the most part, sound constitutions.* So much for Villermé's opinion regarding the dreadful mortality produced by English manufactures! The evils, physical and moral, attendant on occupations of this nature, are many and formidable; but a *high rate* of mortality in that portion of the population which attain their eighth or tenth year, is not one of those evils.—I am, sir,

Yours respectfully,

JOHN ROBERTON.

Manchester, Feb. 12, 1835.

FECUNDITY OF MARRIAGES.

To the Editor of the Medical Gazette.

SIR,

AFTER insertion of my letter in your journal of the 31st January, I perceived in your next, of the 7th February, a statement by Mr. Rickman, from which it is concluded to be the general average of births to each marriage in England and Wales; and I conceive it indispensable for me to shew that so elevated an average is inadmissible.

Taking for granted that the elements of computation adduced by your correspondent are correct, it is in the first place observable, that not less than *five* hypothetical admissions, the accuracy of each very questionable, have been called in aid towards the conclusions at which he arrives; and this alone ought to caution every one interested in the question against hastily conceding an assent. The fact really is, that there exists not in this country any collection whatsoever of data capable of settling that question, with a tolerable degree of approximation to the truth. Such being the case, however lamentable, there remains no alternative from seeking authentic, complete, and conclusive data, wherever else they may be found. Now we actually do find, in the public records of France, every thing desirable in that respect; and no reflecting and unprejudiced person will stop at the supposition, that, between two neighbouring countries, where all the circumstances bearing upon the question so nearly assimilate, the operations of nature are likely to be sensibly different.

The 23d chapter of my publication "On the Laws of Population and Mortality" has established, I believe upon incontrovertible grounds, that the general average of births to each marriage, in France, does not exceed *three and two-thirds*; and taking into consideration that, in 18 out of 1000 marriages, the female is aged 53 years or more, the inference is, that 3.75 births may be assignable, as a *maximum*, to each marriage within that age, taken as the limit of child-bearing capability. Resting upon this fully ascertained result of investigation, unaided by any hypotheses whatsoever; and having further taken the trouble to note, with the

* Dr. Bisset Hawkins's Appendix to the Report of Factory Commission, p. 234.

greatest care, the individual age of each female party to 121,525 marriages, embracing the whole of those at Paris during the 18 years 1813-1830, I obtained the series which you transcribed in your journal of the 31st January, of the comparative quantities of marriages occurring at each year of age. From these, again, as also by an elaborate method set forth in the 24th chapter of my book, has been concluded, without possibility of erring in any palpable degree, the second series, also there transcribed, of the quantities of births assignable on an average to each marriage, at every year respectively of the wife's age; which last statement, be it always understood, is especially referable to the above admission of 3.75 births to each marriage indiscriminately, but within the limit of 53 years. If, then, the general average of 4.16 found by Mr. Rickman were admissible, it would be necessary, in order to render comparable those diverging quantities, to add to the latter the proportion of about 2 per cent., because of the marriages at ages exceeding the limit of child-bearing, and then we should have 4.25 births to compare with 3.75 only; the discrepancy to be accounted for being as 15 to 17, say no less than 11½ per cent.

It will further be observed, on investigating my last-mentioned series, that the general average 3.75 corresponds with the specific average of births ascribable to marriages at 27 years of the female's age precisely; whilst the average 4.25 would correspond with the specific average of births to marriages at 23 completed years only, or rather 23½, to speak with comparative precision; whence, if by any possibility Mr. Rickman's conclusions were justified, it could be only from assuming that the marriages in England were generally contracted by females *three and a half* years earlier than they are in France.

Limiting myself to the foregoing remarks, I leave the point of discussion for the present as it stands. The grounds of my conclusions are open for investigation; and if I may have lapsed into any error, no man is more competent to detect it than Mr. Rickman himself; nor do I know of one from whom I should should sooner expect the candid acknowledgment of any mistake in his previous statements.

Let me be permitted, in conclusion, to

suggest the probable origin of such mistake:—

Mr. Rickman takes his ground from successive quantities of marriages, and from successive quantities of corresponding births, each of them *averaging so many ANNUALLY*; but if it be taken into consideration that the constantly increasing progressions from year to year, both as to the marriages and to the births during each of those years, do not follow in the same ratio, and that such increase has been more rapid as to the marriages than as to the births, it will immediately be seen, that to conclude any general *annual* average at the expiration of a certain period of years must lead to false results; inasmuch as the anterior marriages will—so long as the population continues in that progressive state which induces a greater number of, and earlier marriages, consequent on a redundancy of *youthful* population in the distribution of the whole—contribute each year decreasing proportions of its manifested births; and therefore no *annual average* at any time admitted, of the marriages and births respectively, can be viewed as strictly comparable quantities.

I believe it, however, very true, generally speaking, that marriages in England are rather more productive than those in France; and I incline to ascribe any difference in that respect, though only very small, to the single cause of earlier marriages in the former; yet I cannot be reconciled to admit that the difference of age actually extends to *three years and a half*.—I am, sir,

Your obedient servant,

FRANCIS CORBAUX.

Lambeth, Feb. 13, 1835.

ANALYSES AND NOTICES OF BOOKS.

"L'auteur se tue à allonger ce que le lecteur se tue à al réger."—D'ALEMBERT.

An Inquiry into the Nature and Causes of Lateral Deformity of the Spine; in reference, more especially, to the pernicious effects of certain moral and physical influences, resulting from the modern system of Female Education: with practical Hints for the Prevention and Cure of this Affection. By EDWARD W. DUFFIN, M.D. &c. &c. Second Edition.

WHEN the first edition of this work was published, we made some objections to

certain views which it contained, and which appeared to us to be erroneous. We perceive that the parts to which we alluded have been modified, and the whole improved by the addition of new matter and numerous judicious suggestions. There is probably no circumstance connected with health which can with so much advantage be brought under the notice of unprofessional persons as the due regulation of physical education; and Mr. Duffin's "Inquiry" contains some very useful practical hints on this subject, particularly on postures and exercise, the effects of which are farther illustrated by some well-executed drawings on stone. We can recommend the volume, as giving a clear and satisfactory outline of the nature and causes of lateral curvatures of the spine, as well as of the best modes of treatment. The evil arises chiefly from the artificial constraints imposed upon girls by the present system of boarding-school education; and its prevention must mainly depend upon opening the eyes of the public to this truth. To impress this fact the more strongly on our readers, we subjoin a *carte* of the manner in which the day is spent at a young ladies' seminary, copied from an article by Dr. Forbes, inserted in the *Cyclopædia of Practical Medicine*:—

"At 6 in the morning the girls are called, and rise.

From 6 to 8, learning or saying lessons in school.

" 8 to 8½, at breakfast.

" 8½ to 9, preparing lessons *out of school* (some of the girls permitted to do so in the garden.)

" 9 to 1, at various tasks, in school.

" 1 to 1½, out of school, but must not go out of doors; reading or working, and preparing for dinner.

" 1½ to 2, at dinner.

" 2 to 5, in school, at various tasks.

" 5 to 5½, at tea.

" 5½ to 6, preparing to go out; dressing or reading, or *playing in school*.

" 6 to 7, walking, generally arm in arm, many with books in their hands.

"Two days in the week they do not walk in the evening at all, being kept in for *dancing*; but by way of amends, they go out on two other days, from 12 to 1, and then they miss *writing*. It is to be remarked, that *they never go out unless the weather is quite fine at the*

particular hours allotted for walking. They go to church all the year round, twice every Sunday, on which day no other exercise is taken."

A List of Two Thousand Microscopic Objects; with remarks on the Circulation in Animals and Plants; the Method of Viewing Crystals by Polarized Light; &c. &c. &c. Forming a Guide for Selecting and Labelling Subjects of Natural History, Botany, and Mineralogy, for the Microscope.

By ANDREW PRITCHARD, Author of the "Natural History of Animalcules," &c. &c. &c.

MR. PRITCHARD has increased much the obligations that microscopists are under to him, by the publication of this little work. Besides the list, which is copious as well as curious, it contains a variety of valuable hints, which must be appreciated by all who are fond of microscopic investigation. The remarks on viewing objects by polarized light are both new and interesting. The price of the whole is only a shilling!

MEDICAL GAZETTE.

Saturday, February 21, 1835.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE LATE BARON DUPUYTREN.

THE death of this great man is an event which France will not be permitted to mourn alone: the sympathy of all Europe attends her. The fame of her Dupuytren—the precepts and the example of her "first of surgeons"—have spread far and wide; and professional men in every quarter of the globe will deplore the loss of one to whom they have long looked up with feelings of pride and admiration.

GUILLAUME DUPUYTREN was born at Pierre Buffière, a small central town of France, on the 5th of October, 1778*. Of his family and early life we believe there is not much to be said: both were

* According to M. Orfila, 3d Oct. 1777.

probably humble: his education, however, was not neglected. He pursued his first studies at the provincial college of La Marche; but whether he discovered, at this early period, any partiality for medical science, we have not been able to learn. It is difficult to suppose that a genius so decidedly medical as his should have been merely acquired. If it be true that the poet and the painter must be *born* to their art, we can hardly be persuaded that such an artist as Dupuytren could be simply *made*. It is said, however, that he owed altogether to chance the opportunity of being connected with that profession of which he afterwards became so distinguished an ornament. The story goes, that as he was one day amusing himself in the streets of his native town—probably he was not more than 12 or 13 years of age at the time—an officer in a marching regiment took a fancy to him, and afforded him the means of visiting the metropolis. It is certain, that so early as his 17th year (in 1795), he was appointed demonstrator (*prosecteur*) in the Ecole de Santé of Paris. He won the office by concours.

His next public trial of skill was, after he had obtained the Doctorate in Surgery, in a contest with Dumeril for the place of *Chef des Travaux Anatomiques*: he lost the appointment by one vote. But in the following year he was more successful, his competitor having been named Professor of Anatomy to the school.

It was now that Dupuytren began to apply himself assiduously to the study of pathological anatomy; and he had the advantage of having Bayle for an assistant. Bichat was at this time running his brilliant career, and Dupuytren enjoyed the friendship of that illustrious person.

In 1802 he was chosen by concours to the second surgeoncy in the Hôtel Dieu; thirteen years after he attained the post of surgeon in chief.

But perhaps the proudest triumph which his great abilities procured for him was in the year 1812, when, after one of the most splendid displays which the concours ever presented, he was appointed Professor to the Faculty, as the successor of Sabatier.

Such briefly are the leading facts relative to the rise and progress of M. Dupuytren: little more of his personal history remains to be told. His attention to the duties of his high and arduous office at the Hôtel Dieu was most exemplary: a large portion of the early part of each day was spent there; and under his guidance and auspices the surgical clinic of that hospital became the first in France—perhaps equal to any in the world.

His private practice was very great; but we believe it was not through that alone that he was enabled to amass his prodigious fortune. He is said to have left property to the amount of about seven millions of francs (280,000*l.*) to his daughter, Mde. de Beaumont; besides 200,000 fr. (80,000*l.*) to found a new professorship in the school.

Our readers are acquainted with the history of the last year of M. Dupuytren's life: we have only to close it by stating that he died, in much suffering, but with great resignation, on the morning of the 8th instant, in the 56th year of his age.

The obsequies were performed on the 10th, in great state. A grand funeral service was celebrated over the body in the church of St. Eustache; after which the *cortège* proceeded to Père la Chaise, the students drawing the hearse all the way. The professors and members of the school, the deputations of the Academies of Medicine and the Sciences, and a guard of honour composed of troops of the line, followed the remains in a lengthened and numerous procession. MM. Rothschild and Lemercier, besides several general officers and peers of France, were also in attendance.

Over the coffin were spread the professor's robe and the insignia of the Legion of Honour.

Orations were pronounced at the grave by MM. Orfila and Bouillaud, in the name of the school; by M. Pariset, on behalf of the Academy of Medicine; by M. Larrey, for the Academy of Sciences; and by MM. Royer-Collard and Tessier, for the students of the Hôtel Dieu. From M. Bouillaud's tribute, which seems to have been most admired, we extract a few passages relating to the last illness of the deceased.

"After much lingering and cruel illness, M. Dupuytren saw that his case was without hope. The resignation which he then displayed has been rarely witnessed: his courage was worthy of a stoic. To the last moment he possessed all his usual presence of mind—his clearness and sound judgment. Not a word of murmuring or weakness escaped his lips. For eight days he thus endured agony, and all that time it was only miraculous that he could continue to exist. It seemed as if death hesitated to strike so noble a victim, or to destroy an organization that nature had so splendidly framed!

"The last thoughts of M. Dupuytren were engaged about the Faculty—that Faculty which was so dear to him, and of which he was one of the greatest glories; to which also he has left so brilliant a proof of his attachment by the legacy he has bequeathed.

"Thus, gentlemen, we find that the intellectual powers of this illustrious man survived his physical nature; and that though thrice scathed by the bolt of apoplexy, his firm and great brain has been the *ultimum moriens*—the last of him to die!"

In person, M. Dupuytren was somewhat above the middle size, stout, and well-formed; his features were regular, and he had a placid, dignified look. His manner was very imposing: there was altogether a majestic air of superiority about him, which bade defiance to rivalry; and certainly, if the profession in France was a monarchy, his was the hand to wield the sceptre. Rivals he had none—at least in France; and

even the most eminent of his *confrères* did not approach him without respect. "Which of you," said M. Bouillaud, in the fervent oration just quoted, "which of you, gentlemen, on seeing M. Dupuytren for the first time, did not feel an internal thrill on coming before the majesty of his person—a kind of secret dread, such as the poets describe as affecting those who stood in the presence of the gods? It was because there was something divine in the glorious professor whom we have lost!"

We can make allowance for the enthusiasm with which this was uttered; but the fact, we believe, is not exaggerated. The pupils ever looked up to him with awe and veneration; and all parties agreed in allowing his transcendent merits. He was, in short, to use the language of some of his admirers, the "Napoleon of French surgery:"—fully as ambitious, too, it might be added, as his prototype, and unwilling to brook a rival near the throne.

There was, however, one little failing which he possessed, in common with the gods and heroes with whom he has been compared: he would sometimes condescend to forget his attributes of meekness, and kindle into fiery rage. We have heard of instances when, on no great provocation, the temper of M. Dupuytren has been ruffled even to ferocity; nor has he abstained, it is said, from acts of absurd violence on these occasions. This was, perhaps, the greatest blemish in his character.

In his private practice, M. Dupuytren was eminently successful. His patients were numerous, and he always took care that they paid him regularly his fee; at least, when they visited him at his own house, he generally contrived that they should not go away in his debt. His mode of managing this delicate matter was ingenious. It is the habit of some people who are clever, but unluckily have short memories, only to recollect the fee on their first visit to their physician;

taking leave on the second without any allusion to the vulgar subject of money. This puzzled M. Dupuytren a little at first, but he soon succeeded in finding a remedy. He had a faithful servant (whom, by the way, he has liberally remembered in his will) who guarded the pass below, and who received a well-known signal when the fee was not paid. On bowing his patient out, M. Dupuytren rung one of two bells; if the fee was paid, the coast was clear; if not, the "no pay" bell was rung, and the visitor, on reaching the hall, was accosted with "*mille pardons!*" and a hint that he had *forgotten* to pay M. le Baron his fee: of course the politeness of the appeal was irresistible. Such is the anecdote that has been related to us, on authority which we believe to be good.

There was another particular which conduced to render M. Dupuytren richer than he probably would have been had he resided in this country. He lived in quite a different way from what persons of his professional rank do here. Whether he was in the habit of giving *entertainments* we know not; but certain it is, that he kept up nothing like an establishment; his residence in the Place St. Germain l'Auxerrois was merely *part* of a house—an *appartement*—a floor, or what our northern friends call a *flat*. The fact of there having been a ball (!) given on the floor above him a night or two before he died—and which it is said, greatly disturbed his dying moments—speaks volumes as to the difference of the style of living between French and English first-rate practitioners.

But with all this, it is doubtful whether the practice of M. Dupuytren, extensive as it was, and thriftily managed, could have enabled him to amass the great wealth he died possessed of. The popular rumour ran that he was fond of play, and that fortune always smiled upon him; but we believe the more trustworthy account of the matter is,

that he had a friend in M. Rothschild, who was more to be depended on than the fickle goddess. The banker looked after his affairs, and turned his money for him with success.

It only remains to treat briefly of M. Dupuytren as a teacher, as an operative surgeon, and as an author; in either of which capacities it were superfluous to describe his great excellence at any length. As a clinical instructor he was unrivalled. His art of detecting and distinguishing disease was admirable: on reaching the patient's bed-side, he seemed to take in at a glance all the circumstances, even the most minute, connected with the case; his questions shewed this; the lecture delivered afterwards proved it. And how splendid was that lecture in both matter and manner! His elocution was at once chaste, calm, fluent, and full of impressiveness. The method and connectedness of his discourse never failed to rivet the attention of his auditory; and we would have defied even the most critical to come away from hearing one of those *leçons*—those finished improvisations of his—without being filled with delight, mingled with astonishment*.

As an operator, M. Dupuytren was unequalled for self-possession, and the felicity of his expedients. In mere manual dexterity he may have been surpassed by M. Roux, and one or two others of his junior brethren; but there is much in an operation besides its mere mechanical part; and for all the rest—the imperturbable *sang-froid*—the general mental resources—the *morale* of the operation—who was to be compared with Dupuytren? The fastidious have sometimes whispered that there was a desire of display in his method of operating; but this, we hold, was

* The last two courses of Clinical Lectures ever delivered by M. Dupuytren, and which were corrected by the Baron himself, are contained in the three volumes of the GAZETTE immediately preceding the present.—E.G.

founded on the confidence of the master.

His published works are not voluminous, consisting only of a few well-known monographs, memoirs, and articles contributed to some of the *Dictionnaires*; his best claims to the gratitude of posterity are to be found in the practical benefits which he conferred on surgical science. These are numerous and highly valuable, shewing that he was at least quite as ingenious in devising new methods in emergencies, as he was dexterous in putting them in execution. In a word, the French have lost in Dupuytren, a surgeon, who, for sagacity in diagnosis, skill and ability in practice, and unrivalled accomplishments as a teacher, could vie with any other in the world. His name will be handed down in the annals of his country along with those of Paré, Petit, and Desault.

DEATH OF M. FODERÉ.

THE distinguished author of the *Traité de Médecine Légale*, and other works on Physiology and Hygiène, died lately at Strasburgh, where he held a professorship. He was in his seventy-second year.

CONCOURS AT MONTPELLIER

For the Chair of Médecine Légale.

AN interesting account is given, in the *Journal Hebdomadaire*, of the opening of this Concours. M. Lallemand presides, and the jury consists wholly of professors and members of the Faculté; none of the practitioners of the town having accepted the proffered honour of a seat on the bench. The candidates are eleven in number—namely, MM. Faure, Eusebe Dessale, Vignier, Kunholtz, Bertin, René, Boileau de Castellan, Jannes, Valette, Trinquier, and Boyer.

Six sittings have already been occupied in hearing the first trial, which consisted in each candidate reading publicly a paper, written by himself, on a given subject. The subject proposed was—"To give a systematic *exposé* of

the knowledge, theoretical and practical, connected with the study, teaching, and practice, of *Médecine Légale*;" and the *concurrents* were allowed eight hours for the composition of their respective papers.

M. René seems to be the favourite so far. "The easy and unconstrained manner of this gentleman," says the reporter of the *Journal Hebdomadaire*, "his agreeable voice, and the novel mode in which he broached his subject, introduced him at once to the good graces of the audience. He received several salvos of applause. M. René has all the air of a finished teacher; and the view he took of the knowledge requisite for, and the duties required of, the medico-legal professor, shews that he is well prepared for such a situation." M. Bertin seems to have acquitted himself next best.

Eusebe Dessale, whose reputation as a writer is considerable, poured out an abundance of erudition, when it came to his turn, which was but coldly listened to by the audience: they gave him no applause, being probably fatigued by his elaborate historical detail. Yet his composition, according to the reporter, exhibited a rich profusion of intellect, combined with the resources of a most brilliant imagination.

But perhaps the most energetic and eager of the candidates is M. Boyer; who, if he did not display a large stock of erudition, did at least his powers of memory. In the course of his paper, having occasion to quote an opinion of Hippocrates, "I give the *text* of this author," says he, "not having time to translate it;" and here followed a long passage in Greek!

CASE OF RUPTURE OF THE TENDON OF THE BICEPS FLEXOR CUBITIS*.

BY SIR GEO. BALLINGALL.

MR. D—, a healthy active man, about 50 years of age, well known to many members of this Society as an eminent chemist and druggist, while raising a heavy weight, with the tips of the fingers of his right hand, suddenly felt a snap, accompanied with a numb pain, in the lower part of the arm, a little above the elbow. The weight instantly

* Edinburgh Medical and Surgical Journal.

dropped from his hand, and he was conscious of an inability to use his arm as formerly. On endeavouring to take off his coat, within a few seconds after the accident, he had great difficulty in doing so, owing to the swelling which had already taken place in the arm. On examination, there was observed a large tumor about the middle of the arm, occupying the seat of the belly of the *biceps* muscle. This being considered by Mr. D. as arising from effusion, he had a pretty tight bandage applied. He now felt scarcely any pain, and comparatively little inconvenience in the use of his arm.

Next morning, on removing the bandage and examining the arm carefully, Mr. D.'s son, a medical man, was of opinion that the tumor, which had now increased much, arose entirely from the retraction and swelling of the *biceps* itself. In this opinion he was confirmed by finding, that, in the hollow which existed below the tumor, there could be detected a body, apparently the tendon of the *biceps*, which was loose at one extremity, and could be moved from one side to the other with great facility. Bandages were now applied, consisting of two pieces of leather accurately and tightly laced, one on the arm and the other on the fore-arm, with a strap passing from the lower to the upper piece of leather, for the purpose of keeping the arm in the bent position. Owing to the patient using his arm much, the bandages were not kept accurately applied, and after ten or fourteen days they were thrown aside.

The tendon has gradually contracted adhesions to the neighbouring parts; and although there is still considerable swelling of the muscle, and some difference between the form of the two arms, yet the patient can use the arm tolerably well. It is not by any means so strong as formerly, and he cannot make any great exertion with it. He experiences difficulty, and some degree of pain or cramp, in attempting to raise a weight with the points of his fingers, and finds the power of pronation considerably impaired in the affected arm.

The preceding history of this very rare accident was drawn up at my request, by my friend, Dr. J. H. Balfour. Having been in the country at the time Mr. D. sustained this injury, I had no opportunity of examining his arm until nearly a week afterwards, when I was led, as others had been, to conclude that

the tendon of the *biceps* was undoubtedly ruptured, or perhaps rather torn from its attachments; for although the tendon could not now be moved freely from one side to the other, yet, upon throwing the muscles of both arms into action by bending the fore-arm against a resistance, the tendon of the left *biceps* sprung out as it were, and became tense, while no such thing happened in the right arm—the flexion of the fore-arm being apparently accomplished by the *brachialis internus*, the flexors of the carpus and fingers.

On examining the arms a few days ago, at a distance of eight months from the accident, I find that there is a considerable difference in their figure—the belly or prominent part of the *biceps* in the right or injured arm being higher up, and somewhat different in shape from that of the left. Immediately below the junction of the fleshy with the tendinous part of the muscle, there is a considerable thickness, or swelling, apparently in the tendon, and when the muscle is thrown into action, the tendon of the injured arm is less prominent and distinct than that of the opposite side. Mr. D. still finds the strength of the right arm considerably impaired. He complains of some difficulty in pronating the hand, and more especially in alternately rotating the radius outwards and inwards, as he has occasion to do in the act of pouring any powdered substance out of a wide-mouthed bottle into the scales. This last-mentioned circumstance I am particularly induced to notice, because, from the actions usually assigned to the *biceps*, it might have been supposed that the act of supination, rather than that of pronation, would have been impaired.

LECTURE ON

HÆMORRHOIDS;

Delivered at St. George's Hospital, Feb. 3, 1835,

By SIR B. C. BRODIE, BART.

IN the present lecture I purpose to make some observations on the disease which we call piles, or hæmorrhoids.

A patient consults you, complaining of swelling, pain, and tenderness, in the neighbourhood of the anus: you examine the part, and find on its verge a number of tumors, about the size of the end of the thumb or finger, with broad bases, not

very distinct from, but running one into the other, covered by the common integuments, and of a more or less purple appearance. If you cut into one of these tumors there is immediately a flow of venous blood, followed by a small quantity of arterial blood, such as might arise from a cut any where else. On making a section of the tumor, it presents to the eye the appearance of dilated and tortuous veins: in fact you cannot doubt that they are dilated veins; they are exactly like varicose veins of the leg. The tumors which I have described are situated below the sphincter muscle, and we call them *external piles*.

Another patient consults you, complaining also of a swelling at the anus, accompanied by pain and tenderness. You examine the part, and find a number of tumors of a different kind. These, too, have broad bases, and run one into the other, forming a circle, which projects below the anus. They are covered, not by the common integument, but by the mucous membrane of the rectum protruded from above the sphincter muscle. On making a section of one of these tumors there immediately flows venous blood, and arterial blood may flow afterwards. On looking at the divided surface, it is evident that the tumor was composed of a large tortuous vein. It is the accidental enlargement of these tumors which causes them to protrude externally; but they are formed above the sphincter muscles, and we call them *internal piles*, or hæmorrhoids.

I cannot doubt that piles are just what I have mentioned—dilated varicose veins. This is the common theory of their formation, and I certainly believe it to be correct. If you cut through piles, and dissect them, as it were, in the living person, you see that they are made of dilated veins; and if you dissect piles in the dead body, you find them just the same. If you insert the pipe of a syringe into the trunk of the inferior mesenteric vein of a person who had laboured under piles, the piles become all dilated largely with the injection. I know that some have held a different opinion concerning the formation of these tumors, and have supposed that they were not composed of dilated veins: but I apprehend that they have been misled by examining the parts in the advanced stage of the disease. If you wish to know what any disease really is, you must make your dissection of it in its origin; for in its progress, one morbid change is followed by another, and when a disease has lasted for a considerable time, you find various appearances in addition to those which existed in the first instance.

Those ultimate changes which take place in cases of piles, are exactly similar to those which occur in connexion with

varicose veins of the leg. You know that at first the veins of the leg are simply varicose, or dilated; that at last they become inflamed; that lymph is deposited in the cellular membrane surrounding them, and that at last there is a great mass of induration, in which the diseased blood vessels are, as it were, imbedded. So it is with the veins of the anus and rectum. At first they become simply dilated; repeated attacks of inflammation cause an effusion of lymph into the adjacent cellular texture, and then the pile appears like a solid tumor; in the centre of which, however, you still find the dilated vein in which the disease originated.

I have divided piles into internal and external; but, in fact, it is the same veins which are affected in both cases. The veins run on the inside of the sphincter muscle, and where the muscle compresses them there can be no dilatation of them: it is a bandage constantly operating to prevent the dilatation in this particular part; but above and below the muscle the veins become dilated.

Whatever tends to obstruct the return of the blood from the inferior mesenteric vein will lay the foundation of piles. It is said that persons with diseased liver are liable to piles; and no doubt they are likely to be so more than others, because the hard and indurated mass of a diseased liver interferes somewhat with the return of the blood from the abdominal viscera through the *vena porta*. However, a great many persons have piles who have not diseased liver. The most common cause of piles is obstinate costiveness. Where the colon becomes loaded, and especially the sigmoid flexure, with hardened feces, there is a pressure on the trunk of the inferior mesenteric vein, which interrupts, in some degree, the return of blood from its branches. Women, during pregnancy, are liable to piles, the pressure of the gravid uterus producing the same effect as an accumulation of feces; and women who have borne children many times are liable to piles ever afterwards, the veins which have been repeatedly kept in a state of dilatation not becoming again permanently contracted afterwards. Piles are more frequent in the upper classes of society than in the lower. You know that in hospital practice you see comparatively few cases of piles, but out of it, I must say that they form a very large proportion of the cases that come under my care. The reason of this difference is to be found in the different mode of life in the various classes of society. The better classes take but little exercise, and they are more liable to constipated bowels than the lower classes, who take much exercise and live a great deal in the open air. There is a notion that those

who take aloetic purgatives are more liable to piles than others; but I must acknowledge that I am not quite satisfied of the fact. I have a respect for all popular notions, believing that there is in general some truth at the bottom; and I will not say, as every body thinks so, that aloe will not make people liable to piles, but I am sure they do not produce that effect to the extent that is supposed; and I could not be certain, from my own observation, that they are productive of it at all. The fact is, that those who are habitually taking aloetic purgatives are persons with costive bowels, who, as I have already mentioned, are just the individuals most liable to this disease.

The symptoms which are produced by piles differ accordingly as they are internal or external; and also according to the stage of the disease. In the origin of the disease, when the piles exist only in a slight degree, the patient complains of a sense of heat and itching about the anus; and every now and then, when he is costive, the external piles become a little swollen and tender; the internal piles become swollen also, so as to fill up the cavity of the gut, thus exciting a sensation as though a stick, or some other foreign body, were lodged in it. The external piles sometimes inflame, swell, and become tender, so that the patient can scarcely bear them to be touched, and cannot walk without difficulty. They may continue thus inflamed for some considerable time, and then the inflammation may subside; the piles generally returning to the condition in which they were before the attack of inflammation came on, but not always.

Sometimes an abscess forms in one of these inflamed external piles, and bursts externally. The abscess may be troublesome to heal, but when it is healed it is found that the cavity of the vein is obliterated, and that it is, in fact, cured. Such an abscess as I have just mentioned must be distinguished from a *fistula in ano*; from which, indeed, it is essentially different, as I shall explain more fully hereafter. Sometimes, when an external pile is inflamed, the blood in it becomes coagulated, and it is then hard to the touch. If under these circumstances you slit open the pile with a lancet, there comes out a mass of hard coagulum, perhaps as large as a pea or a horse bean; the cavity inflames, suppurates, and granulates; the same thing happens as though suppuration had taken place in the first instance, and the pile is obliterated. But if you do not slit open the pile, and leave the disease to take its own course, the cavity being blocked up by the coagulum, the vein becomes obliterated, after which the coagulum is gradually absorbed, and the pile is cured; that which was a pile before being now converted into

a flap of skin. Just the same circumstance happens with varicose veins of the leg, where sometimes there is a natural cure, in consequence of the coagulation of blood in the dilated vessels. Sometimes, when a pile is thus distended with coagulated blood, the skin becomes so much attenuated that it gives way in some one point, and the blood being gradually squeezed out, suppuration probably takes place; and the case proceeds just the same as if you had opened the pile with a lancet. It is very common for external piles to undergo a process of natural cure in one or other of the ways which I have now described; and by examining the parts, you may ascertain whether these changes have taken place, as every one of them, after the cure is effected, becomes at last converted into a fold or flap of skin. Thus, if you see a patient with three or four loose folds of skin at the margin of the anus, you may know that these were formerly piles. At first these folds of skin are large, loose, and pendulous, but gradually they become contracted, till at last they give no sort of inconvenience to the patient.

Internal piles, as I have already told you, in slight cases produce heat and itching; and when inflamed, they give rise to a sensation as if there were some foreign body lodged in the rectum. Sometimes they are so much distended, that the gut is incapable of containing them, and they are pushed out through the anus, forming a tumor, which, while it projects externally, is still covered by the mucous membrane of the bowel. When internal piles are large, they always protrude when the patient goes to the water closet, and afterwards go up spontaneously. If they be larger still, after going to the water-closet they will not return spontaneously, but the patient is under the necessity of pushing them back with his hand. If they be larger still, they come down at other times, especially when the patient is walking, so that he cannot well take any exercise. Sometimes you see one small internal pile permanently protruded, forming a red vascular tumor of the size of the extremity of your little finger. This is painful, and otherwise very troublesome, to the patient, by keeping up a great and constant discharge of mucus. Sometimes there is a large protrusion of internal piles for several days, then they gradually become reduced in size, and go back into their proper place above the sphincter muscle. In short, with respect to the protrusion of internal piles, there are all possible varieties of circumstances: they may protrude occasionally, for a short time, or for a long period; they may be constantly protruded; or there may be a large protrusion at one time, and a small constant protrusion besides. Whenever the protru-

sion, be it large or small, takes place, there is an abundant secretion of mucus from the rectum; the piles themselves are sore to the touch; the surface is red and vascular; and if you put your hand upon them, you find that you can diminish their size by pressure, but the moment you take off the pressure, they are as large as ever.

In the state which I have now described, internal piles are not unfrequently confounded with *prolapsus of the rectum*—nay, in general, patients, and even most medical men, describe the disease under this appellation: but the term is improperly employed. There is prolapsus of the rectum independently of piles: the disease may even originate in piles, and yet, when once established, it is entirely different from them. In a genuine case of prolapsus of the rectum, the gut itself comes down, sometimes several inches in length. When internal piles protrude, of course that portion of the mucous membrane of the bowels covering them is pushed down, because they could not come down without it; but you will easily understand that this is entirely a different matter from the whole length of the rectum, or even a large portion of it, coming down of itself. The distinction between these two diseases is very important, and you should be careful not to confound them together.

Internal piles, in the state which I have just described, give the patient a great deal of inconvenience; besides which, they are liable to irritate the neighbouring parts—sometimes producing the frequent desire to make water, at other times inducing spasm in the muscles which surround the membranous part of the urethra, so as to cause complete retention of urine. Internal piles in this state are liable to discharge a large quantity of blood; and hence it is that they have their name of *hæmorrhoids*. You might suppose that the blood was venous, but it is arterial. Piles do not bleed in the early but in the advanced stage of the disease, when there is an increased determination of blood not only to the veins but to the mucous membrane and cellular texture by which they are surrounded.

The quantity of blood lost from internal piles varies in different cases: sometimes there is a little tinge of blood when the patient goes to the water-closet, and nothing more; at other times a large quantity is lost every time he goes there, so that as much as six or eight ounces are voided daily; and then there are the usual consequences of hæmorrhage—the patient is weak, his countenance blanched, and his appetite voracious. I have known cases in which the patient was in danger of becoming dropsical, in consequence of

the profuse loss of blood going on for a considerable time.

Inflammation sometimes takes place in internal piles, and ends in suppuration. The patient complains of a little discharge of matter from the anus, and you find, in addition to the mucus, that there is a little yellow stain of pus on his linen; and at first you would suppose there was a common abscess about the rectum, such as produces a *fistula in ano*. But if you introduce your finger into the rectum, you feel a small orifice in one of the internal piles, and if you pass a probe with a light hand, it goes to the bottom of the abscess, which is perhaps a quarter of an inch in depth, or thereabout. The parietes of the abscess, however, are very thin and weak, easily broken down, and if the probe be not lightly introduced, it will run through them into the loose cellular texture external to the mucous membrane. The cellular texture also is very loose and yielding, offering scarcely any resistance to the probe, so that it will run in every direction; and hence it is that I have sometimes known a small abscess or an internal pile to have been mistaken for a very long sinus. You ought to be very careful not to fall into this error, which you might easily do—nay, in all probability would do—in the first case of the kind that occurred to you, if I did not give you this caution.

I have mentioned that there is sometimes a natural cure of external piles; and I will now state how a natural cure of internal piles may take place also. Where piles of a large size protrude, completely filling up the orifice of the anus, the sphincter muscle is contracted upon them like a ligature, and causes them to become more swollen than when they were first protruded; just as a ligature on the arm makes the veins of the fore-arm and hand turgid previously to venesection. But the piles may be larger still; the sphincter muscle may contract more powerfully upon them; and then the pressure not only interferes with the return of the venous blood from the pile, but prevents the entrance of arterial blood into it. It acts as a ligature acts in a surgical operation—on a polypus of the uterus, for example. There is not a sufficient circulation in the protruded piles for them to retain their vitality; mortification takes place, sloughing follows, and thus the piles are destroyed. I have known several cases cured in this manner, and there is little or no danger in the process. I have sometimes known medical men to be alarmed at a case of this kind, confounding it with those of mortification from other causes; but the alarm is without foundation. The

late Dr. Pearson, who was for a very long period of time physician to this hospital, was the physician and friend of the celebrated Mr. Horne Tooke. Many years ago I was dining with Dr. Pearson, and after dinner he gave an account of Horne Tooke's illness. He said that he had long laboured under piles; that at last mortification had taken place; that there was no chance of his recovery; and he added, that he had that morning seen him for the last time. I remember that in the middle of this history there came a knock at the door, on which Dr. Pearson said, "Here is a messenger with an account of my poor friend's death." However, it was some other message; but by and by a messenger did arrive, saying that Horne Tooke was much the same, or a little better. It turned out, as I have been informed, that the piles sloughed off, and that from this time he never had any bad symptom. In fact, he was, if I have been rightly informed, cured of a disease which had been the misery of his life for many years preceding, and he lived for some years afterwards.

Treatment.

In considering the treatment of piles, we will first suppose that you are consulted when the disease is in its earliest stage. The patient complains of a sense of heat and itching about the anus, and perhaps there is already a slight protrusion of the piles. You may cure him, in general, by a very simple process. Keep the bowels gently open; take care that he is not constive on the one hand, or violently purged on the other. The best aperient for this case is the following:—One ounce and a half of *confectio semæ*, half an ounce of *sulphur precipitatum*, and then *mel rosæ*, as much as is necessary to make an electuary, and let the patient take about a tea spoonful, or what he finds necessary, of this, every evening. This is all that is wanted in many cases; but at the same time he should avoid drinking much wine; and if he be of sedentary habits, he should if possible alter them, and take exercise. If this should not relieve him, in addition to what I have just mentioned let him inject half a pint of cold water, fresh from the pump, as a lavement, every morning after breakfast, and keep it up as long as he can. This will give him immediate comfort, but it requires to be persevered in for many months; and perseverance in this plan of treatment will sometimes make a cure even of very bad cases of piles. You may, if you please, add something to make the water more astringent, as alum, the *tinctura ferri muriatis*, or the patient may use cold lime water. A friend of mine, a

practitioner at this end of the town, informed me that for many years he had used cold lime water in cases of piles, with the best result; and I have employed it in several instances lately, in which I think it has been serviceable.

There is a medicine that is very often useful in those cases where these simple expedients fail, namely, the *confectio piperis composita*, which is similar to what was once very celebrated as Ward's paste. It is composed of black pepper, fennel seeds, elecampane, and honey; and the dose is a piece of the size of a nutmeg three times a day. It is like eating coarse gingerbread; it may be a little disagreeable to be taken, but still it may be taken easily enough; and the patient must persevere in its use for a considerable time. Very severe cases of piles are sometimes cured by it. A lady came to me with one of the worst cases of this disease that I ever saw: the piles were so large, and protruded so constantly, that I did not think there was any chance of curing her, except by the operation to be hereafter described, and I advised her to submit to it. She said the piles made her miserable, and she should be very glad to be cured on any terms; but she was compelled to pay a visit in the country, which would render it necessary to delay it for a month. I thought the delay for a month could not hurt her, and under these circumstances I recommended her to give Ward's paste a trial, and see what it would do for her. I heard nothing more of her for six or eight weeks, when she came back, and said she was happy to inform me that she had taken the paste regularly, and was now quite well. It is of no use to take this remedy for a week, a fortnight, or a month; it must be persevered in for two, three, or four months.

How does the Ward's paste operate? I know a case in which a patient, labouring under stricture of the rectum, had indiscreetly taken an immense quantity of Ward's paste, and in which the colon was found quite full of it after death. It is evident, that, except any small portion which may be digested, the Ward's paste passes into the colon, and that it must become blended with the feces; and I suspect that thus coming in contact with the piles, it acts upon them as a local application; much as *vinum opii* would act upon the vessels of the conjunctiva in chronic ophthalmia.

In confirmation of this view of the *modus operandi* of Ward's paste, I may mention an observation of the late Sir Everard Home. He had a patient labouring under piles, and he recommended him to take Ward's paste. The patient, little thinking that

something put into the stomach was to cure disease in the rectum, crammed as much as he could bear of it up the rectum. I dare say it gave him a great deal of inconvenience, but, as Sir Everard Home reported, it cured him; and Sir Everard said that since then he had used it as a local application in some other cases, with manifest advantage.

I mentioned that a patient with stricture of the rectum had indiscreetly taken a large quantity of Ward's paste, and that the remains of it were found distending the colon after death. I recal your attention to this circumstance now, because it will serve to impress upon your minds the necessity of always giving the patient some gentle aperient occasionally at the time that the Ward's paste is being taken. This is not the only medicine of this description which may be used in cases of piles. Cubebs pepper, a scruple three times a day, may be given with advantage; it operates, I suppose, in the same manner as Ward's paste. In some cases of this disease, where there is a great deal of irritation, the patient will derive benefit from copaiva combined with caustic alkali; half a drachm of balsam of copaiva, with fifteen drops of *liquor potassæ*, may be rubbed down with two or three drachms of mucilage and cinnamon water, and taken three times a day. This answers a very good purpose, soothing the piles, and keeping the bowels gently open at the same time.

If you are called to a patient when the external piles are inflamed and swollen, your best way is to make him remain quiet in the horizontal posture, which takes the weight of the column of blood off the piles. You may, if you please, apply leeches in the neighbourhood, but not on the piles themselves, for the leech bites will cause them to become inflamed, and to fester; or, if the piles be much distended, you may puncture them with a needle. Acupuncture, on the whole, relieves the patient more than the application of leeches; and there are these advantages in it, that the puncture of the needle does not cause the piles to fester, and that the relief is immediate. By puncturing them in several places you let out a large quantity of venous blood, and the benefit arising from this is great. Besides this, you may keep a piece of rag constantly applied to the part, wetted with some cooling lotion; and the patient should take some gentle aperient, active purgatives being avoided.

When internal piles are inflamed, swollen, and protruded, you should try first of all to push them back into the gut. Take a cambric handkerchief, or a soft old linen rag, squeeze out the blood from the piles,

and, if you can return them into the bowel, it is so much the better; it will relieve the patient very considerably. But if you cannot push them up, or if when pushed up they immediately come down again, you should then keep the parts wet with a rag bathed with a cooling lotion, let the patient remain in the horizontal posture, and keep the bowels gently open, without purging. Here also, as in the case of external piles, the patient will derive much benefit from acupuncture in several places. Punctures made with a needle, neither on this or any other occasion, so far as I know, occasion inflammation or any other inconvenience; they evacuate the blood, relieve the tension and swelling, and do a great deal of good without any harm.

The observations which I have now made relate to the treatment of piles under ordinary circumstances. In more aggravated forms of the disease the patient must be relieved by other methods; but I must defer the consideration of the operation for piles till the next lecture.

ROYAL INSTITUTION.

Friday, Jan. 30, 1835.

Newtonian and Undulatory Theories of Light.

DR. RITCHIE gave a good practical lecture on this subject, cramped only by the difficulty of getting so much matter into so limited a space. He explained how far the Newtonian *fits* of easy reflection and refraction corresponded with the more modern *waves*; and he pointed out the strong analogy between the undulatory theory of light and the received doctrine of sounds. Many of Dr. Young's experiments and diagrams were exhibited; and, in fact, with the exception of a few illustrations by Fresnel, Arago, and one or two other modern *savans*, we could not perceive that there was any thing very important brought forward that is not to be found in Young's lectures and papers in the Philosophical Transactions, published more than thirty years ago. We state this, because we think that due honour is not paid to the merits of our illustrious Young, it being too much the custom to refer altogether to recent authorities, although they have produced very little in addition to his stock.

Friday, Feb. 6.

Dr. Faraday on the Induction of Electric Currents.

It had been announced that Dr. Lardner was to give a lecture this evening on Hal-

ley's comet; but that gentleman not being forthcoming, Professor Faraday was obliged to supply his place, and a subject for the *conversazione*, at a very short notice. With his usual readiness, and consummate ability as a lecturer, he gave the audience an admirable account of his paper on the *Induction of Electric Currents*, which was read before the Royal Society last night. We cannot venture to describe the series of experiments by which he illustrated his facts; but amongst the most striking we must not omit to notice his perfect demonstration that the intensity of the shock from an electric current depends upon the length of the conducting wires. Some of the magneto-electric machines recently constructed for giving shocks were shewn; they seem to have more power, and to be more manageable, than the machines ordinarily used for medical purposes.

MIDDLESEX HOSPITAL.

Lithotomy.—Removal of four Calculi.

JOHN HARRIS, æt. 28, was admitted into the hospital on Tuesday, January 6, with symptoms of stone in the bladder, under the care of Mr. Tuson. The patient having been sounded three times, and a consultation being held, the operation was fixed for Friday, January 23.

A staff being introduced into the bladder, having a groove on its under and right side, an incision was made with a scalpel (which had its cutting edge extending but an inch in length), in the usual place in the perineum, which divided the skin. The superficial fascia and adipose substance was next cut through, and the operator, Mr. Tuson, proceeded to divide the transversus perinei and transversus perinei alter, and the deep-seated fascia, to dissect along the membranous part of the urethra, until he arrived at the lower margin of the prostate gland. The edge of the scalpel was then directed upwards, towards the groove in the staff, and the upper part of the membranous portion of the urethra divided; the scalpel was then placed in a lateral direction, and the prostate gland was cut through, together with the neck of the bladder. The urine having escaped, the index finger of the left hand was introduced into the wound, and three stones were felt in the bladder. The staff was then withdrawn, and the forceps introduced upon the index finger. Two stones were removed with great facility; the third was of a large size, and the outer layer of this stone gave way beneath the forceps, so that it could not be so readily removed.

The scoop was passed into the wound, but ultimately the third stone was removed by the forceps, assisted by the index-finger of the left hand, which was introduced into the rectum for that purpose. A fourth stone was also extracted. Some small fragments of stone were found to adhere to the mucous coat of the bladder, and consequently the bladder was injected four or five times, and the patient was then removed to his bed.

The time the operation lasted, from the first incision to the extraction of the fourth stone, was a few seconds above fifteen minutes. At four o'clock the patient was visited, and he then complained of a sensation as if two bones were grating together. The finger was introduced into the wound, and some coagulum removed, but no fragment of stone was to be felt.

10 o'clock.—Pulse quiet; does not complain of any pain, nor does he feel the same sensation as when last he was visited. The urine flows freely from the wound.

R Tinct. Camph. ʒj.; Mist. Camph. ʒiiss. statim.

24th.—Feels quite comfortable; no pain; urine coming freely from the wound; bowels have not been open; pulse a little excited, the effect of the operation.

R Haust. Salinus, c. Magnesiae Sulph. ʒj. M.

10 o'clock, P.M.—Bowels have not been moved; pulse quiet; skin natural; complains of no pain, either in the wound or upon pressure.

Rep. Haust. c. Tinct. Camph. comp.

25th.—Quite comfortable; no pain; had a very good night, the same as the night before; has not rested so well for many years as since the operation. Urine comes very freely from the wound. The lint that was between the wound has been removed, and an effort was made by the surgeon to introduce another piece, but unsuccessfully, as the patient takes hold of the hands of the surgeon, and will not let him touch the wound. The house surgeon introduced a small portion of lint into the bladder, through the wound, in the course of the afternoon. Bowels have not been moved.

Haust. Sennae, c. Magnesiae Sulph. statim.

10 o'clock, P.M.—Bowels have not been acted upon.

Rep. Haust. Sennae, c. Magnesiae Sulph. statim.

26th.—Quite comfortable; bowels have been moved once; no pain. Urine comes freely from the wound.

27th.—No pain; good appetite; skin

and pulse natural. A mutton chop was ordered for his dinner.

28th.—Going on quite as favourably.

29th.—Just the same. Some porter was given him in addition to the chop.

30th.—Going on well; wound healing, and looking quite healthy.

31st.—Still improving.

Feb. 1st.—Going on quite favourably; wound healing. Some warm water was injected down the urethra, for the purpose of inducing the urine to flow through its natural passage.

2d.—Going on quite well; the wound appears as if it would heal in a few days. The man has not had a bad symptom since the operation.

GUY'S HOSPITAL.

CASE I.—*Lithotomy.*

JAMES SMITH, a healthy looking boy, ætat. six years, had laboured for some months previous to his admission into Guy's Hospital under symptoms of calculus vesicæ.

Jan. 27th.—He was this day brought up for operation, at 1 P.M.

The operation was performed by Mr. B. B. Cooper, in a short space of time, smoothly and distinctly. The steps of the operation being very well performed, a stone, of moderate size and roundish form, was extracted.

The resistance offered by the patient, and the great trouble that was experienced in fixing his pelvis, much increased the difficulty of the operation. The boy was put to bed; he has never had a bad symptom; and at the time I write this, he is walking about the yard, passing all his urine per urethram, and is quite well.

The calculus has been analysed, and found to consist of nitrate of ammonia internally, fusible calculus externally.

CASE II.—*Strangulated Femoral Hernia.*

Elizabeth R —, ætat. 66, a flabby and rather corpulent woman, was brought into Guy's Hospital, February 10th, at half-past one, with symptoms of strangulated hernia. She stated that she had never been subject to hernia previous to Thursday last, the 6th instant, when she first perceived a swelling in her left groin, accompanied with vomiting and constipation of the bowels; this had never gone up, but increased in pain and tenderness until her admission.

Mr. Cooper, having failed to reduce the hernia by taxis, at two o'clock proceeded to operate.

The operation was one of more than common difficulty, owing to a large deposit of fat between the fascia superficialis and the fascia propria, and also between the fascia propria and the sac. Another slight impediment arose from Mr. Cooper having passed the director *through* the fascia propria and *over* a small band of it, which thereby escaped the edge of the knife; this band was then divided, and the intestine returned, but not in a very favourable condition.

Feb. 11th.—The patient's bowels were relieved during the night, but she has had no stool since; the injections have been administered; she has vomited several times; and her present state, combined with her previous habits of life, which have been far from regular, render the prognosis any thing but favourable.

CASE III.—*Lithotomy.*

At this hospital, on Tuesday last, the 9th, lithotomy was ably performed on a child about four years of age, who was admitted into Charity ward. Some considerable trouble was met with in detecting the stone with the sound previous to the operation. When Messrs. Key and Morgan were convinced of the presence of stone, as well as Mr. B. Cooper, the patient was tied up, and the operation commenced and completed by the latter gentleman in sixty seconds, at the moment of the extraction of the stone. The students present simultaneously gave vent to their feelings of approbation, which was immediately suppressed by the operator, who, turning to the pupils, said "that he would never receive such a compliment." Previous to the operation, whilst being sounded, the little patient vociferated most lustily, bestowing no very elegant titles on Mr. Cooper, and used such language as could hardly have been believed capable of being uttered by such a child. The calculus, which was of moderate dimensions, quickly disappeared under the care of some person in the arena, so that the structure of the calculus we cannot form an opinion of.

The circle was unusually crowded with intruders.

ST. GEORGE'S HOSPITAL.

Disorganization of a Portion of the Heart—Mortification of Lower Extremities.

JAMES LANE, æt. 45, admitted November 12, under Dr. Seymour. Complains of pain in the chest, with cough, and a sense of great constriction about the scrobiculus

cordis. The pain is not increased by deep inspiration; there is much dyspnoea, but the chest expands freely; there are occasional shooting pains in the arms; a considerable muco-purulent expectoration. Pulse 100, not hard; tongue moist; bowels open.

Appl. Empl. Canth. pectori.

R Balsam. Peruvian. ʒj.; Mucil. G. Acaciæ, ʒijj.; Mist. Amygdal. ʒx.; Syr. Papav. Alb. ʒj. M. ft. haust. bis die sumend.

17th.—Much relieved.

Rep. Pil. et Haust. Catharticus.

19th.—Dyspnoea and cough again urgent; pulse quick and sharp.

V.S. ad ʒxij. H. Salin. c. Pulv. Antim. Tart. gr. ʒ, 6tis horis. Pil. Scillæ Co. gr. x. h. s.

20th.—Blood not buffed nor cupped; dyspnoea and cough relieved; expectoration mucous and free. Pulse quick, small; a very scanty motion.

H. Salin. c. Pulv. Doveri, ʒss. h. s.

22d.—Complains much of sickness; the other symptoms subsiding.

H. Salin. Efferv. c. Tr. Opii, ʒijj. 4tis horis. Adhib. Cataplasma. Sinapis scrob. cordis si perstet nausea.

In a few days he suffered little inconvenience, except from a very large inguinal hernia of the left side, for which a truss was worn.

Dec. 1st.—The symptoms of distress about the chest have returned; the expectoration is abundant, and tinged with florid blood. Pulse hard; face livid.

V.S. ad ʒxvj. Subm. Hydr. gr. iij.; Opii, gr. j. 4tis horis.

2d.—Blood not buffed or cupped; urgent symptoms have again subsided; considerable general debility.

Resumat Haust. ex Balsam. Peruv.

R Cetacci; P. Gum. Acaciæ, aa. ʒj; Aq. Puræ, ʒss.; Tr. Opii, ʒxv. M. ft. haustus h. s. sumendus.

9th.—Slight oedema of legs; dyspnoea rather on the increase; great anxiety of countenance; gums sore; pulse feeble; cannot lie on left side.

R Haust. ex Potass. Nitrat. c. Tr. Scillæ ʒxv. M. t. d. s.

10th.—Having had a call to evacuate his bowels, shortly after breakfast this morning, he went to the water-closet, without taking the precaution to clothe his

feet. Whilst straining there he felt suddenly a sensation of great cold creeping from the soles of the feet up to the groins. This was immediately followed by pain of the most severe character, running the same course. He had scarcely time or power to reach his bed, when a most violent difficulty of breathing seized him, threatening every instant to end in suffocation; his struggles for breath were so strong as to resemble convulsions. In a short time he regained the power of respiration, but the pain in the legs, extending now only so far as the knees, remained unabated. The cutaneous sensibility below the knees was much reduced, but not destroyed. He states that at the onset of the attack he felt some trifling pain in the chest, but no sensation as if any thing had burst. Pulse very feeble and quick; countenance extremely anxious.

Catapl. Sinapis pedibus. Habeat Sp. Vin. Gall. p. r. n.

R Subcarb. Ammoniacæ, gr. vj.; Tr. Opii, ʒxx.; Sp. Æth. Sulph. Co. ʒss.; Mist. Camph. ʒij. Statim et h. s.

11th.—Coldness and discoloration of the right leg, as from impending mortification; slight orthopnoea; expectoration deeply tinged with blood; pulse 110, stronger; countenance less anxious.

Appl. Lotio Spiritus. tepid. crurib.

R Ol. ricini, ʒss. statim. Ft. in usu Sp. Vin. Gall. et Haust. Opiat.

12th.—Had a quiet night; both legs cold, but especially the right, which is now blue some distance up; pulse 130, weak; respires with facility.

Liniment Camph. Co. cruribus. Rep. alia.

From this time the mortification in the right leg made rapid advances, the limb becoming in two or three days black, cold, and oedematous, with a distinct line of demarcation just below the knee. In a day or two more this boundary was overstepped; black spots made their appearance on the thigh; great pain was felt in the groin, and a disposition to gangrene was also observable in the left leg, accompanied by oedema. The pulse became scarcely perceptible. The symptoms of disease of the chest did not return, and the patient died of the gangrene on the morning of the 18th.

Section cadaveris.—On opening the chest, the left lung was observed to be perfectly sound; the inferior lobe of the right seemed congested, and there was a portion, of the size of a pigeon's egg, in which the minute vessels had given way, forming apoplexia pulmonis. The pericardium appeared healthy; the heart was dilated to

nearly twice its natural size, and its muscular structure exceedingly soft and flabby; the parietes of the right cavities were unusually thin. At the base of the left ventricle the substance of the organ was dark, disorganized, and crepitated when pressed between the fingers; the right coronary artery was obliterated; the aorta was not dilated, but presented the red stained appearance often observed in its inner coat; just above its bifurcation, and extending into the right common iliac, there were evident marks of disease; the inner coat corrugated, irregularly patched with dark red and purplish spots, and the iliac obliterated by coagulated blood, to the extent of about three inches.

REMARKS.—What relation the symptoms under which the patient laboured, on his admission into the hospital, bore to the subsequent singular and fatal attack, it is not easy to say; nor, indeed, is it very manifest that they bore any. His complaint was regarded as an ordinary attack of bronchitis, and it was prescribed for accordingly; but it was observed that his liability to relapses was greater than the circumstances accounted for; that is to say, the freedom he enjoyed from exposure to causes likely to reproduce the complaint, and the care which he took of himself, from a nervous anxiety to recover speedily, seemed oddly frustrated by a repeated recurrence of the severer symptoms of his malady. Hence a suspicion arose that causes of an internal occult nature operated to this effect; but what these causes were, the absence of all intelligible signs previous to the attack of December 10th, left not room even for conjecture.

The suddenness of that attack, and the great pectoral distress which it occasioned, led to the supposition of the rupture of some undetected thoracic aneurism. The patient seemed every instant to be on the point of expiring from suffocation. The idea of a great internal extravasation was further borne out by the extreme pallor of his visage; but his quick revival, and the no less rapid appearance of mortification in the lower extremities, again placed all in doubt; nor did any grounds appear on which to found a safe opinion, till death revealed the truth.

In considering the post-mortem appearances, we are led to ask, was the softened condition of the heart the result of recent inflammation, obscurely indicated by the symptoms which constituted the complaint supposed to be bronchitis; or was it the result of that chronic degeneration of the organ which Laennec imputes to a derangement of its nutrition, and in which the aorta and iliac arteries participated? I am induced to believe that both inflam-

mation and previous degeneration co-operated to produce the pathological condition presented.

A PUPIL.

ON FIBROUS TUMORS OF THE UTERUS*.

By DR. ROBERT LEE.

THE fibrous tumor is sometimes developed immediately beneath the lining membrane of the uterus, or with a layer of muscular tissue interposed. It is in this manner that the greater number of uterine polypi originate. As the tumor, or polypus, enlarges, the cavity of the uterus becomes distended as by the *orum* during gestation, and its walls are excited to contract and expel the tumor, which pushes before it through the orifice of the uterus that portion of the lining membrane of the uterus by which it is covered, in a manner somewhat analogous to what takes place in hernia when the peritoneum is pressed forward by the intestine or omentum through the inguinal or crural canals. By the constant and powerful action of the uterus, the tumor is gradually forced into the vagina, where it undergoes various important changes of structure, both in its covering membrane, peduncle, and deep-seated parts. Its mucous membrane is sometimes pale, and presents little sensible change of structure, but more frequently it becomes highly vascular, hypertrophied, softened, and inflamed; or it ulcerates and sloughs, and gives rise to a sanguineous, purulent, and fetid discharge from the vagina, and to all the other symptoms of malignant disease of the uterus. In some cases the diagnosis between a large fibrous tumor in this state filling the vagina, and a malignant fungous disease of the os uteri, is extremely difficult.

Dupuytren believes that fibrous tumors in the vagina sometimes become cancerous; but this fact has not been satisfactorily established.

We have observed in the same volume (xviii.) of the *Med. Chirurgical Transactions*, that if the tumor be covered only by the lining membrane of the uterus, little difficulty is experienced in expelling it from the cavity, and the pedicle is slender, consisting only of thickened lining membrane, a little cellular substance, and some small blood-vessels; but when the tumor is covered also with a layer of muscular tissue of the uterus, the root is thicker, often as large as the wrist in circumference, and

consists not only of lining membrane and blood-vessels, but chiefly of muscular coat. A longer continuance of uterine action is here required to force the tumor into the vagina, and not unfrequently the patient expires from the loss of blood before the tumor has descended sufficiently low to admit of the application of a ligature around its root. We are disposed to believe, from preparations in our possession, that it is not on the primitive state of the tumor or polypus, as Herbiniaux and Dupuytren have supposed, that the consistence and form of the peduncle depend, but on the quantity of muscular fibres carried before the tumor; and that in most cases where the peduncle is thick and short, it will be found to be composed not only of mucous membrane and blood-vessels, but of hypertrophied muscular structure of the uterus. This account of the formation of uterine polypi, which is confirmed by the observations of Dr. Sims, Cruveilhier, and Boivin, will satisfactorily explain why it is unnecessary, as many have supposed, to pass the ligature for the removal of polypi close to the uterus; and it also explains a circumstance pointed out by Clement and Puzos, that the root of the polypus which remains never grows again after the general mass of the tumor has been removed.

Though it has been demonstrated that the greater number of uterine polypi are merely fibrous tumors which have been developed under the lining membrane of the uterus, and a layer of its muscular fibres, we are not entitled to infer, as some writers have done, that these are the only tumors which pass from the cavity of the uterus into the vagina, and which are not of a malignant nature. We have pointed out other three varieties of tumors of the uterus, to which the term polypus has been applied: first, a tumor with a broad base, and generally of a flattened form, originating in a morbid growth of the lining membrane of the organ, and resembling nasal polypi; secondly, a tumor formed under the mucous coat of the uterus, which is composed of a congeries of small cysts or vesicles filled with a clear or yellow-colouredropy fluid; thirdly, a tumor of the os and cervix uteri, arising from a morbid enlargement of the mucous follicles and glands of the part.

ESSENCE OF MILK.

A PREPARATION bearing the name of *lactoline* has just been presented to the Paris Academy of Sciences. Mingled with nine tenths of water, it yields new milk of the best sort and with the proper flavour. Lactoline is procured from pure milk, principally by evaporation without heat;

and it is said that the globules, when examined by high microscopic power, are found to have undergone no change. When once formed, it remains unaltered by heat or moisture.

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,
Delivered at the London Hospital,
By THOS. DAVIES, M.D.

LECTURE XXII.
DISEASES OF THE HEART.

HAVING thus, gentlemen, given you an account of the local signs of the diseases of

the heart, we now proceed to the description of the affections—

1st, Of the substance of that organ, and its valves.

2d, Of the pericardium.

3d, Of the large blood-vessels.

4th, Of the nervous disorders of the heart and arteries.

And finally, Of malconformations of the heart.

In describing the diseases of the heart and its valves, I shall proceed according to the following arrangement:—

Tabular View of the Diseases of the Substance of the Heart.

Hypertrophy, simple	{	left ventricle.	
		right ventricle.	
Dilatation, simple ..	{	left ventricle.	
		right ventricle.	
Hypertrophy, with dilatation of ventricles.			
Hypertrophy, with dilatation of auricles.			
Valves	{	mitral	1. cartilage, bone.
		semilunars of aorta	2. vegetations { verrucous.
			globular.
Carditis.			
Ulcers of the heart.			
Rupture.			
Hardness of the substance.			
Softness of the substance.			
Surcharge of fat.			
Fatty degeneration.			
Cartilaginous, bony, and other ad entitions deposits.			

Hypertrophy of the Substance of the Heart.

I shall, in the description I am about to give of the morbid anatomy of the heart, adhere closely to the texts of Laennec, Bertin, and Kreyseg, because of their extreme accuracy; these descriptions will also be at once verified and illustrated by the series of preparations I shall place before you.

By *hypertrophy* is meant an increase of nutrition of the substance of the heart, the augmentation of the thickness of its muscular structure, and consequently of the parietes of the cavities of the organ; this thickness is usually combined with increased firmness of the muscular fibres; sometimes, however, though rarely, they are softer than in their natural state.

Hypertrophy may affect the parietes of either cavity of the heart; thus it may exist in one ventricle or in both, and in the auricles also, at the same time, or in a single auricle.

Simple hypertrophy of the left ventricle.—The parietes of this ventricle occasionally acquire an extraordinary thickness, sometimes at the base of the ventricle even to one or two inches. This thickness gradually diminishes from the base to the point, so that at the latter part it may not measure more than a line. The point, however, occasionally participates in the same condition, and increases to three or four lines. The *carneæ columnæ* are usually augmented in volume, although not always. The interventricular septum, generally, though not invariably, is affected in the same manner. The hypertrophy may vary in different parts of the same ventricle, so that it may affect exclusively the point, the base, the septum, the *carneæ columnæ*, or the external parietes. In proportion to the increased thickness of the walls of the ventricle, its cavity diminishes in its capacity; Laennec had seen it so small as to be incapable of holding an almond inclosed in its shell. The right ventricle in this case is flattened along the interventricular septum, and does not descend so nearly to the point of the heart as usual; and in extreme cases it appears even to be hollowed out of the parietes of the left ventricle.

It is from the increased thickness of the parietes of the ventricle being directed towards the interior or centre of its cavity, that Bertin has denominated this form of the disease *concentric hypertrophy*.

Simple hypertrophy of the right ventricle.—The parietes of this ventricle become thicker and firmer than usual; they do not collapse upon their cavity upon a section of them being made. The thickness of the muscular structure is nearly uniform, although it is generally greatest towards the base of the ventricle. The *carneæ columnæ* are always very large. The size of the cavity is rarely much diminished, because the thickness of the walls of the ventricle is not often very considerable: Laennec never found the thickness above four or five lines; Bertin describes a case in which it was from eleven to sixteen lines. I present you here, gentlemen, a preparation in which the parietes of the right ventricle are fully three-quarters of an inch thick, and its cavity is so diminished as to be capable only of holding a small pea: it is the heart of an infant, in whom the pulmonary artery was obliterated at its origin.

Hypertrophy of both ventricles.—When hypertrophy attacks both the ventricles, they

each descend to form the point of the heart. The other anatomical characters are the same as above described.

Dilatation of the ventricles.—This affection is the *passive aneurism* of Corvisart. The cavities of the ventricles become now enlarged, and their parietes much thinner than natural. The muscular tissue is softer, and generally pale; sometimes it is of a violet colour; occasionally it assumes a yellow tint. The softening of the fibres is often so great, especially of the parietes of the left ventricle, that they may be broken down easily with the fingers. The thickest part of the left ventricle may now measure no more than two lines, and its point not more than half a line. The point of the right ventricle often becomes thinner still, seeming, indeed, to consist of the external and internal membrane of the heart only, separated by a small portion of fat. The *carneæ columnæ* of the left ventricle appear as if increased in number, although they are extremely thinned, presenting, by their crossing each other, a finely reticulated character. The intervertebral septum loses less of its thickness and firmness than the rest of the parietes of the heart.

This dilatation and thinning may affect a single ventricle, or both at the same time. When one only is dilated, its point descends lower than usual, although the increase of its cavity is in the direction of its transverse diameter rather than of its length. When both ventricles are affected, the heart is rounder in its form, and is almost as large at the point as at the base.

Burns believed that rupture of the heart might be caused by its dilatation; Laennec conceived also such an event to be possible; Dr. Hope mentions an instance of such an occurrence, and cites another case from Dr. Williams. I present you here with a preparation of a rupture of the upper part of the left ventricle. It seems, however, to be rather a consequence of softening, or ulceration of the muscular fibres, than of excessive dilatation.

Laennec has averted us from the mistake which might be committed, by confounding the dilatation of the heart with its distention from blood. In the latter case, the moment the cavities of the heart are opened, the distending blood escapes, and the organ collapses to its natural size; this does not occur if there be really dilatation.

Hypertrophy, with dilatation of the ventricles.—This combination constitutes the *active aneurism* of Corvisart, and the *eccentric hypertrophy* of Bertin.

Hypertrophy with dilatation of the ventricles is a very common affection; it is much more frequent than simple dilatation, and still more so than the concentric or simple hypertrophy. This disease may

affect either of the ventricles, or both simultaneously. In the latter case the heart often acquires an enormous volume. The muscular fibres become firmer. The heart is rendered rounder at its point. In some cases the ventricles are dilated, and their parietes are of their natural thickness, being what Bertin has considered dilatation of the ventricles, with hypertrophy in the direction of the extent of their surfaces. Dr. Hope states that this variety was unknown to Laennec; but although no special name was given to it by him, yet the following passage clearly denotes that he was aware of it, for in speaking of hypertrophy with dilatation of the ventricles, he says, "A un degré mediocre les ventricules sont dilatés, et leurs parois semblent seulement n'être pas amincies."

It happens, though very rarely, that some parts of the walls of the same cavity present the characters of hypertrophy, and others those of dilatation.

Hypertrophy, with dilatation of the auricles.
—It is very easy to mistake organic dilatation of the auricles with their simple distention from blood; it is as easy, also, to correct the error, by compressing the distended cavities, and thereby forcing the blood from them into their communicating cavities or versels. If they are merely distended, the auricles will then return to their natural volume; if they be permanently dilated, they preserve their size. Laennec also observes, that if their cavities be fully distended, their parietes will appear tense, and the colour of the blood is seen through them; but if they be permanently dilated, their walls are not so tense, they appear capable of holding more blood, and the colour of that fluid can no longer be distinguished.

The dilatation of the auricles, although not so rare as Laennec believed, is yet not so common as that of the ventricles. This dilatation is generally accompanied by hypertrophy, or by hypertrophy and dilatation, of the ventricles. Sometimes the left auricle may be dilated, while its corresponding ventricle is in a healthy state. Laennec states also, that he never met with evident dilatation of the auricles without a certain degree of hypertrophy. There is, however, before you, a specimen of hypertrophy of the left auricle without dilatation; but, generally speaking, his observation is perfectly correct. It requires a certain degree of habitude to distinguish hypertrophy of the auricles; for as their parietes are very thin, it might escape the observation of an unpractised observer even if they were doubled in thickness. The preparation I hold in my hand shews the walls of the left auricle to be nearly three lines thick.

The following combinations of organic

changes in the parietes and cavities of the heart most frequently occur:—

1. Hypertrophy with dilatation of the left ventricle, with simple dilatation of right.
2. Hypertrophy with dilatation of the left ventricle, with simple hypertrophy of the right.
3. Hypertrophy with dilatation of right ventricle, with simple dilatation of the left.
4. Simple hypertrophy of right ventricle, with dilatation of the left.

There are other varieties, which we shall hereafter mention when we consider the causes of these affections.

It occasionally, although very rarely occurs, that a partial dilatation of the cavities of the heart takes place—a dilatation which presents all the characters of aneurism. Corvisart mentions a singular instance of this in a negro, in whom the partial dilatation of the left ventricle was so large as to form a tumor of the size of the ventricle itself. My friend Mr. Langstaff possesses two beautiful specimens of these partial dilatations; the one is of the upper portion of the left ventricle, forming a tumor of the size of a large walnut, which presents itself between the base of the ventricle and its corresponding auricle, the coronary artery crossing it; the other is a still larger aneurism of the left auricle, situated between the appendix and the mitral valves; it contains a considerable quantity of fibrinous substance, precisely similar to that which is so commonly found in arterial aneurisms. I believe the latter preparation to be unique.

Diseases of the Valves.

The valves of the right side of the heart have been rarely seen diseased. Occasionally, however, they have been noticed. Vieussens, Bertin the elder, Horn, Crewel, Burns, Laennec, Bertin the younger, Drs. Hope and Latham, all give instances of cases which they have observed. It must be noticed, however, that the indurations of the valves which they describe are almost all of the cartilaginous character, and that bony concretions have very rarely been seen. In many of these cases, also, a free communication has existed between the auricles, in consequence of the foramen ovale being open.

The cause of the frequency of disease of the valves of the left side of the heart yet remains in great obscurity. Corvisart has supposed that it arises from the fibrous structure partly forming these valves being more complete; and consequently he infers that that structure is necessary to the cartilaginous or ossific deposit. Others think that it arises from some peculiar influence of the arterial blood. I am in-

clined to the latter opinion, because we see that the parietes of all the vessels carrying venous blood, including the right side of the heart, are rarely subject to cartilaginous or osseous induration, while nothing is more frequent than their formation in the valves of the left side of the heart, and between the internal and middle tunics of the vessels carrying arterial blood.

Cartilaginous deposit in the mitral valves.—When cartilage is deposited in the mitral valves, it is always situated within the duplicature of the membrane forming it. The base of the valve is generally the seat of the adventitious matter; the auriculo-ventricular opening then becomes contracted, and assumes various forms, but usually that of a narrow cleft or slit. The edges of the orifice are commonly smooth and polished, and of firm structure. Occasionally the cartilaginous matter occupies the free edge, the middle or even the whole of the valve.

Ossific deposit in the mitral valves.—If phosphate of lime be deposited, it is also in the duplicature of the membrane forming the valve, and may be situated, like cartilage, either at the base, point, or throughout the valve. The bony matter soon perforates the membrane covering it, and forms irregular granular projections, or asperities, bathed by the blood. This osseous deposit never presents the cancellar appearance of healthy bone: it is usually whiter, and breaks down with greater facility. The mitral orifice is often extremely contracted by the ossific formation; it becomes a small and irregular slit, or an opening more or less round, or sometimes even a canal, which has been seen bending like the carotid in its passage through the temporal bone. The chordæ tendinæ have, although very rarely, been observed ossified.

Ossific deposit in semilunar valves of the aorta.—The ossific matter generally commences to be deposited in the tubercula Arantii, then at the base, then on the free edge, and finally on the whole structure of the valve.

When the ossification affects the free edges of the valves only, their movements are yet tolerably complete, and the flow of blood through them is not much impeded; but when their bases and other parts become diseased, the valves unite, curve inwardly or outwardly, as Laennec describes, like certain shells, or sometimes a single valve is curved in one direction, and another in a different. They then become nearly immovable, and remain in the position they have taken: thus they may fall inwards towards the heart, or they may lie along the internal surface of the aorta, or they may be placed permanently across

the origin of that vessel. I present you with a preparation in which the natural orifice between the valves is reduced to a very small size, but, at the base of one of them, ulceration and perforation has taken place, so that two distinct, although small, columns of blood must have passed into the aorta instead of one. I need hardly state that the obstruction of the circulation must be in proportion to the diminution of the opening left by the diseased state of the valves.

Cartilaginous or ossific deposits in the valves have been supposed to depend upon inflammation of the lining membrane of the organ, or of the pericardium investing it, or of the substance of the heart itself, or from any cause rapidly and frequently increasing the circulation, or from some peculiar diathesis. Nothing, however, is positively known upon this subject.

Vegetations formed on the valves and parietes of the cavities of the heart.—There are two forms in which fleshy vegetations grow upon the valves and internal surfaces of the heart: the first is in that of warty excrescences, which have been called, by Corvisart, *vegetations* on the valves; the second, that of globular bodies, often of considerable size, which have been denominated, by Laennec, *globular vegetations*. The latter author gives the following description of them:—

Species 1.—Vegetations on the valves.—These often present a very similar appearance to ordinary or to venereal warts; hence they have also been named *verruous vegetations*. They bear occasionally a striking resemblance to a small raspberry. Sometimes these bodies are greater in length than breadth, and have the form of small irregular cylinders, more or less approximated to each other. They have been seen covering the valves, chordæ tendinæ, and the internal surfaces of the auricles; rendering them rough and granulated. I have observed them extending only in a single row. Their length is rarely greater than two or three lines.

The colour of these vegetations, although sometimes whitish or yellowish-white, is usually that of muscular fibre, or a little lighter. Their texture is fleshy, sometimes similar to venereal warts, although less firm. Their adhesion varies, for it may be so strong that they cannot be torn off, or it may be so slight that they may be easily separated and scraped off by the handle of the scalpel or the finger-nail. In the latter case the vegetations are soft, and of very humid texture.

These substances have been found on all the valves, on the internal surface of the auricles and ventricles.

Corvisart believed the verrucous vegetations to be of venereal origin: there are no

proofs whatever in support of this supposition. Laennec conceived them to be formed by the organization of coagula of blood adhering to the valves and the parietes of the heart: his reasons were, that their texture closely approached to that of the most compact polypiform concretions of the blood; nay, even that a slight coagulum is occasionally found within them. Bertin and Bouillaud attribute their formation to the organization of false membranes, produced by inflammation of the membrane lining the cavities of the heart and forming the valves.

Species 2.—Globular vegetations.—The size of these vegetations varies from that of a pea to a pigeon's egg. I present you a specimen, where there are two attached to the mitral valve, of nearly the latter volume: their form is spheroid, ovoid, or round. They are hollow. The external surface of these cysts is smooth, the internal is rougher. Their parietes are about half a line in thickness, and have somewhat a firmer consistence than boiled white of egg. The matter contained within them varies; it is sometimes similar to half liquid blood, containing also a few coagula of that fluid—it is opaque, and occasionally of a pale violet colour, or of the colour of lees of wine, and of a pulsatious consistence; finally, it is like a thick pus, or to a substance precisely similar to the polypiform concretions which are frequently found interlaced between the *carnea columnæ*. These cysts always adhere by a pedicle which is slightly transparent, and occasionally contains small clots of blood.

Laennec never found the globular vegetation except in the ventricles and in the sinuses of the auricles. The two I present to you are attached, by a common base, to the mitral valve: the disease occurred in a girl of fourteen years of age. I believe it to be a very rare affection.

The same opinions have been entertained by Laennec, by Bertin, &c. of the formation of this disease as of the preceding species.

Causes of hypertrophy and dilatation of the Heart.

I have thus, gentlemen, described the morbid anatomy of the heart, as far as relates to the increased thickness of its parietes, to the dilatation of its cavities, and to the diseases of the valves: I have preferred this order, for these affections are intimately connected with each other, and because valvular obstruction is so commonly, although certainly not the only cause of hypertrophy and dilatation of the heart.

To understand the causes of hypertrophy and dilatation of the heart, the following principle must be advanced: that

whenever any frequent necessity exists for an increased force or exertion of muscular power, the muscles increase in their size to a certain extent, if the subject be healthy. Thus we see that in the workman who wields the heavy sledge-hammer, the arms acquire an extraordinary volume; that the same occurs to the waterman; that the muscles of the back and shoulders of the porter become greatly developed; that the legs of the chair-porter become of a great size.

If we apply this principle to the movements of the heart we may assert that whenever any permanent or even frequent obstruction exists to impede the current of the blood, that obstruction creates a necessity for an increased force or power of muscular action to overcome it, otherwise the circulation would cease. The muscular parietes of the heart then increase in thickness, or in other words, become in a state of hypertrophy.

But, as in the aged, and in persons of lax and weak fibre, or of delicate constitutions, the constant application of physical force only tends to diminish the size and firmness of their muscles, and exhaust their power, so I apprehend that in these individuals the parietes of the cardiac cavities do not increase in thickness and in force to overcome the resistance afforded by the obstruction, but yield, dilate, and become thinner, from the distention produced by the blood accumulating within them. These constitute the cases of simple dilatation of the cavities of the organ.

Mixed cases, however, frequently occur, in which nature lends her aid to overcome the obstruction, by thickening the parietes of the heart, while at the same time the cavities dilate; for if the heart, although thickened in its walls, has not sufficient power to send the due quantity of blood through its orifices at each of its contractions, that fluid must accumulate in its cavities, and ultimately dilate them. These, then, are cases of hypertrophy with dilatation, or the eccentric hypertrophy of Bertin.

Let us now proceed to the particular cases of obstruction to the current of the circulation, and their effects upon the different cavities of the heart.

1. *Obstructions caused by chronic diseases of the lungs.*—It is scarcely necessary to state that the lungs should be in a perfectly healthy condition to admit of a free circulation through them. If these organs become affected by chronic disease, more especially by chronic catarrhs and emphysema, then the blood is impeded in its transit from the pulmonary artery into the pulmonary veins, obstruction is established from the engorgement of the capillary vessels, and the pulmonary artery and right

side of the heart became unnaturally filled with that fluid. Hypertrophy, or dilatation, or a combination of both states, now occurs of the right cavities of the heart, while the left ventricle and auricle remain in their natural condition.

You will understand, however, that these affections of the right side of the heart can only be produced by pulmonary diseases of long standing. Probably many months—nay, perhaps two or three years—are required before such consequences visibly take place. These changes do not occur either from protracted hepatization of the lung, or chronic effusions into the pleura, compressing that organ; for these diseases destroy life before hypertrophy or dilatation are produced. It might be supposed that tubercular deposits would cause sufficient obstruction to the course of the venous blood through the lung, but the quantity of that fluid is then so extraordinarily diminished, that no engorgement ever occurs, sufficient, at least, to require any increased force to overcome it; indeed, the heart then generally, like the rest of the muscles of the body, decreases in volume.

2. *Obstruction caused by diseased aortic valves.*—This obstruction, when considerable, produces the most extensive alteration in the parietes or cavities of the organ,—as you may perceive by the various preparations placed before you. Let us trace its effects.

The *left ventricle*, being placed immediately below the obstruction, becomes first affected; its parietes may be simply hypertrophied, or they may simply dilate from the engorgement of blood within it; or both cases may co-exist. The *left auricle* being a continuation of the ventricular cavity, becomes similarly diseased. As, therefore, the blood cannot flow freely from, but accumulates in these cavities, it follows that the four pulmonary veins cannot either freely pour their contents into the left auricle, and they consequently become permanently filled and engorged to their capillary extremities. If the pulmonary veins are engorged to their extremities, it follows also that the blood in the capillaries of the pulmonary arteries passes with difficulty into those of the veins; and the pulmonary arterial branches, as well as the artery itself, becomes preternaturally filled. The right cavities of the heart, being continuations of the pulmonary artery, become also in an engorged condition; obstruction exists; their parietes are hypertrophied, or their cavities dilate, or there is a coincidence of both conditions; and the heart acquires an enormous volume.

Thus, gentlemen, an obstruction placed at the commencement of the aorta may

affect the parietes and dimensions of all the cavities of the heart.

3. *Obstruction caused by diseased mitral valves.*—If the mitral valves be diseased, so as to cause obstruction, the same effects will be produced in all the cavities of the heart except of the left ventricle, which is placed before the impediment. Thus the left auricle becomes gorged with blood, its walls thicken, and its cavity dilates; the four pulmonary veins and the pulmonary artery are habitually distended; the cavities of the right side of the organ are similarly affected; and hypertrophy or dilatation, or both states combined, are the results.

[Numerous specimens were here shewn, exemplifying the facts, of obstruction of the aortic valves causing hypertrophy or dilatation of the different cavities of the heart, and obstruction of the mitral valves causing the same effects, except that in the latter case the left ventricle was in a comparatively healthy condition.]

But, gentlemen, diseased valves are not the only obstruction to the circulation; there are others, which, because they are not so obvious, are often overlooked: so that the heart often appears enlarged and thickened without apparent cause.

Obstruction from a contracted or dilated aorta.—The circulation of the blood cannot proceed in a healthy manner except there be a due relation between the caliber of the vessels carrying that fluid to and from the heart, and the capacities of the cavities of the organ itself. The vena cava, the pulmonary arteries and veins, are rarely diseased; but it is not uncommon to find the aorta considerably diminished or enlarged in its diameter; and either of these states becomes a cause of obstruction as much as diseased valves.

Let us suppose that the diameter of the healthy ascending aorta in the adult be an inch, the circulation proceeds with regularity; but if it be diminished to half an inch, the column of blood passing through it can only have the same diameter, or half an inch; but as the same quantity of blood has always a tendency to enter into the left ventricle, and the aorta is insufficient in breadth to discharge it, it accumulates, there is an obstruction before it in its course, the parietes of the left ventricle thicken, its cavity distends, &c. In fact, precisely the same effects are produced upon the walls and cavities of the heart as if diseased aortic valves were the cause of the obstruction. You see in this preparation [shewing it] that the ascending aorta and its arch is extremely contracted, that the left and right ventricles and auricles are hypertrophied and dilated, and that the heart has acquired an enormous volume.

Let us now suppose that the aorta, instead of being of the normal diameter of an inch, acquires that of two inches.

We will assume that the left ventricle, in its healthy state, can readily overcome the inertia of a column of blood contained in an aorta of an inch in diameter, and that then the force of the ventricle and the resistance of the fluid are so balanced, that the circulation proceeds without difficulty. Conceive, however, that the diameter of the aorta becomes increased to two inches, the column of blood within it will be of course of the same breadth—its mass is increased—its inertia is greater—it offers more resistance—it is a cause of obstruction—and the left ventricle becomes hypertrophied or dilated, to overcome it. The rest of the cavities of the heart participate in the same state, and for the same reasons as I described in speaking of the obstruction from diseased valves.

I believe, also, that obstructions to the circulation often exist at remote distances from the heart, causing that organ to be diseased. Thus it is by no means uncommon to meet with individuals labouring under hypertrophy or dilatation of the heart, who, from their occupations, are almost perpetually placed in bent positions—as tailors, shoemakers, weavers, &c. The tortuous course of the arteries must be as much a cause of obstruction to the current of blood circulating within them, as the sinuosities of the bed of a river retard the flow of the waters within it. Certainly these persons are frequently subject to diseased hearts, and they are often permanently relieved by ceasing their occupation, or by making them work in an upright position.

The parietes of the left ventricle are thicker than those of the right, because the blood has to be propelled to a greater distance from the former than from the latter. I present you with a curious specimen of malformation of the heart, in which the emerging vessels are reversed in their position. The aorta arises from the right ventricle, the parietes of which are hypertrophied; the pulmonary artery from the left ventricle and its walls are very considerably diminished in thickness. Do moral causes affect the dimensions of the cavities, or the thickness of the parietes of the heart? I believe so. But the organ probably then becomes diseased in consequence of the rapid movements it is often thrown into from the frequent anormal influx of blood into its cavities; the heart then has to propel forwards a fluid, and consequently to overcome a resistance too frequently, and finally becomes hypertrophied or dilated.

To sum up our views of the causes of increased thickness of the parietes of the heart, or of dilatation of its cavities, or of a combination of both states, we may observe that these conditions arise from obstructions at some point of the circulation within the organ, or anterior to it in relation to the course of the current of the blood. We may enumerate these causes as follows:—Obstruction from chronic diseases of the lungs; from diseased aortic or mitral valves; from a contracted or dilated aorta; from an habitually bent or curved state of the arterial system; from moral causes, inducing too frequently an excessive influx of blood into the heart; finally, too plethoric or too weak a state of the system may ultimately produce an anormal condition of the heart, as they do of the rest of the muscles of the body, so that it may become in a state of hypertrophy or atrophy.

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Continued from page 717.]

Diminished energy is generally the result of extraneous pressure upon a healthy nerve, or of such disorganization of the nerve itself as to destroy the continuity of the medullary filaments.

THIS is the last of the general propositions with which, in this investigation of the pathology of nerves, I started, and in considering which I shall for the present confine myself to the palsy of particular parts only, to the exclusion of those cases which may be denominated general palsy, whether assuming the form of hemiplegia or paraplegia. The latter diseases, connected as they commonly are with extravasation, effusion, or disease within the cranium or spinal marrow, hardly fall within the scope of my present inquiry; but a consideration of them would afford strong collateral and confirmatory evidence of the views which I entertain of the pathological character of the former.

Paralysis “which affects less than half of the body, or some one particular

part or organ*," has been denominated "partial palsy,"—a designation which has also been applied to those cases where there has been only diminished sensibility and muscular power, without a total annihilation of these functions. A term thus used, in contradistinction sometimes to more general, and sometimes to more complete and perfect palsy of the same part—sometimes meaning partial in extent, sometimes in degree without reference to extent, is somewhat equivocal, and therefore objectionable; and, upon the whole, it would probably be better to substitute, instead of partial, the word local, which conveys a more precise and accurate notion of that state, which has been well defined to be "a diminution, or an entire loss, of the power of voluntary motion, or of sensation, or of both, in some particular part or parts of the body, without coma." It is true that, consistently with the strict rules of nosological accuracy, neither alternative nor negative propositions should be admitted into a definition; but medical definitions are generally abstracts of histories, and in that of Dr. Cooke, the leading features of the malady are pointed out; it includes in its terms both the complete and the partial paralysis, with the affection of one function of a nerve to the exclusion of another, and saves us the necessity of instituting more minute subdivisions, which would enumber the memory without informing the judgment.

Local palsies occasionally arise from affection of the brain or its meninges; in conformity with the statement of Boerhaave, that "stupor and paralysis may arise in one particular muscle, and yet the fault may not be in that particular muscle, nor in the nerve, nor in the artery, nor in the veins, but in some particular part within the cranium." Palsies from such cause require much attention and active treatment, as they are frequently the precursors of more general attacks, being amongst the threatening indications of an approaching apoplexy or hemiplegia, neither to be misunderstood nor neglected with impunity. These often manifest themselves, as is well known, in the retina or other nerves of the outward senses, in the eye-lids, the fingers, or the muscles of the tongue. Examples of these local paralyzes from

congestion, pressure, or disease of the brain, are sufficiently numerous. I shall content myself, however, with one striking illustration, which was mentioned to me some years since by Mr. Stevenson, the eminent oculist, of Margaret-Street. A lady consulted that gentleman about some affection of her eyes, when his attention was much attracted by the extraordinarily slow articulation of the father, a clergyman from the country, who accompanied her. Upon inquiring of the daughter whether this was the father's usual mode of utterance, she did not appear to be particularly alive to any great change; but now that her attention was directed to it, she thought his mode of speaking might be rather more distinct and slow than was common to him. Mr. Stevenson, however, confident that there must be something decidedly wrong in this, strenuously advised that this gentleman should consult some physician of eminence; and he had the advantage of the advice of my estimable colleague, Dr. Maton, under whose judicious treatment his tongue was straightway loosened, and his utterance quickened. Amongst other measures, he was enjoined to observe strictly the regulation of his diet, in which he was to be very abstemious; but upon one occasion, overtaken by a storm, he was driven for shelter into a confectioner's shop, where, to insure his welcome, he devoured a couple of oyster patties. He was soon after seized with fatal apoplexy; and upon examining the interior of his skull was discovered an abscess of the brain, of considerable size, completely circumscribed, and evidently of no recent origin.

But local paralysis is much more frequent from injurious compression of nerves in their course, after they have left the brain or spinal marrow; according to the simple and perspicuous statement of Galen, that "if a nerve be compressed by any hard body which rests upon it, its function is interrupted." The observations and opinions of more recent writers upon this form of palsy, have tended to entangle a subject, in itself simple, in almost inextricable confusion. They have ascribed not only different, but even opposite, effects to the same cause, alleging that these effects will vary not only in extent, but in kind, according to the degree of pressure. A minor degree of compression,

* Cooke on Palsy, p. 46.

it has been alleged, will often be accompanied with excitement of a nerve, involving as its consequences neuralgia, if it be a nerve of sensation; muscular spasm, if a nerve exclusively of motion; and the combination of the two, if the nerve affected be a compound nerve, ministering at once to sensibility and to muscular movement. Such being the supposed result of the smaller, it has been universally believed that a greater and more complete pressure of the trunk of a nerve would occasion a diminution of energy, in the form of either simple anesthesia, or paralysis, or both. With a strange inconsistency, it was at the same time generally conceded that this paralysis might be partial and imperfect from a less, but complete from a greater degree of pressure. It was further thought, that where sensibility was impaired or destroyed, and the power of the muscles preserved, it was the result of a less degree of pressure than when both were affected. It was with them merely an affair of more or less, not of restriction to one set of filaments in the former, of affection of both sets in the latter. Even Mr. Abernethy was not aware that his packet of nerves consisted of fibrils of varied office; a point which it was left for the ingenuity and discrimination of Sir Charles Bell, followed by Magendie and others, to announce and elucidate.

It is obviously unphilosophical to ascribe not only different, but even contrary effects to the same cause; and, as far as I have been able to ascertain, this prevailing dogma is not borne out by facts. A minute inquiry into the details of this subject, an examination of the numerous detached cases to be found in the records of our art, point clearly to the conclusion, that such contrary effects as pain and convulsive movement upon the one hand, and impaired sensibility, with or without defective muscular power, upon the other, are in reality, as they might be expected to be, the result of causes differing rather in essence than degree; and that whilst the former of these effects are the consequence of the various causes of excitement which I have already considered with some degree of minuteness, the latter are the result commonly of pressure. In the former case the function of the nerve is disturbed by a diseased condition inherent in itself; in the latter, an undiseased nerve is compressed by some extraneous agent. The existence of dis-

ease in the nerve, whether simply thickened from inflammation, or the subject of morbid growths within its neurilemmatous investiture, will altogether alter the results of pressure, a slight degree of which, as has been already stated, will then produce agonizing pain, or violent spasms, or even in some instances, as in the case related by Dr. Short, an epileptic paroxysm*. This distinction has been long familiar to my mind, and has not escaped altogether the discrimination of Sir Charles Bell, who has very briefly adverted to it in relating a case in which "swelling of the parts within the orbit, compressing the fifth nerve, caused insensibility of the part of the face to which these branches were distributed, without affecting the motion." "When the tension and swelling subsided, there was returning sensibility; but more than this, the inflammation affecting the nerves in their passage through the orbit, gave the sensation of excruciating pain, perceived as if in the face†." Still, even by this distinguished physiologist and practical surgeon, the difference is neither made a source of leading, or even prominent distinction; nor does he always keep it in view in his writings. Galen was well aware of the difference of effect arising from compression upon the one hand, and inflammation upon the other, and he proposes the proper cure for the latter‡.

This distinction of the effects of pressure upon a healthy and upon a diseased nerve certainly deserves more attention than it has hitherto received, and should constitute an important element in our decision as to the propriety or preference of certain operations, as it will very materially modify the results. In a recent and very valuable paper by Mr. Travers, "On the Local Diseases termed Malignant," is a case of medullary tumor of

* Ed. Med. Essays, vol. iv. p. 334.

† On the Nervous System, App. p. lxxviii.

‡ Sed cum cerebro et medulla spine omnibus mu-culis non parva communicatio est, nam aut a cerebro aut a medulla spine nervum accipiant necesse est: qui visu quidem parvus, sed virtute minime parvus. Cognosces autem ex passionibus; nam incisus, oppressus, contusus, laqueo interceptus, schirris affectus, et putrefactus aufert musculo omnem motum et sensum. Quin et nervo inflammato non pauci spasmus correpti sunt et mente alienati: quorum quidam sic affecti cum sapientiorum medicum nacti essent, nervo inciso statim spasmus et mentis alienatione liberati sunt; sed postea musculum in quem nervus insertus erat insensilem atque inutilem ad motum habuerunt.—*De Motu Musculorum*, lib. i. cap. i.

the ham. "It had been about two years and a half in growth, and *was, from pressure upon the nerves, become exceedingly painful**." The pain was chiefly seated in the toes and outer side of the foot. The tumor was removed by careful dissection; the wound healed by granulation; the patient gradually improved in health, and soon afterwards became pregnant. In this case it is obvious that the fibular nerve was principally implicated, and the symptoms would have induced in my mind the belief that the nerve was inflamed; and unless the inflamed nerve were divided above the seat of inflammation, some recurrence of the symptoms might be anticipated. I would not, indeed, assert that such division would have been proper, because the nerve may have been merely inflamed from long-continued pressure, without partaking of the malignant tendency of the original disease; in which case, if the medullary filaments were not ulcerated through, the nerve might, upon the removal of the compressing tumor, recover its functional power; for, according to Haller, "*solutio vinculo, et in nervo non keso, musculorum usus restituitur.*"

That the operation diminished the patient's sufferings, although not distinctly stated, is to be inferred from the improvement of her health; but time was scarcely allowed for the complete restoration of the nerve to a healthy condition before this lady became pregnant, when again she "suffered from pain in the course of the sciatic and crural nerves,—so much so as to render the use of the limb very distressing. This was attributed to the *obvious circumstance of pressure*, and she was consoled with the prospect of its being soon relieved. However, on recovering from her accouchement, which was perfectly favourable, the incapability, and more particularly the pain, were greatly augmented. The pain followed especially the course of the nerves, but was diffused so as to render the slightest pressure upon any point of the surface intolerable." "There has been no delusion, or benumbing of sensation, such as pressure occasions; the whole character of the present complaint is neuralgia, and the only remedies affording any relief have been those of the tonic class."

This case is peculiarly interesting in

several particulars. It shews what has been the general impression, and consequently the ordinary language, with respect to the compression of nerves; and that it is often employed when the dependence of the symptoms upon pressure has been by no means ascertained. It is stated in general terms as an undeniable, if not self-evident proposition, that the tumor "*was, from pressure upon the nerves, become exceedingly painful.*" But this statement involves two substantive propositions, one being the assertion of a fact, the second a mere expression of an opinion. It is a fact that there was pain; it is merely an opinion that the cause of that pain was pressure. The first admits not of question; the assertion, though expressed somewhat ambiguously, is conclusive. It was, perhaps, rather meant, that the tumor by pressure upon the nerve had occasioned pain, referred to the remote distribution of its filaments, than that the tumor itself was exquisitely painful. That simple compression, however, occasioned the pain, requires evidence in its support, and yet no other proof is offered than that there was a tumor, and that there was pain; and yet "there was no delusion or benumbing of sensation, such as pressure occasions." But notwithstanding the absence of these notorious effects of compression, the intelligent author of the paper on malignant diseases referred the original painful affection of the nerve to that cause, and appears to assent to the proposition, that its subsequent return with aggravated violence during pregnancy was also owing to "the obvious circumstance of pressure." But the pain returned or continued after the causes of pressure had ceased to operate; first, upon the removal of every vestige of the tumor, and afterwards in consequence of the delivery. Even, therefore, if the original painful affection of the nerve was at least the *indirect* effect of pressure, which is not improbable, it was afterwards clearly kept up by some other cause; and the observations I have already made upon the subject of the inflammation of nerves render it extremely probable, that inflammation gluing the nerve to contiguous parts was that cause; and this probability is reduced almost to certainty, when it is considered that after the removal of the suspected causes of pressure—the malignant tumor, and pregnancy—the suffer-

* Med.-Chir. Trans. vol. xvii. p. 330.

ings returned with even "aggravated violence," not only in the branches of the nerve within the range of the tumor, but also in those of the anterior crural, which was completely beyond its reach. Such being the condition of the nerve in this, as in all similar instances, the slightest pressure either from within or without would produce a paroxysm of pain, or aggravate the suffering.

Analogous facts were observed, and similar opinions entertained, by the late Mr. John Pearson, with regard to the instances which he has minutely detailed, of what, since his time, has been described by Mr. Wood and others, under the designation of painful subcutaneous tubercle. The symptoms seated in the leg were very similar, were aggravated by pregnancy, and came on without assignable cause several times in the day. It was also observed that the severity of suffering was increased not only during pregnancy, but even during menstruation; and that, in the latter months of gestation, the duration of each paroxysm was extended to an hour and a half. "Each of these attacks was accompanied with an increased redness, and a sensible elevation of the indurated part; and the paroxysms of pain were excited by every thing that accelerated or otherwise disturbed the circulation of the blood, whether applied to the induration, or affecting the general system; as, all strong exertion of the muscles, external impulse, or mental commotion." Mr. Pearson, however, in conformity with the opinions then, as now, prevalent, "that a certain degree of pressure upon a nerve will produce pain, spasm, and convulsions," considered that all these causes acted upon the principle of compression; the nerve, though surrounded by inflammatory thickening, not being in a diseased condition. In pregnancy he thought the aggravation of the symptoms was owing to distention of the vein, which, together with the nerve, was "included in the tumor. This fact was clearly demonstrated after the exfoliation of the eschar; for I then saw a portion of the vein hanging down at the superior part of the sore, and the naked nerve in contact with it." He further imagined, that during parturition her sufferings were increased by the greater quantity of blood sent to the part by the violent action of the heart and arteries, for then, "to use her own expression,

she had 'all her labour pain in her legs.' " Thus the increase of pain is referred to mere venous distention at one time, to vehement action of the arterial system at another, both, however, being supposed to act upon the simple principle of pressure; for, adds Mr. Pearson, "we may, perhaps, venture to conclude, that the vein and the nerve being confined within a substance that could not easily be distended, whenever the vein became preternaturally turgid, the nerve was compressed between its parietes and the internal surface of the induration; and that, consequently, the symptoms were connected with this state of the part." The proof, however, of the distention of the vein is very unsatisfactory, and, indeed, is only offered as a probable explanation, in these terms: "it is *highly probable* that the portion of vein which passed through the tumor was unusually distended with blood at the time of the paroxysm; for upon these occasions the morbid surface became redder than common, and the tumor was sensibly elevated." Now without entering into any minute critical analysis of this sentence, it may suffice to state, that there is no proof adduced of such enlargement of the vein, and that in another case, although it was suspected that the tumor might be connected with the saphena minor, and might, consequently, "include or compress a small branch of the sciatic nerve," yet, as the cutaneous veins of the leg could not "be rendered turgid by moderate pressure, its exact situation could not be ascertained." Besides, mere distention of a venous trunk does not produce surrounding redness; redness may occur without venous enlargement, and above all, this redness, with even slight intumescence, is of constant occurrence in parts the subject of neuralgia, where there is no tumor to be influenced and no contiguous trunk of a vein to be distended. The redness noticed by all the best authorities, including Earle, Swan, and Descot, is now universally ascribed to an increased action of the arteries of the part, and is generally the consequence, rather than the cause, of the attack. I know that upon this point there has been some discrepancy of opinion, and that Mr. Earle is disposed to think it rather the cause than consequence; but in general the weight of testimony is in favour of the opposite relation, although occasionally,

or by reflux influence, vascular excitement may at least aggravate a paroxysm. An attack of neuralgia of the face has been very frequently induced by a current of cold air, which can hardly increase the circulation in the part—by the slightest touch, as in Mr. Wardrop's case—by the pressure of the stocking, or the bed-clothes, as in one of the instances which fell within my own observation, and in one related in Mr. Wood's communication in the *Edinburgh Journal*; and in these it must be clear that the impression was made first upon the nerve, and that the redness was a secondary effect.

But in combating an impression so general as that which I have been considering, it may be requisite that I should examine more at large the evidence upon which it rests; and I shall do so with, I trust, all becoming deference to the opinions of my predecessors and contemporaries, who are perhaps, after all, better able to come to right conclusions upon the subject. One of these, whose eminence as a surgeon and whose erudition have raised him far far above my censure or my praise, thus represents the state of our knowledge at the period at which he wrote:—"I do not suppose (says Mr. Pearson) that it will be necessary for me to undertake a proof in detail, that a certain degree of pressure upon a nerve will produce pain and spasms; it may be sufficient for my purpose to refer to a few of the many instances which are recorded in medical books*." Of these he has collected many examples, with which his literary habits readily supplied him, and it will be seen in the sequel how little they bear him out in the enunciation of his principle, which he evidently believed to be of universal application. His first case was one, not of extraneous pressure upon a healthy nerve, but a disease which I have already noticed amongst the causes of excitement—the hard, gritty, or cartilaginous tumor itself; and cured, not by the excision of the tumor to the exclusion of the nerve, but, as Mr. Pearson himself states, "by removing the tumor and dividing the nerve." Had the disease consisted merely of a tumor covering and compressing the nerve, without their being glued together by inflammation, or without the tumor being incased in the substance of the nerve, there could have been no ne-

cessity for dividing and removing a portion of the nerve, as was done, together with the tumor; the removal of the latter would have been sufficient. It appears, however, that Dr. Short thought it requisite at least to divide, or rather to excise, the portion of the nerve on which the disease was seated. "It was a hard cartilaginous substance, or ganglion, seated on a nerve which I cut asunder and took out the tumor." The pathological character of this substance identifies it as a disease of the nerve itself; for the tumors of smaller size, which are frequently found in the substance of nerves, are commonly gangliform enlargements of the nerve itself, of a gritty or cartilaginous hardness; according to the majority of the French writers, of a scirrhous character, and even essentially carcinomatous, blunting the knife with which they are cut, and producing, when cut into, a grating sound like the cutting of bone or gristle. The symptoms also, identical with those which present themselves in the painful subcutaneous tubercle, and other tumors of nerves, mark the case as one, not of simple pressure of a tumor upon a subjacent healthy nerve, but rather a morbid interstitial deposit in the nerve itself, rendering it peculiarly sensitive to the slightest impressions; so that, in Dr. Bisset's case, "on being rudely touched with a finger, or the skirts of her petticoat, the spasmodic pain was instantly excited*."

Still less does the case quoted briefly from Guattani afford even corroborative evidence of the truth of Mr. Pearson's general statement; for in that instance, if the morbid condition was really that of pressure, it is clear that the nerve must have compressed the tumor, rather than the tumor compressed the nerve. In the delineation of the parts which accompanies and illustrates that case, the popliteal nerve is distinctly represented running over the aneurismal tumor, upon which it was expanded like a girdle. The nerve was flattened by gradual extension, so as to be at least three quarters of an inch wide, and seems from the engraving to have adhered to the surface of the tumor. This circumstance renders it more than probable that inflammation had occurred in the nerve itself, and this opinion is much confirmed by the following considerations:—1st. That although there was

* Med. Facts and Obs. vol. vi. p. 101.

* Mem. of the Med. Sec. of Lond. vol. iii. p. 60.

pain near the tendo achillis, yet no violent spasms occurred in the limb until after the application of strong pressure to the tumor, with a view to the cure of the aneurism by the obliteration of the artery; and it is unnecessary to point out how likely this kind and degree of pressure was to aggravate, if not to produce, inflammation of the nerve thus expanded over the tumor, and thus subjected to such powerful compression. 2dly. That this was the only instance of popliteal aneurism in which Guattani, with all his experience, had ever met with such convulsive pains, which must have occurred, if "a certain degree of pressure upon a nerve will produce pain, spasms, and convulsions." 3dly. That Guattani assures us of the impracticability, in that instance, of tying the vessel without including in the ligature both the nerve and the vein; and, lastly, that the tumor could not even have been opened without wounding the expanded nerve*.

These were the impressions upon the mind of the author, from an examination of the parts after death; and such observation would have been little better than absurd, if the nerve had really not been agglutinated by inflammatory adhesion to the surface of the aneurism, over which it was spread. Had it remained loose and moveable, though stretched, it surely could have been pushed to one side during the operation, as the par vagum and other nerves are frequently held beyond the reach of the knife in surgical operations upon contiguous tumors or arteries, and this could not have escaped the sterling common sense of Guattani. Besides, the vein was tied by inflammation to the tumor, and it was this adhesion which rendered the application of a ligature, without including the vein, impracticable: it is probable, therefore, that the nerve also adhered to the tumor, and that this would have rendered it impossible to tie the vessel, or even to open the tumor for the purpose of securing the artery, both above and below the opening, without also including in the ligature, or the incision, the nerve itself.

[To be continued.]

A FEW OBSERVATIONS
ON THE
PARALYSIS PRODUCED BY LEAD;
With Cases.

By H. M. HUGHES, M.D.

[Concluded from p. 727.]

SIR GEORGE BAKER, on the authority of Dr. Reynolds, mentions the case of a gentleman, who was affected with temporary paralysis of the sphincter ani after the use of Goulard's lotion to piles. Dr. Cook relates that of a gentleman who suffered from temporary loss of power of one side of the face, for which no cause could be assigned but that of sleeping for two or three nights near a door recently painted "dead white," the part affected being that which was most, if not solely, exposed to the long-continued influence of the deleterious mineral vapour. Dr. Percival has placed upon record three cases illustrative of the present subject: that of a child, which was allowed by its nurse to run about with naked feet on the warm sheets of lead in its father's workshop, and which was in consequence affected with severe colicky pains, delirium, and temporary loss of power in the left leg and arm; that of a man, accustomed to sit before the fire with his feet upon a piece of lead, whose lower extremities were the seat of slight temporary palsy; and that of a dog, which, from constantly lying in the same situation, was deprived of the use of its limbs. Many individuals, accustomed when at work to handle lead, have suffered primarily and solely from a paralytic state of the hands; but I do not recollect to have seen or heard of an instance of *partial* palsy from this source, without preceding or attendant colic, in which the lead had been taken internally. It is almost universally found, that the right hand, as that most used and exposed, is the first and most severely affected. Clutterbuck relates the case of a painter, whose right hand failed so much as to incapacitate him from grasping the brush; it was therefore transferred to the left, which was at the time in perfect possession of its power; in a short period, however, (I think about two weeks), this also was so completely enervated as to compel him altogether to resign his occupation. The same general inference

* Ad perficiendam vincturam necesse fuisse nervum nervumque simul constringere.—Multo minus expediebat methodum aggređi aperiendi tumoris, quod hoc in casu fieri non poterat quin necessario ita expansus nervus in ipsa apertione dissecaretur.—Guattani, in *Louth's Collection*, p. 165.

may be drawn from the particular affections to which the different workmen in lead are especially prone. Thus, from my own observation, I should say that type-founders and printers' compositors are decidedly most liable, if not solely, to palsied hands. The persons employed in the white lead factories, where large quantities of the dust may be reasonably supposed to be inhaled and swallowed, are more generally attacked with colic and constitutional symptoms; while painters appear to hold a middle rank, sometimes being first attacked with colic, at others with external paralysis. Similar conclusions may, I think, be derived from the comparative effects of constitutional and local remedies; for though I am aware that in some instances in which the health has suffered from long exposure to a poisonous atmosphere, or from continually swallowing small portions of the metal in the shape of medicine, ordinary beverage, or diet, much benefit is derived from improving the constitutional powers,—though balsam of Peru and tr. guaiaci volat. were considered almost as specifics by Sydenham and Fothergill,—and though, when opposing the opinion of metastasis in colica pictorum, Van Swieten says he has cured several persons affected with palsy of the hands by internal remedies and applications to the abdomen, without doing any thing to the palsied limbs,—yet there are, I am convinced, some cases—and those not a few—in which, the general health having suffered but little, or been restored, constitutional means produce little or no effect; but local stimulants are exceedingly and immediately beneficial. Perhaps *nux vomica*, and its active ingredient strychnia, may be considered as an exception; but even this, acting *through* the general nervous system (when its effects are moderate), exerts its specific influence upon the nerves of the parts paralysed. This is, however, certainly not always the case, as I have seen it not only produce no good effect, but appear really injurious; and in other examples have known the muscles of almost all the external parts violently affected by its use, *except* those of the paralysed hands.

The case in which Dr. Pemberton first employed splints is curiously confirmatory of the local nature of the disease. He applied the board, in the first instance, to the right hand and arm

alone. In two months this had perfectly regained its power; while the left, being unsupported, remained as enervated and useless as before. The splint was now applied to it, and the nervous energy returned in three months as perfectly as it had previously in the right.

On the supposition that lead had been absorbed and still existed in the body of persons affected with this species of palsy, sulphur has been recommended and used, with the intention of forming, by their combination, an insoluble, and therefore inactive, sulphuret. Though, when conjoined with other topical and constitutional remedies, I have given sulphur with apparent advantage, yet, when given alone for a fortnight, though the general health seemed benefited by its exhibition, not the slightest improvement took place in the palsied limbs.

Mercury was several years ago recommended by Dr. Clutterbuck, in consequence of its inducing a state of the system directly opposed to that which is the result of the poison of lead. I have not felt justified in producing salivation in this affection in persons whom I had usually an opportunity of seeing only once a week; but in a man who was constitutionally and rather severely influenced by mercury in alterative doses, there appeared, in consequence, little or no improvement in the power of the arms; on the contrary, blisters to the wrists, stimulating liniments, the support of splints, electricity, and the local applications of the water of the hot springs of Bath, have been universally efficacious. Many of the above statements will, I think, be confirmed by the following cases, which I have related with all possible brevity consistent with distinctness as to their leading features, but in each of which will be found, if I mistake not, some points of interest.

CASE I.—Alfred Green, aged 28, of healthy appearance and clear florid complexion, and visibly cleanly in his habits, had been a painter for fourteen years, but never suffered from colic or local palsy. For the last two years had experienced weakness in the left leg; this, during the last three months, had extended to both arms, and was accompanied with a sensation of tightness, stiffness, and debility on motion, in most parts of the body; he had never been troubled with giddiness or headache;

had no pain or tenderness of the spine; recollected no accident or particular exposure to cold which could account for his present symptoms; his general health was good; bowels usually constive; tongue pallid, moist, and creamy; pulse small and frequent.

Ordered, January 19th.—

Pil. Coloc. c. Pil. Galban. c. aa gr. v. omni. nocte, with Inf. Gentian. c. ʒiiss.; Sodæ Carb. gr. x. bis die.

Jan. 16th.—

Inf. Gentian. c. ʒiiss.; Magnes. Sulph. ʒss.; Tr. Hyoscyami, mxx. ter die; with a stimulating liniment to the affected parts:

By the use of which he is gradually, though very slowly, recovering from his complaint.

CASE II.—William Hobday, aged forty-three, a “musician,” or, in other words, a pale, thin, sickly-looking, itinerant performer on the clarionet, feeling unwell, applied, two or three weeks before I saw him, to some quack, who gave him pills, which produced a very severe salivation, with ulceration of the lips and cheeks; for this he was successfully treated with saline aperients, tonics, with the mineral acids, gargles, &c.; but as I observed a want of power in the right arm and wrist, I inquired the cause and duration of the complaint, and found that seven years previously he had been a painter, and had before that time been more than once attacked with colica pictonum and partial palsy; also, that though when in good health he enjoyed the perfect power of the part, whenever he suffered constitutionally, the “right hand dropped.” On this occasion, as before, in proportion as the general strength returned, the local affection decreased, and at length it altogether disappeared.

CASE III.—Samuel Dunnington, aged 39, a slight, pallid, delicate-looking man, employed for the last sixteen years as a type-founder, had never suffered from colic, or previously from palsy, but observed, four days ago, that the ring and little fingers of the right hand were powerless. He made no other complaint excepting of slight pains in the shoulder and arm, but his bowels were constipated, and his countenance indicated sluggish hepatic circulation. On inquiry it appeared that his particular department was to rub, for the purpose

of smoothening the recently-cast type, and that for this purpose he used the fore and middle fingers alone. If the metal acted as a direct local sedative, these, therefore, appeared the parts that should have been affected by it; but I found that these two fingers were constantly guarded from the small rough projecting portions of the composition by a thick and strong piece of leather, and that the other two hung loose, and came, therefore, in frequent contact with powder and abraded particles removed by friction.

October 10th.—After a free action upon the bowels, he was ordered the

Peruvian Balsam, in the form of mixture, and a blister to the wrist.

17th.—Fingers stronger, and health improved. Ordered

Pulv. Nucis Vom. gr. iij. omni nocte, and a stimulating turpentine liniment.

24th.—No spasm or twitches from the nux vomica, but fingers increasing in power.—Pergat.

He had not the specific effects of strychnia produced, but gradually, though, as is usual in these cases, slowly, regained the use of his fingers.

Here is what I consider to be a very singular exemplification of the local sedative operation of lead, though perhaps by some it may be regarded simply as a coincidence; if this be true, it is certainly a very curious one.

CASE IV.—Joseph Spearman, aged 39, pale in countenance, sickly in aspect, and apparently not very cleanly in habits, had been a painter for eighteen years; had been attacked with colic two or three times, and was two years ago under my care for palsied hands, of which he was cured rather quickly by blisters to the wrist, and general stimulants. His present affection was preceded by colic, and was extremely well marked, both hands being badly, but the right the more severely, paralysed. After some aperient medicine, he was ordered

Sulph. Subl. ʒj. bis, terve die.

But though in a fortnight his health was good, there was not the slightest perceptible change in the hands, and he was anxious to return to the plan formerly so efficacious. I thought myself justified in withholding it no longer; he was therefore ordered

Blisters to the wrists, to support his hands on splints, and to take a mixture of Gentian and Ammonia.

In a week's time he said his health was as good as it ever was in his life; and, indeed, in each succeeding week much progress was made as to the power of the hands, till three grains of powdered nux vomica were directed to be sprinkled every night on the blistered surface of one side. After using it for a few days, he said that though no spasmodic twitchings have occurred, the hand and wrist to which it was applied became much weaker; an observation which I was enabled to verify by experiment: it was therefore discontinued. His mixture was occasionally altered for one of balsam of Peru, and he latterly employed a liniment of turpentine, mustard, and ammonia, with excellent effect. In this man I observed, what, in cases of long standing, I presume uniformly occurs—viz. that when regaining the power of the parts, he could extend either the fingers or the wrist separately, but not at one and the same time; and that both actions were performed by the extensor digitorum communis. The advantage thus gained by the muscle is too obvious to require explanation. Does it shew that though the nervous energy had returned, the muscles, wasted by long inaction, had not yet regained their accustomed vigour? The next two cases are given from recollection, as of them I took no notes.

CASE V.—, aged about 35, a tall, thin, but healthy-looking man, had been (I think) a printer's compositor for many years; had never suffered from colic, or previously from palsy, but now had a paralytic *right* hand and wrist. He was ordered simply an occasional aperient, a blister to the arm, on which was to be sprinkled, every night, pulv. nucis vomice, gr iij. The blister was repeated weekly, and the powder slightly increased. Spasmodic twitches were frequent in the affected limb, of which he completely, and rather quickly, regained the use.

CASE VI.—, aged about 45, for many years had been a printer's compositor, of not unhealthy aspect, had never been afflicted with colic, but once before had a slight paralytic affection of the hands. Some weeks previously to coming to me, he felt a weakness of the

right hand and fingers, which increased so much as to incapacitate him to grasp the type. The left hand being very little, if at all, enervated, he picked up the letters with it, and transferred the "frame" to the right; but, in a short space of time, the left also became so powerless as to oblige him to resign his work. When first seen, the right hand was very severely palsied, the left in a slighter degree: his general health was tolerably good, though his bowels were irregular.

Ordered splints; Sulph. Sublimat. ʒss. ter die ex haust.; Bals. Peruv. &c.

He improved considerably under this plan, which, with slight modification and the addition of a stimulating liniment, was continued till he was able to return to his work, which, however, did not take place till after the expiration of a considerable time.

The two succeeding cases occurred in the clinical ward of Guy's Hospital, and were there seen by me during the last and the present session.

CASE VII.—Thomas Sadler, aged 42, a painter for 28 years, but never suffered from his business till eight years ago, when he had paralysis of the hands, of which he was cured in eleven weeks, by the water of the hot spring at Bath. Since this, he has been twice attacked with colic. Three months ago he observed that his hands were again becoming weak. This weakness increased till his admission into the hospital; when, in addition to the local palsy, he complained of severe abdominal pain, increased on pressure; the bowels were confined; tongue loaded, and moist; pulse 64. He was treated as usual for the abdominal affection, with the addition of cupping and alterative doses of blue pill, &c. by which he was (I believe) unintentionally, but rather severely, salivated for a week. He then took a mixture containing Peruvian balsam, used splinters, &c. but by neither was the paralysis much, if at all, affected; he was therefore ordered to be electrified. This was done with benefit for two days; but as he was rather frightened at the electric effect, he left the hospital for Bath, where he had been previously cured.

CASE VIII.—Thomas Keen, aged 36, a painter from youth, but had (I think)

never been attacked with colic. He was, three weeks previously, obliged to leave his work in consequence of weakness of the hands. He also suffered from pain of the shoulders, arms, and back; his tongue was loaded; his bowels open from medicine; pulse 72; general health good.

Nov. 1st, ordered Tr. Guaiaci Volat. ζ ss. ter die. 28th, Pergat. To be electrified.

December 10th.—But little improvement.

Mist. Balsam. Peruvian. ter die. The hands to be supported by splints.

22d.—Little alteration. Strychnia, gr. $\frac{1}{4}$ ter die, was then ordered, and continued, with some variation of dose, to January 15th, when a blister was applied to the left hand, and strychnia gr. $\frac{1}{4}$, sprinkled upon the blistered surface.

16th.—So much spasmodic twitching of the muscles as to prevent sleep.

Rep. Strychnia altern. auroris.

19th.—Last evening attacked with violent tetanic spasm of the muscles in the throat, neck, abdomen, back, and lower extremities; but the forearms and hands were not affected in the slightest degree. The dressings were removed, and a poultice, sprinkled with a few drops of tinct. opii, applied with advantage. Quiescent.

24th.—Very slowly progressing; 1-16th of a grain of strychnia was now introduced into the back of the hands alternately, by means of a small incision, with the effect of inducing twitches in the parts to which it was applied, but with little improvement in the disease.

February 4th.—Thirst.

Balsam. Peruvian. ter die.

10th.—Very trifling improvement. The electric anra, with a few shocks, was now administered by the clinical clerk (Mr. Bird), with decided advantage, and he was discharged on the 24th, very considerably relieved.

A glance at the preceding briefly related cases will shew, not only that (as in No. 1.) lead produces general muscular debility—a fact that must be familiar to most persons accustomed to hospital practice, and that many who suffer from external local paralysis have not previously been attacked with colica

pictorum (as in Nos. 3, 5, 6, 7, and 8), but also that some individuals whose hands have solely come in contact with the poison, have been affected in those alone (as Nos. 3, 5, and 6.) It will also appear from No. 2, that when the hands suffered from this species of palsy, though many years have elapsed since the apparently perfect restoration, the local affection or paralytic weakness is liable to return, under severe disorder of the system at large. This I consider interesting, as shewing the cause of the secondary or subsequent attacks being more tardy of cure than the primary, and as appearing to prove that, at least in this one instance, a permanent impression had been made upon the nerves of the limb. It will also be seen from almost all, that topical applications of a stimulating kind, as, indeed, has been before observed, are most effectual in removing the local complaint.

From all that has been written, perhaps I may be allowed to suggest the following deductions:—

1. That different individuals, and the same individuals at different times, vary extremely in their susceptibility of the operation of lead.

2. That this mineral, when taken in small repeated doses, is capable of producing general paralytic weakness.

3. That from its action, true paralysis of the muscles occurs in other parts beside the upper extremities.

4. That the colon, or other part of the intestinal tube, is especially liable to be affected by it.

5. That this affection probably depends on debility of the muscular coat.

6. That it is doubtful whether the pains in colica pictorum are attributable to spasm, or to spasm only.

7. That the muscles of the hands are, perhaps, particularly obnoxious to its deleterious influence.

8. That it frequently produces palsy of the muscles moving the part to which it is applied; and from this cause the hands are more subject to palsy, occasioned by it, than other parts.

9. That its operation appears to be that of a sedative, whether general or local in its action.

10. That the local paralysis is most effectually removed by topical stimulants, if the general health has not materially suffered.

13, Wellington-Street,
London-Bridge, Feb. 6, 1835.

ON A NEW SYSTEM OF WEIGHTS
AND MEASURES FOR THE
PHARMACOPŒIA.*To the Editor of the Medical Gazette.*

SIR,

As it is understood that the College of Physicians have in preparation another edition of their Pharmacopœia, and as the practice of medicine in this country is likely, in other respects, to be shortly made a subject of legislative regulation, it seems to be a suitable season for inviting attention to any points in which there are useful alterations to be made, and requiring the sanction of authority. The system of weights and measures, at present employed in medicine, is very obviously one of these; and the legislature has of late directed its attention to this subject in general, and actually introduced, by force of law, several considerable innovations, whose utility will no doubt in due time be fully appreciated. There can be little doubt that should the College be desirous of taking the opportunity to introduce an improved system into the medical department, they would find no difficulty in obtaining the sanction of the higher powers. Nor do they want a precedent for such a step, as they have already, and recently, done a similar thing in the instance of our fluid measures. I am not aware whether any thing of this kind is actually in contemplation; not improbably this is the case. But as the subject is really one of much interest and practical importance, I hope it will not be thought unbecoming, even in a country practitioner, to offer a few suggestions respecting it.

At present we use two distinct sets of weights—not to say three; for our system of fluid measures, which is regulated by weight, involves the recognition of a third: thus we have the troy ounce, of 480 grains; the avoirdupois ounce, of 437.5 grains; and the fluid ounce measure, containing 454.5 grains of distilled water. This is not only exceedingly inelegant and clumsy—it is not only troublesome and vexatious—but it almost inevitably leads to confusion and mistake. This is too obvious to require proof or illustration: every practitioner, every chemist, feels it for himself. The inconvenience of the present system is so great, that we cannot for a moment suppose that any difficulty would be en-

countered in obtaining the practical concurrence of the profession in any judicious alterations that might be introduced by proper authority. Nor is it, I think, difficult to determine the principle on which those alterations should be made.

The late acts of the legislature have established the avoirdupois pound as the basis of one system both of weights and measures, for all general commercial purposes. The avoirdupois weight is further recommended by its antiquity, as its ounce is considered to be as nearly as possible identical with the ancient Roman ounce. I suppose, therefore, that there can be no doubt that if it should be decided to abandon one of our two present systems of weights, that one must be the troy. Indeed, the sapient maxim, which tells us to go to the mountain when we find that the mountain will not come to us, requires this. The authorities of our profession are able to substitute the avoirdupois for the troy in medical practice, but they have no power to induce the commercial dealers to do the reverse.

Assuming, then, that we must retain the avoirdupois pound and ounce, it is evident that the desideratum will be avoirdupois grains; and the only question is, into how many ought the ounce to be divided? I shall not pretend to decide this question with confidence; but I beg leave to propose what has appeared to me, on reflection, to be most advisable;—this is, to divide the ounce into 400 grains, instead of 437.5, which it now contains. We shall thus go with the commercial dealer as low as the quarter of the ounce (which I believe as low a weight as is much used in commerce) on the principle of halving and quartering, and then, for our own and scientific purposes, we shall begin with decimals. Taking the $\frac{1}{4}$ ounce to be units, the grains would be in decimals; thus 3.25 would give 3 quarters and 25 grains. It might be proposed to divide the ounce into 500 grains; but this, I think, would be less convenient, because the number 500 can be only twice divided by 2, whereas 400 can be four times so divided; and this is not more than is required to correspond with the present dram avoirdupois, and therefore not more than we may presume to be found convenient for commercial purposes. Our plan would give the dram avoirdupois the lowest commercial

weight, equal to 25 grains. Retaining the present relative value of our dram and ounce, the former would of course be 50 grains; and it might perhaps be well to let our scruple pass for 25 grains; but this is immaterial. Our enlarged avoirdupois, or rather our new apothecaries' weight, would then stand thus:

Pound.	Ounces.	Quarters.	Drachms.	Grains.				
1	=	16	=	64	=	128	=	6400
		1	=	4	=	8	=	400
				1	=	2	=	100
						1	=	50

It is of course in some measure objectionable to give, as we here do, a new value to the old denominations of drachms and grains; but there is no alternative but that of introducing names absolutely new. The change in value here proposed is so slight, that it does not appear that any practical evil can result from retaining the old names. The relative value of the new grain to the troy grain will be as 437.5 to 400, or nearly as 12 to 11; which I think is too inconsiderable a difference to produce any injurious mistakes, even in the administration of the strongest medicines.

The ease of our fluid measures is very simple: it is but to make our fluid ounce measure such as will contain an avoirdupois ounce of distilled water. The fluid ounce might, as now, be divided into 8 fluid drachms. As regards the minims, which ought, for practical purposes, to represent, as nearly as possible, natural drops, or guttæ, and that perhaps rather of spirituous than of aqueous liquors, it might be proper to ascertain what numerical relation between them and the fluid drachm would be most suitable to this purpose, and to assign their value accordingly.

I am, sir,
Your obedient servant,
T. F. BARHAM, M.B.

Exeter, Feb. 15, 1835.

EXTIRPATION OF FUNGOUS TUMORS OF THE ANTRUM.

To the Editor of the Medical Gazette

SIR,

IN a clinical lecture on Diseases of the Maxillary Antrum, by Sir B. C. Brodie,

which I have lately seen in the 366th number of the MEDICAL GAZETTE, it appears (p. 351) that that eminent surgeon disapproves of the practice recommended by Desault, of extirpating fungous tumors of the antrum, and endeavouring, by the free use of the actual cautery, to prevent their regeneration; and he doubts the reality, or at least the permanency, of the cure, in a case reported by Desault.

This opinion seems to be the result of one, and only one, unsuccessful case in Sir Benjamin's own practice, where, however, the actual cautery was not used immediately on the removal of the fungus, but only after the failure of "blue lint," and other escharotic applications.

I agree entirely with Sir Benjamin as to the fatal tendency of this disease when it has burst the boundaries of the antrum and cheek; but as he seems to consider it uncontrollable before this period, and has not pointed out any means of subduing it even at an early stage, I consider it of some consequence to decide how far it is warrantable to attempt a cure under such circumstances.

With reference to this point, therefore, I take the liberty of referring such of your readers as may be interested in the subject to a case which I have reported in the second volume of the Glasgow Medical Journal (p. 74), where a tumor of this kind was extirpated after it had produced complete absorption of the bone, and where the actual cautery was freely applied to the whole of the diseased surface.

This patient died of pectoral inflammation *five years and a half afterwards*, when she had just recovered from the operation of removing nearly the whole of the *lower* jaw. On a minute examination of the antrum, which I believe is still in the possession of my friend, Professor Burns, the former disease was found to have been permanently cured by the operation.

I shall not occupy more space in detailing the particulars of this case, as it is already published; but I shall feel indebted to you, or any of your correspondents, who will refer me to other published cases, or communicate any of their own, together with the mode of treatment which may have led to a permanent cure.

In the meantime, I confess that in such a case as that above noticed, even in the face of an authority so deservedly high as that of Sir B. C. Brodie, I should scarcely be disposed to relinquish the prospect of a similar result by leaving the patient to his fate.

I am, sir,

Your obedient servant,

A. D. ANDERSON, M.D.

M.R.C.S.

EXCISION OF NERVES EXPOSED IN AMPUTATION.

To the Editor of the Medical Gazette.

SIR,

DR. LEE, in one of his late interesting communications on the Pathology of the Nerves, has stated the opinions and practice of Mr. Langstaff and Mr. Swan in favour of the occasional excision of an additional portion of the principal nerves which have been exposed in amputation, in order to prevent the occurrence of any painful affection of the stump (p. 659).

Whether Baron Larrey has recommended this practice in any of his works I cannot tell, but I saw him adopt it in a case of amputation of the arm, which I witnessed at the Hôpital de la Garde Royale, in December 1828. The patient was a soldier. The case was, I believe, scrofulous disease of the elbow-joint. There was considerable emaciation both of the body and of the diseased member. After the amputation, the operator drew out first the median, and then the other principal nerves, and cut off a portion about an inch in length from each. The reason assigned by the Baron was, that he wished to prevent adhesion of the nerves to the cicatrix, which, when it was allowed to take place, frequently caused an irritable stump.

Yours respectfully,

JOHN MANX.

SOME OBSERVATIONS ON PHLEBOLITES*.

BY DR. JOHN REID.

THE accompanying preparation is a portion of one of the broad ligaments of the uterus, in the veins of which are observed a number of small, rounded, osseous-looking bodies, which have received the name of phlebolites. They are described by Beclard, in his *Anatomie Générale*, under the chapter on Veins, and by Jules Cloquet, in his *Pathologie Chirurgicale*; but I am not aware of their having been noticed by any English author†, though they must have occasionally been seen by those much engaged in dissections. Their presence does not appear to be attended by any bad effects, and they consequently possess little practical importance; but the nature and cause of their formation may, ere long, become an object of considerable interest in physiology, as serving to strengthen or confirm some of the doctrines concerning the living fluids of the body. They cannot be considered as of rare occurrence. I have now seen them in five instances, and four of these have been within the last twelve months. In three of these they were found in the uterine veins; in one (a male) in the vesical veins; and in the present case both in the vesical and uterine. They varied in size, from that of a millet-seed to that of a large pea. They varied in number, from two to more than a dozen. In all the cases in which I have examined them, they seemed to be placed loose in dilatations of the veins, allowing sufficient space for the blood to pass between them and the coats of the vein. Some of these veins were of very small size in the undilated portions, and required a careful examination to be convinced that they were placed in veins; while others were of sufficient size to render this almost apparent at the first glance. The subjects in which I found them were all advanced beyond the middle period of life.

Beclard and Cloquet describe them

* Edinburgh Medical and Surgical Journal.

† They have been well described by Dr. Robert Lee, in his article on the Pathology of the Veins, in the *Cyclopædia of Practical Medicine*, and in the pages of this journal.—*Ed. Gaz.*

as being most frequently inclosed in layers of fibrinous matter, or coagulated blood; but in all, except in the present case, I have found them without any covering whatever, and in nearly all of them of a bony hardness throughout.

In the preparation before you a very large one may be observed with a clot of blood. Several smaller ones were also observed enveloped in coagulated blood. The spermatic veins in this case, in the branches of which these were deposited, were much enlarged.

According to Cloquet and Beclard, they have been also found in the hamorrhoidal veins, in the spermatic veins of the male, in the saphenæ veins, and twice in the *vena cava inferior*. In one of the cases described and delineated by Cloquet, he states that the smaller ones were formed of a little soft clot of blood; that those of a larger size contained in the centre a nucleus of white fibrinous matter; that the largest had in their centre an osseous-looking nucleus, upon which the white fibrinous matter was arranged in concentric layers; the internal very hard, the others becoming gradually softer as they approached the surface. He also gives a drawing of a round fibrinous mass taken from the *vena cava inferior*, containing an ossific-looking matter in the centre, from which a number of rays of the same substance passed through the fibrinous matter towards the circumference. Another specimen similar to this was seen by Cloquet in Soemmering's museum, and was said to have been taken from the *vena cava inferior* of a child.

I am not aware that the chemical composition of these bodies has been accurately ascertained. Cloquet speaks of them as composed of phosphate of lime, but he does not state that they were analyzed. Mr. Kemp had the kindness to analyze two of them taken from different subjects. He has not yet been able to obtain accurate results; but he states that he is certain that both were principally composed of phosphate of lime, of carbonate of lime, and of animal matter, and that it appeared to him that these earthy salts and animal matter were nearly in the proportions that exist in the bones. He has promised to make a more accurate analysis; and we will then see how far they differ from, or agree with, the osseous texture in their chemical composition. It may also be stated, that the animal mat-

ter seemed composed in a great part of gelatin; but this would require farther researches.

It becomes an interesting subject of inquiry, whether these bodies are formed by a deposition of the earthy salts contained in the blood, mixed with some of the animal matter, or whether this depends upon some vital action in the fluids corresponding to the formation of the osseous texture. Neither Beclard nor Cloquet give any opinion upon the cause of their formation. The fact of their being only found in the depending veins, where the flow of blood is retarded, and the improbability of the formation of any osseous texture in the interior of these vessels, strongly favour the notion of their being merely depositions from the blood, as urinary calculi are from the urine; while the nature of their formation, the gradual conversion of the fibrinous layers into osseous, the radiation of the ossific matter through the fibrinous clots, and their chemical composition (if their similarity to bone is confirmed), must strongly incline us to ascribe their origin to something more than mere physical or chemical laws. Additional observations, by furnishing more extensive data, may enable us to come to more decisive conclusions on this interesting question.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

INTERNAL REFORM IN THE COLLEGE OF PHYSICIANS.

AN idea has gone abroad, partly, we believe, in consequence of our silence last week, that the measures of reform which have for some time been under consideration in the College of Physicians, have been abandoned: this rumour is unfounded. The various important changes which we formerly announced, have been carried, and the delay which has since occurred is occasioned entirely by the time necessary to throw the resolutions into the form of

statutes. When thus prepared, they will have to be submitted, in their new form, to the College; and we entertain no doubt of their adoption.

The circumstance which misled some, who ought to have been better informed, into the idea that the proposed changes had been abandoned, was the smallness of the majority in their favour; but the fact is, that the minority, who tried to get rid of the proposals of the Committee, did so, not because they thought them too liberal, but because they thought them not liberal enough. Those who voted on this side, preconceived their plans so as to be all present, while many on the other side, not aware of their intentions, were absent; but as this will not occur again, there can be no reasonable doubt of a considerable majority agreeing to the proposals of the Committee as soon as they are sent up to them in the form of statutes. The measures in question, though not precisely what we have contended for, are nevertheless liberal beyond any thing which has ever before emanated from the College, and but a short time ago would have been received with general satisfaction. It is with this, however, as with all similar questions—the longer the settling of it is postponed, the more does the demand accumulate, and the larger is the share of concession required.

On the effects which are likely to follow this new construction of the College (for it amounts to nothing less), we have already expressed our opinion; and there cannot, perhaps, be a better tribute to our impartiality than this—that while some silly journalists vent their petty spleen by calling us the organ of the College, we know that many in that respectable but somewhat aged corporation hold that we are too much tainted with radical propensities. We cannot, however, like some of our flippant contemporaries, be the slaves of every change, and vary with each turning of

the wind; and while we shall never be led to deny to the College of Physicians its proper rank among the medical institutions of the country, and to its Fellows the humble meed of our commendation, as being for the most part accomplished gentlemen, and learned as well skilful physicians, so, on the other hand, no veneration for antiquity, nor for the *prestige* of distinguished names, shall prevent us from using our utmost efforts to promote the cause of those physicians who, we think, by an unjust spirit of monopoly, and by a short-sighted policy, have been excluded from all participation in the benefits of incorporation; and who, while they might have been secured as allies, have been driven, in self-defence, to become opponents.

As to the permanency or stability of the proposed changes, that will depend upon the result of yet more important questions. If the present administration should be able to weather the storms which gather so rapidly around it, or if it be succeeded by a Whig administration, such as that of Earl Grey or Lord Melbourne, the College of Physicians will certainly maintain its ground, and extend its influence, under the operation of those liberal measures which we have detailed in some recent numbers. But if the changes in the political world bring a radical cabinet into power, then most assuredly the College of Physicians will be swept away altogether, and all the medical corporations, as well as schools, be sacrificed to the needy shareholders of the establishment in Gower-Street.

Should this happen, we predict that a more aristocratic and exclusive institution than any we have yet seen in medicine, would immediately follow. The most influential and distinguished members of the profession would unite to form an association, which would be in medicine what Almack's is in the world of

fashion, or the Royal Academy in the fine arts. Composed of the *élites*, and limited to men of superior attainments, such an institution (which, we repeat, we are confident would be established) would render nugatory all the levelling of the radicals.

It is true, we are not yet quite reduced so far; but, supposing for a moment that the "one Faculty" were established by law, it is evident that to belong to such a congregation of all sorts and denominations could never confer distinction; while, to be admitted into a body known to be select would become an object of ambition, and would give the individual a certain rank in public estimation. The legislator may control acts and alter forms, but he cannot fix by statute the subtle influence of opinion.

SUPPLEMENTARY NOTICE OF DUPUYTREN.

Our personal memoir of this illustrious man (see our last number) would be incomplete, were we not to give the following *addenda*.

Postmortem Examination of the Body.

In conformity with the last wishes of M. Dupuytren, his body was examined thirty-two hours after death, by MM. Rufz and Teissier, *internes* of the Hôtel Dieu, in presence of MM. Broussais, Cruveilhier, Ilusson, and Bouillaud, the latter of whom drew up a most elaborate *procès-verbal* of the autopsy. We shall select a few of the more remarkable appearances.

Thorax.—The right side of the chest was found, by measurement, to be somewhat more capacious than the left; and upon plunging a trocar into that side, about four pints of a milky-looking and muddy serum issued forth. On examining the interior of the chest, the lower and middle lobes of the right lung appeared to have been much compressed backwards and upwards by the effusion. The tissue of the lower lobe was condensed, and quite destitute of air; it sunk in water. In short, the only portion of sound lung on the right side was about the summit of the upper lobe. In the left side of the chest there was about half a pint of serum, slightly tinged

with blood; but the lung of that side, with the exception of a little infiltration, was in a sufficiently normal state. The pericardium contained only a few drops of serous fluid. The heart was robust, visibly hypertrophied, but preserving its natural proportions; there was abundance of fat upon it, but the muscular tissue of the organ was flabby, brownish, and apparently fast approaching a state of decomposition. The ventricles rather capacious; all the valves perfectly sound.

Abdomen.—The stomach was large and distended, as were the intestines generally, with gas. The gastric mucous membrane was of a uniform red colour,—more deep, however, in the vicinity of the spleen,—soft, and easily torn. The œsophagus lined with a false membrane, *diphtheritique*, of no great consistence. The liver somewhat more voluminous than natural, its tissue rather flabby and yielding; the spleen in much the same state. Gravelly matter was found in the kidneys, which organs had also undergone some morbid changes, chiefly of enlargement and softening. The bladder was in a healthy condition.

Head.—The various diameters and other measurements of the head were exactly taken; but the only thing worth noticing on the subject, is the fact that the right and left cavities of the cranium were not symmetrical, the left being, on the whole, more ample than the right. A cast was taken of the appearance of the cerebrum when the top of the cranium was removed, although the convolutions presented nothing very striking. The weight of the cerebrum, cerebellum, annular protuberance, and medulla oblongata, taken together, was 2 pounds 14 ounces; the cerebellum alone weighed 4 ounces 5 grs. In the right lateral ventricle there was observed the vestige of some former lesion; it was a sort of yellowish cicatrice, about an inch long and half an inch wide: its depth, however, was very slight, and the substance of the brain beneath it was quite sound. A little deposit of blood was observed on the centre of the right optic thalamus. "Apoplectic excavations" were found in both the corpora striata. Nothing particularly worthy of observation was met with in the vessels of the brain.

His Contributions to Medical Science.

The labours and researches of M.

Dupuytren were principally employed about anatomy (natural and morbid), and surgery. But as our space is limited, we shall confine ourselves to a rapid view of his surgical achievements. He seems to have enriched the art of surgery in every department. In the treatment of phlegmonous erysipelas, he is said to have been the first who applied blisters; and it was he who explained the nature of inflammations with strangulated bases, as in furunculus and anthrax,—where he devised the plan of large and deep incisions, in order to arrest their progress. Burns he divided into six species or degrees, and assigned an appropriate treatment for each. He it was who first tried caustic in sores affected with hospital gangrene; who employed epispastics for the radical cure of hydrocele; who modified successfully Foubert's method of treating fistula lachrymalis; who struck out a new process for the cure of ranula (*grenouillette*); and it was he who originated certain important precepts for the forcible and successful removal of sarcomatous polypi of the nose and maxillary sinus. From him we learned the advantages of excision in preference to ligature, in treating uterine polyp; and he it was who first performed the operation of complete amputation of the neck of the uterus, when affected with scirrhus, or cancer. He it was who first recommended the semicircular incision in removing carcinomatous upper lip, leaving it to nature to supply the deformity in her own best fashion. Who was more clever than he in diverting the patient's attention during the attempt to reduce luxations? For cata-ract, his experiments for ascertaining the comparative merits of extraction, keratonyxis, and depression, are all well known; and how he preferred the latter, and invented a needle for the purpose, in many respects superior to that of Scarpa.

There are also numerous other operations for which the medical world is indebted to the genius of Dupuytren—such as amputation of the lower jaw, and new processes for removing limbs at their articulations—at the elbow, for example, the hip-joint, and the knee. Among his improvements we may notice the rejection of the ligature of reserve (*d'attente*) in the treatment of aneurism; and among his inventions, the instrument which he substituted for the tourniquet of Petit, and that which he

contrived for cutting the intestine without danger (the *Enterotome*) in artificial anus. To him we also stand indebted for the rules he has laid down for the treatment of prolapsed rectum by incision; for his practical suggestions on the nature of callus; and for the inclined plane which he devised for the management of old fractures. His ingenious method of bandaging in fractures of the fibula and radius are well known. For the treatment of recto-vesical and recto-vaginal fistulae by the actual cautery, he has been celebrated; he has removed with success a portion of the sternum and contiguous cartilages affected with caries; and who has not heard of his bold and successful cure of wryneck by division of the sterno-cleido-mastoid muscle,—a plan which has since been followed by M. Amusat with complete success? Nor should we omit to add to this hasty list his admirable investigations, in conjunction with M. Therard, relative to the asphyxia produced by sulphuretted hydrogen and nitrogen gases*. In short, it may be said, that perhaps there has never been any one man from whom the practice of surgery has derived so many and so great benefits.

His fame as a pathologist is only obscured by his superior lustre as a surgeon: yet it should not be forgotten that he was one of the founders of pathological science in France. It is true that Bayle, and Laennec, and Broussais, and Andral, have opened mines of wealth in this department; but Dupuytren was *among* the first, if not *the* first, to give an impulse to their labours.

COLLEGE OF PHYSICIANS.

SIR H. HALFORD, BART. IN THE CHAIR.

THE second meeting for the season took place on Monday last. Two papers were read; the first of which, by Dr. Hope, we subjoin.

On the Connexion of Apoplexy and Palsy with Organic Disease of the Heart. By Dr. HOPE.

Apoplexy and palsy—the one causing sudden death, the other often miserably

* We do not pledge ourselves for the completeness nor the correctness of this list of M. Dupuytren's contributions to medicine and surgery: we have merely copied it from an article, by M. LAZARUS, in a recent number of the *Gazette des Hôpitaux*.—ED. GAZ.

crippling both the body and the mind—are maladies which have always been regarded with peculiar dread by the patient, and have excited a corresponding degree of attention on the part of the medical faculty. It is therefore surprising that their most frequent and certain cause should have remained unknown until within a very recent date.

The modern researches of Richerand, Bertin, Andral, and others, have completely demonstrated the connexion between apoplexy and thickening of the left ventricle of the heart; and Richerand has, with great truth, pronounced this thickening, or hypertrophy, to constitute “a predisposition more allied to apoplexy than what is denominated the apoplectic constitution;” that is, a robust, square frame, with a short neck and full habit. “It may even be added, (says Bertin), that, in general, the individuals who present the apoplectic constitution described by authors, are at the same time remarkable for the size and thickness of their hearts.”—(P. 351.)

Notwithstanding these remarks, it appears to me that the *full* extent of the connexion between the diseases of the head and those of the heart—in reference, not to hypertrophy alone, but also to dilatation and disease of the valves—is not even yet duly estimated, either by the writers in question, or, still less, by the general body of the profession.

This connexion having arrested my attention many years ago, while conducting researches on diseases of the heart in general, I determined to make it the subject of a separate series of investigations; and I have availed myself of my opportunities as physician to a very large institution (and one containing wards specifically for old apoplectic and paralytic patients), to carry this determination into effect.

From the 12th December, 1832, to the same date in 1834, forty-two patients who had died of apoplexy, or epilepsy, were examined *post-mortem*, in the St. Marylebone Infirmary. The following are the results, according to the journals of Mr. Hutchinson, the able resident surgeon of the institution:—

Of the forty-two cases, four died of apoplexy and two of epilepsy, between birth and 40; nine died of apoplexy and one of epilepsy, between 40 and 50; six died of apoplexy, between 50 and 60; seven between 60 and 70; eleven be-

tween 70 and 80; one between 80 and 90; and one between 90 and 100.

Hence it would appear that the periods of life during which fatal apoplexy is most prevalent, are between 40 and 50, and between 70 and 80.

We have now to examine in what proportion of these cases disease of the heart existed.

In four of the forty-two, the heart was found “quite healthy.” In eight cases more, no remark is made in the journals as to its condition; it may therefore be presumed to have been healthy. This affords a total of twelve cases out of forty-two, in which the heart was sound: in the remaining thirty it was diseased.

Thus, taking all the ages collectively, disease of the heart accompanied fatal apoplexy in no less than thirty cases out of forty-two—*i. e.* in five out of seven.

We will now examine at which of the above periods of life disease of the heart, in connexion with fatal apoplexy, was most prevalent.

Between *birth and forty*, disease of the heart was found in two cases only out of seven. Between *forty and fifty*, it occurred in eight out of nine!—a remarkable increase. Between *fifty and sixty*, it occurred in four out of six—a decrease. Between *sixty and seventy*, it occurred in three out of seven—a further decrease; and between *seventy and eighty*, it occurred in ten out of eleven!—another remarkable increase.

It would thus appear that the periods of life during which fatal apoplexy is most prevalent, are precisely those in which concomitant disease of the heart is of most frequent occurrence—namely, between *forty and fifty* and between *seventy and eighty*.

It was stated above, that, taking all ages together, disease of the heart occurred in five cases out of seven of fatal apoplexy. Now *this* proportion is, I apprehend, *much* greater than is generally imagined or believed; and it sufficiently evinces the importance, in medical practice, of carefully studying how far the state of the heart and that of the brain may be allied, as cause and effect.

But in the two apoplectic periods of life (if I may be allowed the expression), between 40 and 50 and between 70 and 80, the proportion is much greater; for instead of being five cases out of seven, it is in the proportion of nine out of

ten. Hence it is desirable to direct our attention, in the treatment of apoplexy, to these two periods more especially; and in order to do it with effect, it is necessary to investigate the causes why fatal apoplexy occurs in connexion with disease of the heart, during these periods in particular.

Now, on examining the cases occurring between the ages of 70 and 80, seven out of ten present ossification of the heart. On the other hand, between 40 and 50, disease of the *muscular* structure prevailed, while ossification was comparatively rare.

Hence it appears deducible, as a generalization, that it is disease of the *muscular* structure more especially, which causes apoplexy in the earlier period of its prevalence; and it is mainly ossification which occasions it in the more advanced period.

It will now be asked, *why* disease of the muscular structure occasions fatal apoplexy between the ages of 40 and 50 in particular? To this question, the *history* of disease of the muscular structure affords a reply. Such disease is not, in general, expeditiously fatal. It usually commences insidiously, and steals on gradually—often subsisting from ten to twenty years, or more, before it produces its fatal effects. If, then, we consider that it is principally between the ages of 25 and 40 that the *causes* of disease of the muscular structure are brought into operation; if we reflect that this is the period when intellectual exertions are the most intense and sustained—when the exciting and depressing passions have the strongest and most permanent hold—when the physical system is subject to the greatest variety and severity, and continuity of efforts; all of which causes, by preternaturally stimulating the heart, predispose it to disease—we shall not be surprised that the seeds of destruction, sown during this period, should yield their fruits during the subsequent period—namely, between 40 and 50.

It will next be asked, why ossification causes fatal apoplexy between the ages of 70 and 80 in particular?

It is not until towards the age of 60 that the ossific tendency which characterizes old age comes very decidedly into operation. Between the ages of 60 and 70 it makes silent progress, and between 70 and 80 it produces its fatal effects; these effects being, no doubt,

assisted by the *general* failure of the powers of circulation, which accompanies the progress of decay.

I have hitherto spoken of apoplexy alone; but what has been stated applies equally to palsy, when connected with derangements of the circulation through the brain; for, under these circumstances, it is only a younger brother of the same family. In many of the forty-two cases above quoted, *several* apoplectic fits had preceded the fatal attack, and, in a large proportion, the fits had been followed once or more by palsy, either transient or permanent.

Many presented vestiges in the brain of *several* apoplectic clots, in progressive states of absorption, corresponding with the number and epochs of the previous apoplectic or paralytic attacks. In one remarkable instance, no less than three old clots and two cavities were found in the brain, corresponding with five apoplectic fits during the last eight years of the patient's life.

Assuming, then (so far as a limited number of cases will authorize us), that fatal apoplexy is most common between the ages of 40 and 50, and of 70 and 80, and that, during these periods, it is accompanied in the great majority of cases with disease of the heart, the resulting inquiry is, whether a knowledge of these facts will enable us, by the resources of our art, to diminish the mortality from this fearful disease. I believe that it will contribute to produce this effect, and in the following manner:—

Not many years ago diseases of the heart were involved in deep obscurity; they could seldom be detected before they were so far advanced as to be incurable; and their pernicious influence on the brain was unknown as a general fact. Under these circumstances no precautions were, or could be taken, to protect the brain from their influence. Nor was this all: the modes of treatment adopted were often precisely the most injurious that could have been devised. For instance, a person of the alleged "apoplectic constitution," but *really* labouring under undetected hypertrophy of the heart, would judge, from stunning headaches and rushing noises, &c. that he had a "fulness of blood in the head." To remove the supposed cause—his full habit—he would (after a cupping, perhaps) betake himself to the daily use of the boxing

gloves, the foils, or to some other violent exercise. The result would be an apoplectic fit.

Another patient, affected with enlargement of the heart, is subject to palpitations, and invariably finds them aggravated by flatulence, or acidity of the stomach; his inference is direct, that it is "all indigestion." Amongst the remedies to be adopted, "air and plenty of exercise" of course take a prominent place. The result is an apoplectic seizure.

Now exercise is, of course, very suitable for reducing mere fulness of habit, and also for invigorating the digestive powers; but by stimulating the action of the heart, already too energetic for the brain to bear, it proves the destruction of the patient in such cases as the above.

Another patient is languid, sluggish, exhausted by slight exertions, always ailing, yet without any specific malady, — symptoms which are common in females affected with dilatation. The friends of the patient rally her on her indolence; tell her that "she only wants rousing," and "should stir about," &c. She makes the attempt; the congested brain becomes still farther gorged, and she falls a martyr to apoplexy or palsy.

Such were the disasters that often occurred, when we had no means of ascertaining the existence of disease of the heart in its early stages. At present we are in possession of those means; the discovery of auscultation having rendered the detection of these diseases as easy and certain as that of any other great class. Experience subsequent to the discovery has also completely proved, that, when detected in their early stages, they are, in a large proportion of cases, susceptible of a radical cure; and, in many others, may be so far counteracted as not to curtail the life of the patient.

Under these circumstances, then, we may, I think, reasonably anticipate a diminution of the mortality from apoplexy and palsy. The diminution would refer more especially to these maladies as occurring before the age of 50; because affections of the muscular structure are the most remediable forms of disease of the heart. Between 70 and 80, a less diminution of the mortality is to be expected, because we possess no

means of removing ossification. Yet even here the apoplectic tendency may be greatly obviated by suitable precautions, and life in many instances extended to its natural span.

It would be in my power to corroborate the above abstract of *fatal* cases by about 200 more which have come under my observation *without* proving fatal; but as these cases have not the certainty which can only be afforded by post-mortem examination, it would be unphilosophical to generalize from them, whatever degree of evidence they may afford to myself.

The fatal cases quoted included three of epilepsy, in all of which death occurred before the age of 41; and in two the malady was connected with organic disease of the heart. I may add, that I have repeatedly found epilepsy exhibit this connexion, and I believe that such is not unfrequently its unsuspected source.

The second paper, from the pen of Dr. Vetch, related to Cholera. This disease, the writer remarked, had, as a general rule, prevailed most extensively and fatally at the estuaries of rivers, in alluvial formations. He suggested that sulphur might be tried as a prophylactic, having understood that the seapoys sometimes used it for this purpose. Analogy also, he observed, favoured the idea, sulphur having some power in guarding against ague and some other diseases.

ON THE UNION OF BONE;

*Being the Substance of an Essay which obtained
the Jacksonian Prize.*

By B. PHILLIPS, Esq.

SINCE the time of Fabricius Hildanus, who died in 1634, the uniform and almost unvarying opinion which had been cherished was, that the consolidation of fractured bones was effected by means of a gelatinous fluid extravasated between the fractured ends of a bone, and which (gradually becoming more consistent and viscid) contracted adherence with the fractured extremities, and established between them a firm union. This process was supposed to be accomplished in a manner similar to the coaptation produced in two

pieces of wood by the interposition of strong glue.

This gelatinous fluid was named *osseous juice*; and to secure its deposition in sufficient quantity, it was thought necessary that the patient should be fed upon glutinous matter, vegetable as well as animal.

If this theory were correct, it must follow of necessity that the callus should be organic.

As it is incontestible that no union can take place in an organic body through the medium of an inorganic substance, the illustration of our predecessors is essentially inapposite. Observation has clearly demonstrated that callus is susceptible of becoming organised; and we can place no distinctly marked demarcation between the points where callus ceases to be termed callus, and where it undergoes its first change in its progress towards ossification.

As I believe the opinion in the present day is almost universal, that it is through the medium of this "callus" that union is first procured between fractured bones, and as I presume this opinion to be the correct one, the questions which naturally arise next in order are—How and when is this substance deposited? What are the characters and changes which are presented in the different stages of its progress toward that period when osseous matter is deposited, and the union becomes solid?

No rational opinion appears to have existed on the nature and mode of deposition, or secretion, of the substance termed callus, until the early part of the eighteenth century. In the years 1739, 1741, 1742, and 1743, that excellent naturalist, Henri Louis Duhamel du Monceau, sent to the Académie des Sciences at Paris a series of essays, for the purpose of demonstrating the importance of the periosteum in the formation of bone. These essays were based upon experiments he had made by feeding animals on madder; their results I shall shortly describe. He endeavoured to establish an analogy between the mode of development of bone and that of the ligneous fibres of plants.

His opinion (founded upon a very extended series of experiments) was, that the callus is entirely formed by the periosteum, which he regarded as the organ by which ossification was accomplished.

"When," says he, "a bone is fractured, the periosteum of the two fragments first becomes agglutinated and tumefied, and forms a kind of collar around the fracture: the periosteum, tumefied and penetrated by the fluids which flow into it, becomes softened, and assumes a gelatinous appearance, and is not long in passing into the state of cartilage; vessels are developed in

this cartilaginous substance; osseous nuclei are formed in considerable numbers, and are united with each other; and when the whole of the periosteum adjoining the fractured portion is thus hardened and ossified, it forms a species of collar, by which the union is maintained."

The opponents of Duhamel, and particularly Bordenave, raised against the theory the following objections:—If we split a bone longitudinally, at the situation of an old fracture, we shall find the fragments completely identified; that there is not merely a contact, as is the case when two pieces of wood are maintained in apposition by means of glue.

In answer to this objection, he stated that the periosteum is elongated from the circumference towards the centre of the bone, and that the prolongation of this membrane experiences the same changes as the adjoining portion, and thus unites the two fragments between which it is interposed. He stated also, that in some cases the internal periosteum, or medullary membrane, may furnish prolongations which may be also interposed between the fractured portions, like those of the external, with which it becomes united.

Such was the celebrated theory of Duhamel, which during a long period of time was destined (in spite of the great talents of some of its opponents) to hold, in almost entire control, the schools of Europe.

Among the more powerful of its opponents were Haller and his pupil Dethleef, who (after numerous and ingenious experiments) became convinced of the correctness of the theory of the ancients, which was, "that the callus was formed by a glutinous juice which flowed from the fractured extremities of bones, and was extravasated around the fractured portion; that this substance became organised, presented a cartilaginous appearance, and ultimately was ossified by the successive deposition of earthy nuclei."

However different in appearance may be these two theories, they are in entire accordance as to the means by which the union is effected; their difference is solely as to the manner in which this gelatinous fluid, or lymph, is produced: Duhamel maintaining that it is produced exclusively by the periosteum, whilst Haller and Dethleef state that it is a lymph proceeding from the fractured ends of the bones.

It is now generally admitted that Duhamel attributed too much of the process to the periosteum, and that Haller and Dethleef were incorrect in their ideas regarding the production of the lymph.

The experiments of Haller and Dethleef were repeated by Bordenave, Professor in the Ancient School of Surgery in

Paris, and the results obtained by him served to confirm, in the main, those of Haller, but his mode of explanation was different.

Instead of attributing the formation of the callus to the periosteum, like Duhamel, or to the transudation of lymph, like Haller and Dethleef, Bordenave thought that the union was effected in a manner similar to that to which nature resorts in the union of soft parts. His opinion was founded on the following circumstances: "that there is in bone a vascular tissue, destined to maintain in it the circulation of the nutrient fluids; that this tissue is dilated in the period of union of fractures, as is seen by the tumefaction which exists at the situation where the callus is deposited, and that without this tumefaction no union is effected."

It is singular that so much acrimony should have characterised the discussions which took place between the disciples of Haller and Bordenave; for I can scarcely distinguish any important difference between the theory of Haller and that of Bordenave; each is not far from the truth. Up to a very late period these were the opinions generally professed on this important subject.

In our own times the opinions of our countrymen have been much modified by those of John Hunter; he explained the formation of callus, by explaining the changes which occur in the blood, which is extravasated at the seat of fracture. "This blood," says he, "is coagulated, loses the greater part of its colouring matter, is penetrated by vessels, passes to the state of cartilage, and then becomes ossified; and that the magnitude and the form of the callus is dependent upon the quantity of blood extravasated."

These opinions of Hunter have been revived by Howship, who has succeeded in demonstrating and injecting vessels which ramified in the callus; but I am not aware that he has prosecuted his experiments beyond the thirty-second day.

The opinions of Bordenave, which are somewhat similar to those of Hunter, have also been reproduced by J. Bell, Bichat, Scarpa, Richerand, Boyer, and other modern physiologists.

Some years since, Dupuytren, supported as well by direct experiment as by the evidence afforded by examination after death, discovered that the cause of the contrariety of opinion existing on the subject was, that all of the theories which have been successively promulgated, instead of including all the facts of which the process of consolidation is composed, was each based upon the observations afforded by the examination of only one or

two periods of the process. Their inventors thought that the single circumstance which they had seized amply served to explain the whole of the phenomena of the operation. I am not aware, either, that before the researches of Dupuytren any important distinction was well established between the phenomena which are observed in the formation of callus in simple and in complicated fractures.

Whatever be the mode by which callus is produced, one thing is well established, and that is, that in the first fifteen or twenty days the substance called callus is deposited, and that from the thirtieth to the fiftieth day this substance acquires much solidity.

Before I proceed to detail the experiments which I have made, I may remark, that in the perfect union of fractured bones, as in the cicatrization of wounds in the soft parts, it is necessary to distinguish union with from that without suppuration. Whatever be the tissue in which a cicatrix is to be formed, the proceeding by which it is to be effected is alike; but we must carefully distinguish union by the first from that of the second intention.

Bones, like the soft parts, offer these two modes of cicatrization; but though the results of each mode may be the same, the attendant circumstances are widely different; for in the dense tissue of bones, the process of inflammation is not easily excited, and when excited, is long in passing through the several stages necessary to the production of union, while the soft parts readily enter into this state, become by this process consolidated, embrace the fractured bones, and thus secure them against the probability of displacement, which without this arrangement would no doubt frequently occur. [Here follows a series of experiments and observations.]

"In the conclusions I shall draw from the preceding observations, and which are, I think, fairly deducible from them, I state, first, that neither the theory of Duhamel, of Haller, of Bordenave, of Hunter, of Howship, nor of J. Bell, appear to me (from the result of these experiments), to be the correct method of explaining the mode of union in fractured bones; though each may satisfactorily explain certain stages of the process. For neither is the union dependent exclusively upon the ossification of the periosteum, as maintained by Duhamel; on the transudation of a peculiar fluid from the fractured ends, as maintained by Haller and Dethleef; nor on the existence of granulations upon the fractured extremities, as maintained by Bordenave, Camper, Boyer, Richerand, and Scarpa; but it appears to result from the conjunction of two or more

of these processes, according to the circumstances of the case."

All the phenomena which are presented in the union of simple fracture of bones, are merely so many stages of a common adhesive inflammation developed in the tissues which are implicated by the fracture.

The consequence of the injury which has occasioned the fracture, is the production of a certain quantity of laceration of the medullary membrane, periosteum, and the surrounding tissues, as well as of the vessels they contain, and the consequent escape of a certain quantity of blood. This is the first and immediate consequence of such an injury; and it is demonstrated by the cases which I have detailed.

The common effect of such injuries is the development of acute inflammation, which is manifested successively in the cellular, muscular (if implicated) fibres, and osseous tissues. This I have also demonstrated.

The successive changes which then follow are merely so many forms presented in the accomplishment of the various phenomena incidental to such a disease.

The quantity of blood poured out into the tissue, in the vicinity of a fracture, is variable; dependent upon the quantity of injury inflicted upon the soft parts, and upon the plethora of the subject.

The extravasated fluid soon coagulates; its colouring matter, its fluid portion, and much, if not the whole, of its lymph, are absorbed in a few days.

Here, therefore, I maintain that the doctrine of the Hunterian school is on this point incorrect; for the size of what is termed the callus is no further dependent upon the quantity of blood effused than this—that the quantity of blood effused is a tolerably fair criterion of the quantity of laceration which has occurred; the quantity of laceration indicates, to a certain extent, the quantity of irritation produced; the latter, of the extent of inflammation; and upon the quantity of inflammation is the size of the callus almost entirely dependent.

The surrounding vessels are first infiltrated with blood; in a few days its lymph is removed, and we then find these tissues merely gorged with serum.

Inflammation being excited, it occasions a deposition of lymph in the cells of all the affected tissues; and we find, that in proportion to their susceptibility to inflammatory excitement is the rapidity with which the deposition occurs in the cells of each tissue.

So we find that it occurs first in the cellular tissue, which acquires more density and a great increase of bulk; next we

find (when the muscular is implicated), similar phenomena are manifested in it; next in order is the fibrous tissue, which acquires an increased thickness, with a loss of density, because here the matter deposited in its cells has less density than the tissue itself.

The inflammation of this latter tissue is always accompanied by a tendency to generate and deposit a substance, which forms a sort of frame-work for the reception of earthy matter, which is deposited as soon as the frame-work is completed; and it is by this process the medullary canal becomes lessened. It is never deposited over the fractured point until the continuity of the fibrous tissue is established. From such an arrangement, this deposition has no tendency to give solidity to the bone before union has been effected.

Soon after the development of inflammation in the fibrous tissue, the medulla becomes similarly affected, and it becomes transformed into a dense semi-cartilaginous mass: that contained in the one portion of the bone becomes united to that contained in the other, and in this manner a cylindrical plug, like mass, is formed, which really does contribute powerfully to the support of those bones which are in apposition the one with the other.

The last tissue which becomes inflamed is the osseous; and in this, inflammation is more tardily excited. When excited, it is long in developing itself, and the thickening, or tumefaction, is not ordinarily well marked before the fortieth day; lymph is soon after thrown out at the ends of the fractured bone, and it connects the one portion with the other: this lymph has to acquire a cartilaginous consistence before a particle of osseous matter is deposited in its cells.

In bones subjected to inflammation, an absorption of the earthy matter invariably occurs, and the deposition of new earthy matter does not occur until the connecting medium has attained a consistency equal to that of the original bone from which the earthy matter has been removed. In the union of fractured bones, the deposition of osseous matter, then, in the newly-formed tissue does not commence, in an adult, until from the seventy-fifth to the ninetieth day, and is not concluded (by which I mean that it has not acquired the form and the density which was possessed by the bone previous to the occurrence of the accident) before the 200th to the 250th day.

The bones are retained in contact partly by the tumor which is formed around them by the deposition of coagulable lymph in the cells of the cellular and other tissues, occasioned by the inflamma-

tion which has been set up; partly by the plug which is formed internally, and partly by the interposition, between the fractured bones, of a substance which adheres to them. This substance is first a portion of the coagulable lymph derived from the extravasated blood, and after the removal of this, it is a substance deposited by the surrounding inflamed membrane; this becomes fluid, and is absorbed, when the deposition from the ends of the bones commences.

As soon as the inflammation is sufficiently subdued, the absorption of the coagulable matter constituting the tumor begins, and continues until it is removed. It must be evident that no definite time can be named for this occurrence; it must be dependent on the quantity of injury and on the constitution of the patient: as an average time, however, may be some satisfaction, I would say that in the adult it usually commences about the fortieth day.

The phenomena of inflammation are, in their development and in their removal, more tardy in the medullary than in the cellular and muscular tissues; so that the internal plug remains stationary for a much longer period than the external collar, and, on an average, is not entirely removed before the 250th day.

If the fracture be comminuted, the detached portions of bone lose their earthy matter, and become almost confounded in the medium by which the fracture is united.

The point of union is no longer visible externally after the 130th to the 160th day. The periosteum usually acquires its continuity from the 95th to the 115th day, and, when this is entirely completed, a deposition of bone commences, by which the point of union and more or less of the old bone is covered. This appearance does not cease for a very long time.

Such, then, is my method of explaining the mode by which union is effected in the simple fracture of bones; it is warranted by the facts which I have recorded, which, I submit, constitute an irresistible support to the conclusions I have detailed.

The principles are somewhat modified by the circumstances which occur in compound fracture (by which I mean here those only which communicate with the exterior), and I shall proceed to detail the phenomena which have been observed in a few cases of this kind, and then conclude my explanations of "the mode of union in simple and compound fractures."

By a compound fracture I must be understood, in this place, to mean any fracture (either with or without comminution) which has a communication with the exterior.

I insist upon this distinction simply because the continued contact of atmospheric air appears to be the great agent by which certain material changes occur between the mode of union in simple and compound fractures.

The observations which will be found detailed in support of the opinion I shall hereafter express on this subject, are only ten in number; but I trust that, after a perusal of them, it will be conceded to me that they are sufficient to give an unyielding support to my theory of "the manner in which union is effected."

Here follow the experiments and observations.

Such are the facts which I have to offer in support of the opinion which I shall presently express, as to the mode by which union is effected in compound fractures. I have not detailed cases in which, in consequence of certain peculiarities, suppuration has continued for many months, because, whatever may be the time at which, in these cases, union is effected, the process is the same, but the length of time occupied in its performance is different. The cases I have detailed were favourable, and were, as I conceive, those best adapted to the elucidation of this very important subject.

Whenever inflammation is developed in cases of fracture, it is a constant consequence either of those injuries by which the fracture has been occasioned or of those produced by the violent displacement of the bone.

It has been found that exposure to the atmosphere has a tendency to keep up this state, and that in such cases it very often proceeds to suppuration.

That this effect may be fairly attributable to atmospheric influence, is rendered most probable by the fact, that if we can effectually exclude the air by uniting the lips of the wound, we shall most probably arrest the progress of the inflammation, and, in fact, resolve the case into one of simple fracture.

When a surface has become the seat of suppuration, that surface can be healed only by the development of granulations, by which the loss of substance is repaired. The time when these granulations will appear is of course uncertain, and dependent on a variety of circumstances; but it appears to be necessary that the quantity of inflammation requisite for the existence of suppuration, shall have somewhat abated before their development can occur.

Upon the surfaces of the fractured bone a similar production is developed: those on one portion form a junction with those on the other, and in this way a kind of granular union is brought about.

These granulations are not developed upon the ends of the bone until the latter becomes inflamed and suppuration has been established.

As a consequence of the existence of inflammation, the bony tissue loses much of its density by the absorption of its earthy matter; which always occurs under such circumstances.

When this kind of union is produced, much time elapses before solidity is acquired; the newly-formed tissue gradually acquires more and more density, until it becomes cartilaginous; the deposition of earthy matter then commences, by means of which perfect consolidation is produced.

It has now been demonstrated, that in the union of simple and of compound fractures, a different process is employed, and I will state that difference in its simplest form. The ultimate union is effected in simple fractures by the development upon the fractured surfaces of a species of albumino fibrinous matter, which, by its viscosity, attaches the portions of bone to each other. This matter continues to acquire more and more density, until it arrives at a state when it is adapted for the reception of earthy matter, by which consolidation is completed.

In compound fractures, instead of the albumino fibrinous product, granulations are developed upon the fractured surfaces; they become united to each other, and retain the bones in apposition, as is the case with the fluid I have described in simple fracture. These granulations follow a similar course in their progress toward the period when they are adapted for the reception of that earthy matter, through the agency of which solid union is accomplished.

LITERARY INTELLIGENCE.

Preparing for publication, by Subscription, in folio, *Fractures of the Extremities*, exhibited in twenty Plates, shewing the Causes of Displacement: with an Explanation of the Appearances, and Mode of Treatment. By G. W. Hind, M.R.C.S. Lond. formerly House-Surgeon to the Middlesex Hospital, and late Curator of the Museum of Anatomy of the University of London.

Andral's "Clinique Medicale," translated and condensed, with Practical Remarks, by Dr. Spillan, will speedily be published.

In the press, and nearly ready, Dr. Underwood's *Treatise on the Diseases of Children*; with Notes and Observations, by Dr. Merriman. This Edition (being

the ninth) has received considerable additions, and is brought down to the present time, by Dr. Marshall Hall, F.R.S.

The Sphygmometer; an Instrument which renders the action of the Arteries apparent to the Eye. Being a Memoir presented to the Institution of France, by Dr. Julius Herisson; with an improvement of the Instrument, &c. by the Translator, Dr. E. S. Blundell. 8vo.

In the press, *Practical Observations on the Physiology and Diseases of the Teeth*. By Mr. J. Mallan.

LECTURE XXIII.
DISEASES OF THE HEART.

SIGNS OF DISEASES OF THE HEART.

I now proceed, gentlemen, to the description of the signs of the diseases of the heart and its valves, after which I shall detail the treatment of these affections.

Simple hypertrophy of the left ventricle.—If the stethoscope be applied between the cartilages of the fifth and seventh ribs, a strong impulsion is communicated to the head of the observer. The force and duration of this shock is proportionate to the degree of hypertrophy of the ventricle. This impulsion is immediately followed by an apparent sudden recession of the heart from the parietes of the chest, which Dr. Hope denominates the “back stroke.” The sounds of the heart now become very indistinct; that produced by the contraction of the ventricle, which is naturally slight, is almost entirely lost; and that caused by its dilatation is of much shorter duration, and less noisy, than in the healthy state.

The extent of surface on which the pulsations of the heart are heard becomes diminished; it is often confined to the space comprised between the cartilages of the fifth and seventh ribs, or to a surface over the ventricle equal only to a square inch.

The patient, although not subject to strong palpitations of the heart, except when under excitation, feels almost constantly, the sensation of the beatings of the organ. Irregularities or intermit- tences of the pulse are also rare in this case; Laennec thought they sometimes occurred from partial hypertrophy of the walls of the cavity.

The pulse is often strong and developed, but occasionally it is reduced, so as to give the sensation of a mere thread feebly vibrating under the finger. Indeed, you should never rely upon the force of the pulse at the radial artery as indicating the force of the action of the heart; for often the pulse will be feeble, and the move- ments of the heart strong; and sometimes the reverse will take place—that is, the pulse will be strong and the heart feeble. The face is frequently of a bright red colour, and it is said that apoplexy super- venes upon this form of cardiac disease more frequently than upon any other.

Simple hypertrophy of the right ventricle.— When the stethoscope is applied to the inferior half of the sternum, the impulsion of the right ventricle is very distinguishable; it is precisely similar in character to that given by hypertrophy of the left. This sign, when marked, may be considered as certainly indicating this disease.

According to Corvisart, the dyspnœa is greater in this affection than the preceding; this probably arises from disease of the lungs being usually its primitive cause. The face also assumes a more livid tint.

Lancisi was the first to announce that a swelling of the external jugular veins, accompanied by pulsations analogous and synchronous to those of the arteries, was a sign of hypertrophy of the right ventricle. Corvisart denies this sign to exist. The observations of others have, however, confirmed that of Lancisi, although the jugular pulsations are most common when the hypertrophy of the ventricle is combined

with its dilatation. Bertin explains this, by saying that where there is hypertrophy and dilatation of the right ventricle, the tricuspid orifice becomes larger, and consequently the valves do not meet at their edges so as to close it, and that therefore, at each contraction of the ventricle, the blood regurgitates into the right auricle, and communicates its impulsion into that contained in the jugular veins. Dr. Hope asserts that the valves always enlarge with the dilatation of the orifice sufficiently to close it, so that no regurgitation can take place, and that the ventricular contraction impels the blood against the closed valves, which communicate the shock to the blood contained in the right auricle and external jugular veins. I have twice seen the right jugular vein pulsating, and not the left: this is an anomaly difficult of explanation.

Hypertrophy of both ventricles.—When the two ventricles are affected, the signs consist of a reunion of those proper to each ventricle, but, according to Laennec, with a constant predominance of those indicating hypertrophy of the right ventricle.

Simple dilatation of the left ventricle.—The impulsion given by the contraction of the ventricle is now entirely lost; its dull sound is converted into a clear loud noise, similar to that of the ventricular dilatation. The heart's beatings are so feeble that they are often not to be felt by the hand; and the sound on percussion is dull over an extent of the chest proportionate to the degree of dilatation of the ventricle. The pulse is generally soft and weak, and there are feeble palpitations.

Simple dilatation of the right ventricle.—The pathognomonic signs of this disease are not only derivable from the absence of all impulsion at the inferior portion of the sternum, but from the presence of a clear noisy sound heard in that situation, and to a distance beyond, according to the extent of the dilatation. I refer you to the scale of progression of sound, which I gave in the first lecture upon diseases of the heart, and to the exceptions to the general rule I there announced.

It has been observed, also, in this disease, that the pulse offers nearly the same characters as when the left ventricle is similarly affected. Palpitations are felt, generally consisting of an increase of the frequency and noise of the beatings of the organ; the impulsion, instead of being augmented, is generally diminished. Irregularities of force and frequency of pulsations accompanying the palpitations rarely occur; still, however, they are more frequent than when the heart is in a state of hypertrophy. Compared with dilatation

of the left ventricle, it is seen that, in that of the right, the dyspnoea is more intense, that there is a greater tendency to dropsy, that hæmoptysis is more frequent, and that the face is tinged with a deeper violet or lead colour, although sometimes it is remarkably pale.

Extended absence of sound on percussion is not always constant in simple dilatation, as Corvisart supposed, but it is rather found in cases of hypertrophy with dilatation.

These general signs may occur in other affections of the heart when arrived at a certain degree of intensity, and are therefore not to be depended upon, except when confirmed by the local signs.

Hypertrophy with dilatation of the ventricles.—This, the active aneurism of Corvisart, is by far the most common affection of the heart; its local signs are composed of those proper to hypertrophy and dilatation. Thus the contractions of the ventricles give an impulse to the head of the observer by means of mediate or immediate auscultation, in proportion to the thickness of the parietes of the heart. This impulse seems to be formed at first by the application of only a small part of the heart to the corresponding internal parietes of the chest; immediately afterwards it is felt as if produced by the whole mass of the heart, which then instantly recedes, giving the "back stroke." In extreme cases it produces the sensation of a large mass of flesh rolling, or irregularly revolving, in the chest. I have seen the force of the ventricular contractions communicate their shocks to the whole person of the patient—nay, even to the bed on which he was placed, so that the pulse could easily be counted by the movements of the bed-furniture; this was the case in the individual from whom I obtained this enormous heart [presenting it.] The impulse of the ventricles can easily be felt also by the hand, which is, as it were, repelled by short and sudden blows, especially at the moment of palpitation of the viscus: to use the words of Corvisart, if the cardiac region be compressed, the heart "seems to be irritated by the pressure, and reacts stronger still." The beatings of the temporal, radial, and other superficial arteries, are perfectly distinct. The pulse is often strong, hard, and vibrating, particularly when the disease attacks the left ventricle; this is, however, not constant, for I have met with cases in which, although the heart beat thus violently, yet the pulse could not be felt until after a slight bleeding and the administration of digitalis. Palpitations of the organ are frequent, although irregularities of its movements are rare, except towards the approach of death,

or when there is great weakness. The dull sound of the ventricular systole now becomes much louder, and the clear and quick sound of the diastole is lost.

The distance to which the pulsations of the heart may be heard is now great; thus it may not only be distinguished in the precordial region, but, as the organ increases in size, all over the surface of the chest.

If the left ventricle be alone affected, the impulsion and noise will be great between the cartilages of the fifth and seventh ribs, and to the left side generally. If the right ventricle be hypertrophied and dilated, the same signs will be evident beneath the sternum, and towards the right side. If both ventricles be diseased, a combination of the signs proper to both affections will exist.

Signs of hypertrophy and dilatation of auricles.—The signs of these affections are yet extremely uncertain. The left auricle is usually thus diseased in consequence of a contracted mitral orifice; and it may be inferred, when a “bruit de soufflet” exists produced by that contraction, that in all probability the auricle is diseased. The signs of hypertrophy and dilatation of the right auricle are still more obscure.

Laennec makes the following important observations in relation to the local signs of diseases of the heart:—

Great errors of diagnosis may be committed if you make but a single exploration of the condition of the organ; it is necessary that you should repeat your examinations, taking also into consideration the general and functional signs which may co-exist; for nervous emotions, so commonly observed upon a first application of the stethoscope to the chest of a patient, may produce palpitations, which, to an inexperienced observer, may give the signs of hypertrophy or dilatation, when really neither of these states are present. Sometimes, too, in consequence of the carelessness or insufficiency of the investigation, these affections may be overlooked. Examine, therefore, closely, carefully, and repeatedly, before you conclude as to the nature of the disease.

There are, perhaps, few individuals whose hearts are in the precise relation of volume or force to the rest of the organs of the body. A large-sized heart may in one case produce no distressing effects, if the chest be ample; while, if the organ be of a similar size in a person whose chest is contracted, death may soon be the consequence. It is therefore of great importance, in establishing our prognosis, to examine the capacity of the chest at the same time with the general volume of the heart.

In children the heart is generally larger

in proportion to the rest of the organs than in the adult, and they often present the signs of hypertrophy with dilatation; but as they arrive at the age of puberty, an equilibrium is commonly established.

Individuals, either at the youthful or the middle period of life, if possessed of a good constitution, may have the heart moderately hypertrophied or dilated, without any very perceptible inconvenience, perhaps being merely subject to occasional palpitations, or slight dyspnoea. In the lower order of people the organ is doubtless often diseased for a long time, and they pay no attention to their symptoms until they are seriously incommoded by them.

But if any disease supervenes, or as age advances, so that the body becomes thinned, and the powers of the individual diminished, the disproportion between the heart and the rest of the organs becomes more evident, and symptoms of cardiac disease will manifest themselves. A delicate female, or a man of sedentary occupations, will soon experience serious symptoms from this disproportion.

The stethoscope may therefore exhibit proofs of hypertrophy and dilatation of the heart, and yet the general and functional signs of such states may not exist. The knowledge, however, that the organ is too thick or large is of great value, as it indicates the necessity of recommending means to diminish its too active nutrition and force; for it is much easier, especially in young persons, to prevent the occurrence of the general and functional signs of these diseases, than even to relieve a single symptom of them.

All the local signs of hypertrophy and dilatation disappear under two circumstances:—1. During the agonies of death, or the dyspnoea which usually precedes it for some days, or even weeks, the impulsion of the heart, and the sounds of its movements, cease almost entirely, whatever be the size of the organ; but the frequency of the pulse is often so great, that it cannot be counted. Corvisart observes, that the movements of the heart are then changed into a “bruissement étendu, un tumulte obscur et profond, impossible à décrire.” 2. The coincidence of any affection capable of producing considerable dyspnoea, as peripneumonia, œdema pulmonum, hydrothorax, empyema, &c. tends to diminish the force of the impulsion of the organ very considerably.

Signs of diseased valves.—The general signs of obstruction caused by diseased valves are associated with those of the affections of the heart itself; I shall therefore describe them at the termination of this subject, and proceed at present with their special symptoms only.

Signs of diseased mitral and aortic valves.—When these orifices become contracted to a certain degree, the “*bruit de soufflet*” becomes apparent. This sound, as I have already mentioned, is similar to that produced by the blowing of a bellows whose valve makes no noise; it is sometimes like that heard from the sawing or rasping of wood at a distance. Dr. Hope states that the latter sound is produced by the blood rushing over a rough surface, as of that of an ossified valve, where the phosphatic matter is denuded in consequence of the membrane forming the valve being partly destroyed. Occasionally the “*bruit*” offers a musical intonation; but I have never heard this except in the arteries.

But as the *bruit de soufflet* occurs under circumstances of nervous agitation, as well as when the orifices are obstructed, it is of great importance to observe whether it be constant or not. If it be present for weeks or months together, you may be assured it depends upon organic lesion; if, however, it be fugacious, so that it may be heard one day and not another, then you may be equally assured that it is not caused by any permanent obstruction, but in all probability by some peculiar excitement of the nervous system. Sometimes, too, the *bruit de soufflet* is so slight that it cannot be distinguished by a common observer. Occasionally, also, the heart, although manifestly diseased, will not produce this sound if the patient be in a perfectly quiescent state. Desire him to walk quickly up a flight of stairs, or as rapidly as he can along a plane surface, the circulation then becomes quicker and more energetic, the blood rushes through the impeded orifice with greater force, and the *bruit de soufflet* becomes louder where it was but slightly audible, and often perfectly distinct where before it was not to be distinguished.

When the aortic orifice is obstructed, a distinct *bruit de soufflet* may be heard superficially under the centre of the sternum, coinciding with the contraction of the ventricle. When the mitral orifice is in a similar state, that sound is then heard towards the left edge of the sternum; it is then more obscure, evidently deeper seated, and coincides with the ventricular dilatation, the noise produced by that dilatation being entirely obscured by it. Another mode of detecting which orifice is affected, is by feeling the pulse at the radial artery whilst you are listening to the *bruit de soufflet*; for if that sound is synchronous with the elevation of the vessel, it is the aortic orifice which is affected; if with the depression, it is the mitral; for the contraction of the ventricle, the passage of the blood through the opening into the aorta, causing the *bruit*, and the pulsation of the arteries,

occur at the same moment of time, or sufficiently nearly so for all practical purposes, as to be considered at the same instant; while the dilatation of the ventricle, the passage of the blood through the left auriculo-ventricular orifice, causing also the *bruit*, and the depression of the arteries, occur also at the same moment.

If the valves be so diseased that the orifice they should close remains always open, then a second and a slighter bellows-sound will occur immediately after the first, in consequence of the reflux of the blood. The same double sound would also be produced if both the valvular orifices of the left side were affected, and therefore the diagnosis is rendered difficult. If, however, the aortic orifice admitted the reflux, the second bellows-sound would be heard nearer to the centre of the sternum, more superficially and louder than if it was caused by a reflux at the mitral opening: in the latter case, too, the *bruit* is heard towards the left edge of the sternum.

But, gentlemen, although the *bruit de soufflet* be always occasioned by obstruction to the circulation, caused by diseased valves, yet that sound may be caused also by other impediments to the current of the blood, especially in the aorta; thus I have met with this sign when that vessel has been contracted or dilated in its ascent, and where it forms its arch. I have before explained that these two opposite states are equally causes of obstruction to the current of the circulation. I think, therefore, we may be justified in saying that all organic causes presenting an obstacle to the passage of the blood from the auricles into the ventricles, and from the ventricles into the aorta or pulmonary artery, may produce the *bruit de soufflet*.

I have never had an opportunity of examining after death a case in which I had supposed the valves of the right side of the heart to be diseased. If the orifices of that side were rendered narrower, no doubt the bellows-sound might be distinguished towards the centre of the sternum.

The *fremissement cataire*, or purring vibration, is felt when there is a considerable obstruction at the left auriculo-ventricular, or at the aortic orifice. I have always found the intensity of this vibration to be in proportion to the loudness of the *bruit de soufflet*, and, like it, it may be increased by accelerating the circulation. This is often produced by nervous causes, but then it is never permanent, as when it arises from organic disease.

General signs of diseases of the heart.—When simple hypertrophy exists, the heart is thrown into frequent palpitations upon any mental or physical excitement. The pulse varies exceedingly; sometimes it

is strong and hard, corresponding with the vigorous and impulsive movements of the organ; at others it is small and thready, and bears no relation to the force of the action of the heart. Active hæmoptysis, or apoplexy, are occasionally the results of this form of disease, from the too forcible impulsion of the blood into the pulmonary and cerebral arteries. The turgid arterial capillaries tinge the face with a florid red colour. Œdema of the subcutaneous cellular tissue sometimes also occurs.

When hypertrophy and dilatation of the left cavities of the heart take place, especially if combined with obstruction at the aortic or mitral orifices, a series of symptoms arise, dependent upon the retardation of the flow of blood through these openings; by which retardation that fluid tends to accumulate in a direction retrograde to its current, and consequently too great a quantity is thrown into the venous system.

Let us suppose that the obstruction exists at the aortic orifice; the blood cannot pass it freely, it consequently accumulates in the left cavities of the heart; the movement of the organ is impeded, and it often struggles and palpitates in throwing forwards the fluid it contains. The pulse therefore varies in character; it may be feeble, if the ventricle be simply dilated, or it may be full, strong, and hard, as in hypertrophy with dilatations; although, in the latter case, it is sometimes exceedingly small. As the blood cannot readily flow through the left auricle and ventricle, congestions take place in the pulmonary veins and artery, their capillaries become gorged, and dyspnœa is the result. The distention of the pulmonary capillaries is occasionally so great, that apoplexia pulmonum and hæmoptysis frequently follow. This distention of the vessels causes also serous effusions, as I have already explained in speaking of dropsy; œdema pulmonum, or hydrothorax, or both states occur, aggravating the dyspnœa which previously existed. The dyspnœa is also increased by the enlarged heart pressing upon the lungs and diminishing the space in which these organs have to perform their functions.

The venous blood now preternaturally distends the right side of the heart, in consequence of the obstructed circulation through the pulmonary artery and veins. The superior cava can therefore no longer pour its contents freely into the right auricle and ventricle, and the blood accumulates in the whole of its system. The external jugular veins are filled, the superficial veins of the face and neck become turgid, the countenance is coloured of a bluish or slaty tint; the lips swell and project; the face becomes tumefied from œdema of its subcutaneous cellular tissue.

The deep seated veins of the neck, the sinuses of the brain, and the cerebral capillary vessels, become engorged; the latter occasionally burst from their distention, and instantaneous apoplexy is the consequence; or, what is much more common, the increased quantity of blood accumulated in the vessels of the brain presses upon the organ and induces a slowly increasing sleepiness or coma, from which the patient can be aroused with difficulty. The pressure is also increased by the increase of serum in the ventricles, and he frequently dies in a state of apoplectic lethargy.

If the system of the superior cava be thus gorged with blood, there is still greater reason that that of the inferior cava should be in a similar state, since that fluid has to mount against its gravity. Thus we find that the venæ cavae hepaticæ, the vena porta, and their capillaries, are always highly congested; the consequence of which is that the biliary secretion is augmented (at least the urine often assumes a deep yellow colour, as in jaundice), and the conjunctivæ and skin are similarly tinged, especially towards the termination of the disease. The mesenteric and splenic veins, to their minutest ramifications, participate in the general fulness; the intestines present a bluish tint; the capillaries of their veins are seen meandering and distended beneath their mucous surfaces; ecchymoses form in their sub-mucous cellular tissue, or blood is even extravasated upon the free surface of the mucous membranes; which fluid, in passing with the fecal matter, gives the latter a black or melanotic appearance: sometimes even pure blood is discharged in coagula. Serum also accumulates in the cavity of the peritoneum, so as to form ascites to a greater or less degree.

If we trace the inferior cava downwards, we shall find that it and the veins supplying it are in a similar state of congestion: the saphena and its branches become varicose. I have seen the superficial veins of the belly even largely dilated. Œdema of the inferior extremities is also a constant result of this state of the veins.

You thus see, gentlemen, that in consequence of the obstruction to the current of the blood in the left side of the heart, the largest quantity of that fluid is thrown into the venous system. I have chosen for this demonstration an extreme case. You are not to suppose that these symptoms are always thus completely formed, nor that they always appear rapidly: it requires many months, nay, I have seen years elapse, before the above state of things becomes complete.

[These demonstrations were illustrated by drawings and diagrams.]

Treatment of diseases of the heart.—Simple

hypertrophy, or hypertrophy with dilatation, when arising from diseased valves, or contraction or enlargement of the aorta at its commencement, are states which I believe to be incurable, because the organic derangements which cause them are permanent; but I believe, also, that these conditions of the heart, produced by the long-continued and habitual positions of the body I have described, or by plethora or nervous causes, may be relieved, or even cured, by a judicious and persevering mode of treatment. Those cases, however, which cannot be cured, often admit of great palliation.

Our indications of treatment of simple hypertrophy, or hypertrophy with dilatation, are, in the first case, to diminish the action of the heart by diminishing the thickness of its parietes; and in the second, not only to lessen the thickness of its walls, but to cause a contraction of its enlarged cavity. Our first object should be to remove the cause of the disease. If it arise from the occupation of the patient, let him at once alter the position he is accustomed to, or change the nature of his business altogether: the latter is almost impossible to the lower classes, and the former often difficult. The shoemaker may, however, be made to work before an upright frame; the clerk can assume a less inclining position at his desk; but the weaver is unfortunately unable to change his position, as his loom is so constructed that he cannot work otherwise than in a bent posture. Persons of this class very often present themselves at the Lung Infirmary, or at the hospital, and it is surprising the relief they experience from changing the curved position they have been habituated to when at work, to an upright one. If the causes of the affection be diseased valves, or contracted or dilated aorta, we cannot hope to remove them by any means we possess in the present state of medical science.

To answer the indications laid down, the patient should be enjoined to take all the repose that is compatible with the continuation of his general health; all violent emotions of the mind or body should be sedulously avoided. The treatment proposed by Valsalva and Albertini for aneurism, should be adopted, but such is its severity that you will scarcely find any patient will submit to it for a long period. Their plan, however, although not carried to the extent they proposed, is always of advantage.

This treatment is most efficacious at the beginning of the disease. It consists in bleeding the patient copiously, although not to syncope, every two, four, or eight days, or more, until the palpitations and impulses have ceased. The food should, at the same time, be diminished

until his muscular powers be greatly weakened, avoiding all stimulants. If, after continuing this plan for two months, he feels no palpitation, and the strong impulse of the heart has ceased, then he may be gradually placed upon a more liberal diet. It will be necessary, of course, to return to the plan of treatment if the symptoms recur.

When the secondary symptoms of hypertrophy, or hypertrophy with dilatation of the heart, present themselves—as dyspnoea, anasarca, ascites, hydrothorax, or oedema pulmonum, manifesting a general dropsical state—bleeding, either topical or local, may yet be had recourse to; but more caution should be now used; a smaller quantity should be abstracted each time, recollecting that your object is not to relieve any inflammatory state, but that it is to remove the venous congestions which cause the serous effusions.

When a partial or general serous deposit takes place, diuretics have often been used with much advantage; although it must be admitted they are frequently very uncertain remedies. According to my experience, they are rarely useful except administered in large doses, and for a longer time than they are usually given. The diuretics in use are the nitrate, super-tartrate, and acetate of potash, digitalis, and squills: the latter may be given alone, or combined with mercury. Digitalis appears to me to have an effect upon hypertrophy of the heart perfectly independent of its diuretic qualities. No means, excepting the abstraction of blood, diminishes the impulsion of the organ so completely and so certainly. I have been in the habit of using it for several years for these affections, and have rarely seen it fail in producing at least temporary relief. I use the digitalis in the form of tincture, giving it in doses of ten drops three times a day; I continue it for a considerable time, taking care to suspend its administration for a short time if vertigo or nausea be produced by it. The hydrocyanic acid has also been used with a similar intention, but I have not seen it produce such decided effects.

If diuretics do not diminish the quantity of the serous effusion, some of the drastic purgatives may be combined with them; of all that class, the elaterium stands pre-eminent. I have frequently seen a distressing dyspnoea, general anasarca, and ascites, completely disappear under the influence of the repeated and copious discharges produced by this hydragogue purgative. It should be used with some caution, as no medicine varies so much in its activity; a quarter of a grain from one specimen may produce the most violent effects, while two, three, or four grains from another will hardly operate. I usually combine the

claterium with calomel, and give it every other day, or twice a week, according to its effects upon the dropsical effusion, watching, however, that it does not distress or debilitate the patient too much. It often produces considerable nausea and vomiting before and during its operation upon the intestines; but the patient usually submits willingly to these distressing sensations, in consequence of the relief he receives from the diminution of the dyspnoea and general anasarca.

Simple dilatation of the heart is not so easily remedied as the simple hypertrophy, or hypertrophy with dilatation. Bleeding should here be avoided, except when there is great congestion of the venous system, and then but a small quantity of blood should be taken for the purpose of relieving it, otherwise a fatal syncope might be indeed. If dropsy supervene, then diuretics and purgatives should be had recourse to, although sparingly, and with caution. Tonics should also be given in this disease—as the bark, bitters, iron, and the carminative plants. When the pulse is very frequent, I often combine the digitalis with these means, and with good effect.

Such is the general method of treating these affections of the heart; but, gentlemen, you must rarely expect to cure them: palliation alone is usually effected; but to relieve is to do much. You can often protract the duration of life for years by perseverance, and sometimes, even when the disease does not depend upon a permanent obstruction to the circulation, a cure may be performed.

It were unnecessary to say a word as to the mode of treating diseased valves; for no means have yet been devised by which any effect can be produced upon them.

Carditis.

By carditis we mean an inflammation of the muscular substance of the heart: this disease is rare, and little is yet known either of its morbid anatomy or of its symptoms.

Paleness, redness, softening, and hardening, of the muscular texture of the heart, have each been considered proofs of inflammation of the organ; these, however, are but very equivocal evidences of this disease. The only appearance which may be considered as certainly demonstrative of carditis is the presence of pus infiltrated among the muscular fibres.

I am aware of but two cases recorded of universal carditis; the one is mentioned by Meckel, in which pus was found infiltrated into the muscular substance of the heart: this case was, however, combined with pericarditis; the other occurred to Dr. Latham, who describes the whole

heart as being tinged of a deep red colour, that its substance was softened, and that innumerable small points of pus oozed from the section of the muscular fibres.

Partial inflammation, characterized by abscesses or ulcerations, are more frequent. Benevenius was the first to describe an abscess of the heart; Bonetus, in his "*Sepulchretum*," mentions also several instances. Laennec met with an abscess in the parietes of the left ventricle, near its base, of the size of a nut; pericarditis was also present in this case. The same author met with another instance, in which concrete pus was intermixed with the muscular fibres of the left ventricle: the patient had presented symptoms of acute inflammation of one of the thoracic viscera, although it was not possible to decide precisely its seat: an inexpressible anguish and orthopnea were the principal symptoms.

Ulcers of the heart.—Ulcers of the heart have been seen more frequently than abscesses. Care must be taken, however, not to confound a rough and unequal false membrane, which may be the result of pericarditis, with ulcerations of the muscular texture of the heart. Oläus Borrichius has described a case of ulcer of this organ. I here present you a specimen [shewing it] in which you perceive an ulcer is situated at the upper part of the left ventricle; it is about the third of an inch broad, and an inch in length: this heart is also ruptured. Laennec describes a case almost precisely similar to this.

Rupture of the heart.—This fatal lesion of the heart rarely occurs without previous ulceration of its muscular tissue. Haller and Morgagni have, however, detailed cases in which this accident has resulted from violent efforts. The heart occasionally becomes so thinned and softened, especially towards its point, that it is surprising it does not rupture in that situation frequently: such an accident is rare. Dr. Hope, however, mentions two instances of rupture from softening of the organ, one of which occurred to himself, the other to Dr. Williams.

These ruptures commonly take place at the upper portion of the posterior surface of the left ventricle, about an inch from its base. My friend, Mr. Langstaff, has two specimens of rupture in that situation; I possess two also, which are before you, similarly situated. On examining them, you will perceive that there is evidently ulceration of the muscular substance of the heart, proceeding from within to the exterior, and that this lesion was the cause of the rupture.

Rupture of the anricles, with or without ulceration, is still more uncommon than

a similar lesion of the ventricles. Bertin describes two instances of this accident—the one was the consequence of a fall, the other had no appreciable cause. Portal met with an instance of rupture of the superior vena cava at its junction with the auricle, in a young female, who died suddenly in a cold-bath.

Corvisart has described three cases of the rupture of the cordæ tendinæ and carnae columnæ, occurring from violent efforts. A sudden and intense feeling of suffocation was the effect of these accidents, and finally the general symptoms of diseases of the heart were developed. I present you with a specimen of rupture of one of the carnae columnæ of the left ventricle: but this is evidently the result of ulceration.

I have met with but two cases of ruptured hearts [they were exhibited], and instant death was the consequence in both. This fatal result is not always so immediate, for the blood accumulated in the pericardium occasionally forms a solid coagulum, preventing, for a time, a farther effusion. Cullerier mentions an instance of this kind in the *Journal de Médecine* for 1806.

Hardness of the substance of the heart.—The muscular substance of the heart sometimes becomes so hard in cases of hypertrophy, that it resounds, when struck, like horn; the scalpel cuts it with difficulty, and gives a creaking or crepitating sound in passing through it: the heart, nevertheless, retains its proper colour. The creaking or crepitation produced by the section is only heard when the firmness of the tissue is very great.

Softening of the substance of the heart.—The substance of the heart is now flaccid; it appears withered, and may be torn with the greatest facility; it is sometimes so soft, that the fingers easily penetrate into the ventricles by a slight pressure; the heart is rarely gorged with blood, but appears half filled, and is slightly flattened and collapsed. If an incision be made into the ventricles, they collapse equally, whatever may be their thickness. The colour of the organ is usually changed: sometimes it becomes intensely red, or of a violet aspect, particularly in fevers of a putrid character; more commonly it is of a yellow tint, like that of a pale dead leaf. This yellow-coloured softening may pervade the whole organ, or it may affect only a part; it is generally found where there is dilatation with moderate hypertrophy, or it may occur where there is simple dilatation only, although in the latter case the muscular substance of the heart is generally deeply red, or violet.

Signs of softening of the substance of the heart.—Laennec, who was the first parti-

cularly to describe this affection, gives the following signs by which it may be determined.

The sounds of the movements of the heart are duller and more obtuse, but never present the characters of bruit de soufflet. A total softening of the heart is perhaps always accompanied by a cachectic state. In persons thus affected, though they may possess a certain degree of health, the skin is yellowish, colourless, and withered. The organ may also be inferred to be softened, when an individual, attacked with dilatation with or without hypertrophy, has had long and frequent fits of suffocation, when the sufferings preceding death have been of long continuance, and when the violet tint of the face, extremities, and other parts of the surface of the body, has announced that a congestion of the capillary system has been formed for a considerable time.

When the heart gives equally moderate and dull sounds in its movements without impulsion, it is probably softened, but of good proportions.

When softening exists without dilatation, the sound, although louder, is yet duller than in simple dilatation.

When softening coincides with hypertrophy, the sound of the ventricular contraction is no longer audible, especially in extreme cases; these contractions then become also slower. Sometimes, however, during palpitation, the heart beats with great energy, and its contractions are quick and short, and similar to the blows of a hammer. After this effort, which may last many days, the organ falls into its habitual state of languor.

Softening of the substance of the heart co-exists with fevers of the adynamic or typhoid forms. Laennec does not assert that this state exists in all fevers denominated essential, but believes it to be always most marked where the signs of an alteration of the fluids are most evident.

Bonillaud attributes the softening and the hardening of the substance of the heart, as well as the alterations of its colour, to inflammation. It is replied to this supposition, that although the organ has been seen so soft that its fibres have broken readily between the fingers, yet pus has never been found among them; nor are there any local pains or general symptoms indicating an inflammatory condition, precedent or present; and finally, that the treatment which is efficacious for softening of the organ is exactly opposed to that for inflammation.

The treatment for softening of the substance of the heart should be similar to that recommended for dilatation with thinning of its parietes; I refer you, therefore, to that subject.

Of surcharge of fat, and of fatty degeneration of the heart.—The heart is occasionally found covered by a large quantity of fat, which is deposited between its muscular substance and the serous membrane immediately investing it. This fat adheres firmly, and is placed principally at the base, edges, and point of the organ, and along the course of the coronary arteries; the posterior surface of the right ventricle is also sometimes covered by it, but it is very rare to find any upon the centre of the posterior surface of the left ventricle.

The parietes of the heart are generally diminished in thickness in proportion to the quantity of fat accumulated upon them; sometimes the thickness is reduced to almost nothing, particularly at the point, and at the posterior surface of the right ventricle.

When the heart is in this state, there is usually also a large accumulation of fat in the inferior part of the mediastinum, and particularly before the pericardium, between it and the pleuræ; this fat is firm; a number of fine blood-vessels ramify upon and through it, giving it a reddish tint; it sometimes pushes the pleura before it, and enveloped by that membrane it projects into the thoracic cavity, and forms irregular fringes, something like the comb of a cock. The fat directly applied upon the muscular substance of the heart is of a pale yellow colour, and of moderate consistence.

No signs have been found by which this state can be discovered.

Fatty degeneration of the heart consists in an infiltration of its muscular substance of a matter precisely similar to fat. This change is usually found in a small portion of the heart only, usually its point; but I present you, gentlemen, with a specimen, which I believe to be unique, and in which you perceive the whole heart to be in a state of fatty degeneration. The form of the muscular fibres is still very apparent, but their red colour has entirely disappeared; instead of which, they are of a pale yellow tint. If a scalpel be plunged into the organ, or paper be rubbed upon its surface, they become greased, as if by butter or lard. When, however, the degeneration is partial, it seems to commence from the external surface to proceed inwardly, so that near the cavity of the ventricles the muscular texture is very apparent; more externally it is less evident; and upon the surface it is often lost.

There are no symptoms yet known indicative of this condition of the heart.

Of cartilaginous or ossific deposits in the muscular texture of the heart.—The muscular substance of the heart has rarely been seen ossified. Haller relates the case of a child, in whom the inferior portion of the right

ventricle, the most fleshy part of the left ventricle, the semi-lunar valves of the aorta, and pulmonary artery, and the aorta, were in that state. Renauldin published a most extraordinary case, of a student in medicine, of the age of 33 years, in whom the heart was found extremely hard and heavy; its muscular substance was in a state of petrification, presenting in some parts a sandy appearance, in others, that of a saline crystallisation. The *earnæ columnæ* were ossified without their form being changed, although they had increased in volume, some of them being as large as the extremity of the little finger, and appearing like stalactites, placed in different directions. The right ventricle was healthy; the temporal, maxillary, and a part of the radial arteries, were ossified on each side.

The symptoms of this case were strong and frequent palpitations of the heart; the cardiac region gave a dull sound on percussion, and when the hand was applied over the organ, a sort of separation of the ribs was felt; upon slight pressure, considerable acute pain was produced, which remained some time after the hand was removed.

Burns also mentions a case of ossification, in which some of the *earnæ columnæ* were transformed into bone. There are a few instances on record of ossification of the auricles.

Cartilaginous deposits are occasionally found in the muscular substance of the heart; but they are generally interposed between the internal membrane of the organ and its muscular fibres, and are rarely of considerable extent or thickness.

Laennec believed that an extensive ossification or cartilaginous induration of the heart would produce a considerable increase of the sounds of its movements, and that these sounds would probably be heard at some distance from the patient.

Other accidental deposits in the substance of the heart.—Tubercles have been found in the substance of the heart. Recamier records an instance of a part of the heart being converted into a scirrhus mass. I have seen a deposit of medullary sarcoma between the serous membrane enveloping the organ and its muscular fibres [shewing it]. Laennec, Andral, and Bayle, mention similar instances.

Serous cysts have also been observed between the serous membrane and the muscular fibres. Dupuytren met with one in the substance of the organ, projecting into the cavity of the right auricle.

OBSERVATIONS
ON THE
PATHOLOGY OF PHLEGMASIA
DOLENS;

*With the History of a Case which presented
several unusual appearances*.*

By — ANDERSON, ESQ.

Surgeon, Manchester.

THE recent investigations of Dr. Davis, Mr. Lawrence, and particularly of Dr. Robert Lee, in this country, and of Bouillaud, &c. on the continent, all tending to one result,—and that result being the clearest possible elucidation of the pathology of this heretofore obscure disease,—have rendered further researches for its proximate cause almost superfluous; but the additional evidence which the case I am about to relate will afford, is strongly corroborative of the truth of their opinions, and would of itself, I am disposed to think, be an incontrovertible proof, if one were needed, of their accuracy in stating the proximate cause of this disease to consist essentially of inflammation of the coats of the veins.

In taking a survey of the opinions of those who have more particularly devoted themselves to the study of this disease, there will be found an admirable uniformity in their descriptions of the symptoms, and quite as wonderful a diversity in their opinions upon its pathology. Mauriceau, who is perhaps the first author who recorded his opinions on this subject, gives an account of the symptoms and progress of the ailment, quite as clear and as accurate as any who have followed him. He imputes the disease to a metastasis of the lochia into the lower extremities; he evidently perceived the corded state of the veins, but he had mistaken it for a nerve. Mesnard, thirty years afterwards, did nothing more than tread exactly in the footsteps of Mauriceau. Until the middle of the last century, Mauriceau's theory was universally adopted by the medical world; but at this period Puzos and Levret advanced their opinions upon the subject. They were the authors of the celebrated doctrine of metastasis of milk (*dépôts du lait*). This theory maintained for a long time a brilliant reputation, and was at length superseded by the lymphatic theory. This latter hypothesis was first advocated by Dr. White, of this town, and strongly supported by Dr. Ferriar. They believed that the lymphatics of the lower extremities, in their passage through the

pelvis, were injured to such an extent by the pressure of the fœtus upon them during parturition, as to excite in them a spreading inflammation, producing the phenomena of phlegmasia dolens. Dr. Trye, of Gloucester, afterwards supported this theory, but with this singular modification—that the lymphatics, in their passage over the brim of the pelvis, were absolutely cut through; and he inferred this from the fact, that up to that period the disease had never been known to occur twice in the same individual; and that this circumstance could arise only from the total destruction of the lymphatics.

Up to the time of the appearance of Dr. Hull's work, in 1800, not the slightest reference had been made by any author to the actual condition of the blood-vessels. Every writer had perceived the painful cord in the direction of the femoral veins, yet not one for a moment conceived the possibility of the blood-vessels being inflamed. It has been already stated that Mauriceau considered it a swelling of the nerve; Puzos and Levret believed it owing to an infiltration or metastasis of the milk into the cellular sheath of the vessels; and White and Trye looked upon it as an evidence of the truth of their opinion, that the lymphatics were in a state of inflammation. It is surprising that this corded state of the vein, which is invariably present, and, in fact, is the essential symptom of the disease, should have been considered merely as a casual circumstance, and have obtained so little notice. Dr. Hull was the first who declared that the phenomena of the disease could not be satisfactorily accounted for without a considerable primary affection of the blood-vessels. Of the manner in which he has disproved all the previous hypotheses on this subject, Dr. Davis says, "Dr. Hull, in his Essay, has criticised at some length, and with the ability which both his friends and his enemies have well known how to appreciate, the doctrinal speculations of his predecessors."

But he has not confined himself to proving the fallacies of previous writers: he has given us a more full and elaborate account of the disease, and has presented us with a body of clinical information and such acute and appropriate observations, as have obtained for its highly-respected author the reputation which he enjoys. His work is one which will at all future times, whatever may be the opinions of the pathology of this disease, be consulted with the greatest advantage. It is worthy of remark, that until twenty-three years after the appearance of Dr. Hull's work, not a single opportunity had occurred of verifying, by anatomical investigations, his opinion, that the sanguiferous system was

* Read before the Manchester Medical Society.

affected. In January, 1823, however, Bouilland, in the *Archives de Medecine*, related several cases and dissections, in which the crural veins were obliterated in women who had suffered from this disease. In the following May, Dr. Davis read his essay to the Medical and Chirurgical Society of London, in which are reported four cases, with the appearances after death; in all of these the iliac and femoral veins had undergone considerable alterations in their structure, evidently the result of inflammation of their parietes. To Dr. Robert Lee, however, we are mainly indebted for the great advances which have been made in this branch of pathology. In his work on the Diseases of Women, recently published, he has recorded not less than twenty-five well-marked cases of this disease, twelve of them occurring in puerperal women, eight of which were fatal; and in these eight fatal cases, by an appeal to morbid anatomy, he has most satisfactorily demonstrated the fact, that venous inflammation is the cause of this disease. He has not only collected more information, but he has advanced further than any of his predecessors in this path of investigation. In all the fatal cases occurring in puerperal women which have fallen under his notice, he has been able to trace the inflammation into the uterine sinuses. He gives it as his opinion, that the inflammation commences in the uterine veins, and from thence spreads along the hypogastric into the iliac and femoral veins, and so along the lower extremity; and by this he is enabled to solve the mystery *why this disease should exist so frequently in the puerperal state*. In all the other cases of phlebitis which he gives an account of,—some of which were owing to violence done to the vein itself—some to the local application of cold—to ulceration of tissues through which the inflamed vein passed,—the attendant phenomena were precisely those of puerperal phlebitis; and in those fatal cases where opportunities were afforded of examining the tissues, the veins presented the same morbid appearances.

As the following case is, I think, a remarkable illustration of phlegmasia dolens,—being nothing more or less than phlebitis, with the consequences which must inevitably result to the tissues in the immediate neighbourhood of the affected veins,—I will at once proceed to relate it, with as much brevity as will just enable me to make myself understood.

The patient was 25 years of age, of the decidedly nervous temperament. Four years previous to conception had been very delicate; had suffered severely from chronic hepatitis, but at the time of conception was without absolute ailment, though

reduced from previous attacks of inflammatory disease. During utero-gestation she gained flesh, and was not only exempted from all the usual ills of pregnancy, but had experienced a total cessation of all her previous ailments. At 1 o'clock on the evening of the 21st June, in the ninth month of pregnancy, the membrane ruptured, without the slightest perceptible contraction of the uterus, and the whole of the waters were evacuated. Half an hour afterwards labour pains came on, and continued increasing until 11 o'clock, when the os uteri was found dilated to the size of a shilling. Having ascertained that for the last few days the bowels had been rather confined, an aperient enema was directed to be administered, which very satisfactorily cleared them. The pains then continued increasing until 9 o'clock the next morning, when she was delivered of a female child. Immediately after the expulsion of the child, nearly a quart of blood was expelled from the womb; the placenta, which was found detached, was instantly withdrawn, and a perfect contraction of the uterus immediately brought about by manipulation—dashing cold water upon the abdomen, and applying cold cloths to the vulva. The patient remained in a state very nearly approaching to syncope for upwards of an hour. She was gradually restored from this state, and in the course of two or three hours was considered out of danger. She convalesced well up to the third day after labour; it was then thought advisable to administer an aperient, as the bowels had not been moved since delivery: a few relaxed motions were procured, and from that time forward the bowels were continually more or less griped. On the 8th of July (the fourteenth day after delivery) the affection of the bowels was so severe as to necessitate the employment of opiates; these were alternated with aperients, and she gradually improved until the 14th, three weeks after delivery.

On the 15th, she complained, for the first time, of an obscure pain in the left side, groin, and hip, but declared it to have existed for a few days, and gradually increasing: at this time there was not the slightest constitutional symptom, or disturbance of any function. On the 17th the pain had become very acute, and had extended down the thigh; still not the slightest constitutional disturbance, or any perceptible swelling or redness. Concluding the pain to be rheumatic or neuralgic, a stimulant liniment only was directed to be used. On the 18th, at three o'clock in the morning, I was called up to afford some relief, if possible, to the acute pain of the thigh; rigors had taken place, the pulse was accelerated, and fever had

set in. On applying the liniment to the thigh, the femoral vein was found to be exquisitely tender and painful to the touch, and a slightly corded state of this vein was perceptible. Some degree of swelling of the thigh and groin was now evident. The real nature of the ailment being clearly discovered, thirty leeches were at once employed; the healthy lochia continued to flow, and there was no pain on pressure of the uterine region; the lacteal secretion, which for the last two or three days had been gradually decreasing, was now totally suppressed.

July 19th.—The whole leg, thigh, and foot, very much swollen; the skin white, but every superficial vein of the extremity was visible, of a rich blue colour. These veins were exquisitely painful when touched even with a feather; no relief appeared to have followed the application of leeches, and as the patient was yet in an anæmic state, from the hæmorrhage which had followed delivery, opiates were had recourse to, to mitigate the violence of the painful paroxysms which recurred two or three times a day.

July 20.—The superficial veins on the left side of the abdomen, as high as the umbilicus, and posteriorly on the loins up to the ribs, were precisely in the same condition as those in the extremity; the integuments being white and very much swollen. The pain felt in these parts was precisely of the same nature, and equally as acute, as that felt in the extremity.

July 21st.—The pain, swelling, &c. of the parts affected were at this time at the height; henceforward the pain and sense of tension became gradually less acute, the glossy state of skin became daily less evident, and the swelling began to pit upon pressure. The femoral vein remained hard and corded, and numerous other superficial veins gradually became visible, enlarging from day to day, and clustering together after the manner of varicose veins, evidently loaded with circulating blood. Previous to the paroxysms of pain there was slight rigors; during the paroxysms the pulse rose to 120, the swelling increased, sense of tension of skin, as if cords were pulling the leg, were experienced, and the skin became hot and dry. During the intervals, the pulse fell to the natural standard, the painful sensations passed away, and copious perspirations took place. The tongue was invariably clean and moist. From the time when the inflammatory symptoms began to subside, the disordered state of the bowels began to increase; the motions were green and fetid; at first, three or four were passed in the twenty-four hours, accompanied with rather severe griping.

On the 25th of August, about a month

after the phlegmasia began to subside, the affection of the bowels had become so severe as to threaten the patient's life; she had not less than from ten to twelve evacuations in the day. The motions were dark, green, mucous, and bloody, and each of them passed with the most excruciating spasm of the bowels that I have ever been a witness to. The patient described them to be much worse than the most violent labour pains. She suffered much from a most distressing nausea and vomiting. For three days previous to this date the stomach had been unable to retain for a moment even a tea-spoonful of any liquid. The matters rejected from the stomach were nearly of the same nature as those passed from the bowels, being a dark-green fluid containing flocculi of mucus. On placing the hand upon the abdomen during a paroxysm of spasm, the transverse colon might be felt contracting at different points upon portions of flatus. At the angle connecting the transverse with the descending colon, the bowel remained the most firmly contracted. When this gave way, the flatus and other contents of the bowels might be felt rapidly passing into the descending colon; and at this moment the patient, in a hurried manner, would express an urgent wish to pass an evacuation, which was at the same instant forced from her with the greatest violence.

During the short intervals of ease, when pressure was made on the abdomen, a sense of soreness was produced, and more particularly towards the hepatic region. The pulse numbered from 120 to 140 in the minute, small and feeble; the skin was hot and dry; the tongue remained moist, and of a natural colour; the urine, sparing in quantity, deposited a copious white sediment; the intellectual faculties perfectly unimpaired. As no remedy could possibly be introduced by the stomach, on account of its extreme irritability, opiate frictions were employed externally, and small laudanum injections were thrown up the bowels; but the irritability of the rectum was such, as to reject the enemata a few minutes after they were administered. The disease continued increasing in severity for the next week, perfectly uncontrolled by any remedial means that were employed.

September 1st.—At this time the patient's dissolution was hourly expected. She had the Hippocratic face, cold extremities, and cold sweats; the fits of spasm occurred about every hour; she was emaciated to the last possible degree; her feeble pulse fluttered at 160, and totally failed for a time after each paroxysm. At this time a large injection, consisting of a pint of milk, with two drachms of laudanum, was ordered to be thrown up the bowels, in the hope that a portion at least

might reach the transverse colon, and he retained a sufficient time to tranquillize the bowels. A portion was immediately rejected; but on examining the abdomen the transverse colon was found distended with the injection; it was retained there for seven hours, and had the full effect that was anticipated. The spasm of the bowels did not return until the enema was forced away.

By pursuing this plan the patient gradually rallied. These opiated injections were made as nutrient as possible, being composed of milk, with animal gelatine, and the white of eggs. By these means her strength was not only supported, but she gained flesh. The stomach remained for upwards of a fortnight so irritable, as not only to be incapable of digesting any aliment, but even of retaining, beyond a few minutes, the least portion of liquid. In the end, however, its functions were restored; and by the end of September there remained not the slightest affection of either stomach or bowels. I must observe, however, that as this disease gradually gave way, so did symptoms of disease in another part increase. She all along declared her opinion, that the disease which had afflicted her in the leg had passed into the bowels; and her reason for so thinking was, that during the absence of spasm, her sensations of tight painful cords in the bowels were much the same as she felt in the leg; and during her convalescence from this intestinal disease, she every day expressed her conviction that the disease was slowly but surely travelling towards the other leg. She described the same painful sensations to exist in the right side, groin, and hip, as she had experienced before the left leg was attacked with inflammation.

The patient's conjectures, at least as far as regards the phlegmasia, were perfectly correct, for on the 25th September the disease had fairly declared itself in the right leg. I need not describe its progress down the veins of this extremity; it will be sufficient, perhaps, to say, that it exactly resembled in all circumstances the affection of the left leg, which I have previously read to you; but in its course upwards, upon the integuments of the abdomen, it differed, though in extent only.

On the 26th September it had extended as high as the ribs, both anteriorly and posteriorly. The veins reflected from the groin up the abdomen were felt enlarged, hard, and painful. On the following day these veins were traced as high as the epigastrium; the day after, the veins on the opposite side of the lower part of the chest were seen in the same condition, but extending no further than, yet exactly up to, the line where the inflammation

had extended itself when the left side was attacked. She now complained of inability to breathe, from a sensation which she experienced of cords binding down the chest, and preventing its expansion. On the following day the veins round the whole of the chest were evidently affected as high up as the axilla, and the embarrassment of breathing still greater; suffice it to say, that it spread into both axillae, down both brachial veins to the ends of the fingers, up both the jugulars, and along the facials over the margin of the lower jaw.

During the whole progress of this inflammation over so vast a surface, there was not the slightest disturbance of the intellect; the tongue, too, remained always moist and clean,—in fact, there were nothing like typhoid symptoms. The febrile symptoms were certainly more remarkable than those which accompanied the attack upon the left leg; otherwise, the constitutional symptoms were such as I have described to attend the first affection. This disease gradually subsided; and about six weeks after the disease appeared in the left leg the patient was pretty free from complaint.

In order to give a more accurate idea of the consequences which have resulted from this ailment, I may as well describe the state of the patient at this day. She is pale, even chlorotic, in her appearance; she complains still of great weakness, but is able to take very moderate out-door exercise; her digestive organs are in perfect order, but she still remains very thin; the respiratory apparatus is without fault, with this exception, that when any muscular effort is attempted, violent palpitation ensues, and the breathing becomes for a time hurried and embarrassed. The external appearance of the chest, abdomen, and lower extremities, is rather remarkable. Upon the body clusters of veins may be observed, assuming a varicose state; they are very compressible, but rather painful to the touch. In other parts sinuous indentations are visible, and on pressing the finger upon them they give the feeling of minute cords, marking no doubt the site of obliterated veins. The legs are still œdematous, particularly towards evening. Both the femoral veins may be felt large and hard, rolling under the fingers, and still painful to the touch. The internal saphena veins are both very much swollen, but soft; they may be traced easily to the top of the thigh. The external saphenas are in the same state, and may be traced into the popliteal space.

On reviewing the history of this case attentively, and observing the order in which the various symptoms presented themselves, it will at once be obvious that phle-

bitis was the first cause of all the morbid changes.

In the first attack I recognised the swollen and hard condition of the femoral vein before I was enabled to pronounce upon the character of the disease. The swelling of the integuments and glossy whiteness of skin invariably succeeding to the altered condition of the vein, must be regarded as its consequence. The course which the disease observed, not only in the direction of the femoral vessels, but likewise in that of the superficial veins of the rest of the body, will at once prove the identity of phlegmasia dolens and phlebitis. Whether the phlebitis originated in the uterus or not, it may be a difficult point to determine, but I am disposed to conclude the affirmative. Dr. Robert Lee states that he has invariably perceived symptoms of uterine inflammation precede the development of this disease; and from the obscure deep-seated pain which the patient felt in the back, hip, and pelvis, before the disease was evident in the thigh, I am disposed to regard it as corroborating his opinion. It is possible that the cold effusion employed to restrain uterine hæmorrhage might have been the exciting cause.

From the total absence of all typhoid symptoms, I am disposed to believe that the suppuration of the internal coat of the vein, which is described as generally occurring in phlebitis, did not take place in this case. The typhoid symptoms produced by phlebitis have been attributed by all writers to the purulent secretion poured out from the inflamed inner coat of the vein mixing with the circulating blood, and thus acting as a general poison. From the beginning to the end of this case, we had nothing from which we could infer a poisoned circulation. From this absence of pus in the blood I have come to this conclusion,—that all the phenomena of phlegmasia dolens may be produced without any inflammatory affection of the internal coat of the veins.

If purulent inflammation be synonymous with excessive inflammation, we should have had it here, for it has been severe enough to obliterate a great number of veins, and considerably to diminish the calibre of many others—the femorals, for instance; for the saphenæ of both legs empty their blood as usual into the femorals, but are amazingly distended, no doubt from the difficulty they have in forcing their contents through the narrower tubes of the femoral veins.

I have formed an opinion, then, that phlegmasia dolens is essentially phlebitis, but that it exists in the proper or outer coat of the vein. That the inner coat of

the veins have been found diseased, and the veins themselves filled with pus, in those fatal cases which have been examined after death, I can very easily suppose; this only proves that when the internal coat inflames and suppurates, death is the result; and from the many cases of recovery from this disease, I am led to believe that generally the inflammation confines itself to the outer tunic. The affection of the bowels which supervened upon the first attack has ever been to me an obscurity. The patient's opinion is perhaps as correct as any I can form—viz. that the disease extended from the legs into the bowels. From the patient's sensations of pain in the bowels resembling that felt in the legs when inflamed—from the gradual increase of this ailment as the inflammation of the left leg subsided—and from the gradual progress of the disease towards the right leg as the affection of the bowels became less severe, I am inclined to concur with her, and to suspect at least that this intestinal disease was owing to inflammation of the portal veins. I am further warranted in stating this, from the fact of the hæmorrhoidal veins being found in an acute state of inflammation at the termination of this attack.

The disease could be neither called peritonitis nor muco-enteritis, nor by any other name that I know of, unless the one I have suspected be the right one. Dr. Lee, in his article on Diseases of the Veins, in the *Cyclopædia of Medicine*, quotes a case from Dr. Oslander, of inflammation of the umbilical veins in a child, which exactly resembled the one I have related. It is not difficult to suppose the inflammation might have travelled from the extreme branches of the hæmorrhoidal veins, by means of those anastomosing branches which connect it with the mesenteric veins, or along the vena cava to the liver, and so on through its ramifications upon the bowels.

As this case is not one which could at any time be looked upon as a standard for the efficacy of any plan of treatment, on account of the debilitated state of the patient prohibiting the employment of those active antiphlogistic means which are so strongly recommended by all practitioners, I will merely observe, that the greatest advantage was obtained from the free use of opiates. When the disease was at the worst, the patient took as much as four grains of the acetate of morphia in the twenty-four hours. Every means that could be devised to mitigate her sufferings were had recourse to; and by a steady perseverance in this plan, and by using every exertion to keep up her strength, we were enabled at last to bring about her recovery. Dr. Hull's assistance was obtained very

early in the disease; and it is to his diligence mainly, and to his unwearied perseverance in the employment of the means used, and to the many valuable suggestions which he made from time to time, as the symptoms of the disease changed, that we are indebted for her recovery.

Feb. 1835.

OBSERVATIONS
ON THE
PATHOLOGY OF NERVES.

BY HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Concluded from p. 765.]

THE next instance upon which Mr. Pearson relies, as a proof and illustration of his opinion, is thus noticed:—"In the Essays and Observations, Physical and Literary, Vol. III., the late Sir John Pringle has published a case where a tumor, formed by extravasated blood, by pressing upon the intercostal nerves produced pain, irritation, and, perhaps, hiccup, which could not be stopped." Few would suppose from the terms in which this case has been alluded to, that it was an example of aneurism of the abdominal aorta, communicated through Dr. Donald Monro amongst his "Cases of Aneurisms, with remarks;" or that by the "intercostal nerves" Sir John Pringle meant merely the visceral nerves of the abdomen; or that the supposition of the dependence upon pressure, of the pain, irritation, and incurable hiccup, was purely a conjectural opinion, and that but an alternative conjecture. No direct connexion between the tumor and any particular nerve was traced upon dissection; but "upon a review of the whole," it was concluded, "that this tumor growing larger, and in time *pressing upon the intercostal nerves, or upon the transverse flexure of the duodenum*, it occasioned the hiccup, which could never be stopped, as the irritation was always increasing." That Sir J. Pringle alluded to the splanchnic nerves generally, is clear from the situation of the tumor, the upper boundary of which being the emulgent arteries, it could not have affected in any way the nerves either of the stomach or the diaphragm, with the morbid affections of which, excepting in states of extreme exhaustion or of

sphacelus, we find hiccup to be so commonly associated. It is infinitely more probable that in this case the constant pain, which is represented to have been towards the left side, was the result of that inflammatory affection which caused the adhesion of the tumor to the duodenum, and that the hiccup was the natural consequence of that distention of the stomach which resulted from mechanical obstruction of the alimentary canal at its upper part*. If any direct influence had been exerted upon the nerves within the cavity of the abdomen, it might have been anticipated that those of the lower extremities would not have escaped; and so in reality it was, for "sometimes he mentioned a numbness in his feet." This last fact adds to the improbability that the spasmodic affection of the diaphragm, which is the essence of hiccup, should have been produced by the pressure upon nerves, as this would imply contrary effects from the same cause—excitement, producing convulsive movement, above the tumor; defective energy, amounting to paralysis, below it.

As to Dr. Bisset's interesting case, like that related by Dr. Short, it is just an example of the painful subcutaneous tubercle, the nature of which was not then satisfactorily determined, (although Camper had distinctly asserted that these "*tubercula intra nervorum tunicas sedem habent*,") but which all accurate pathologists now agree in considering as a disease of the nerve itself, producing in all cases the effects of a morbid excess of nervous energy.

The string of references, which the erudition of Mr. Pearson enabled him to supply, in a foot note to his interesting and valuable communication, has little relation to the immediate subject under consideration. They are either instances of irritable painful tumors, or diseases producing in sensitive habits great nervous disturbance, sometimes even epileptic paroxysms, implicating in some instances contiguous nerves in the same diseased action, as in cancer, and cured either by excision, or escharotics, or the actual cautery; or they are examples of that indefinite, and to this moment altogether unintelligible state of

* This tumor was of a firm consistence, beginning as high up as the emulgent arteries, where it *adhered* to the transverse flexure of the duodenum, and from thence descending till it came near the pelvis.—*Ess. Phys. and Lit.* V. iii. p. 206.

particular nerves, called the "aura epileptica," which, in those who are liable to epileptic attacks so frequently ushers in a paroxysm. But there is not one of the cases or general statements, thus referred to, which gives any countenance to the opinion, that "a certain degree of pressure upon a nerve will produce pain, spasms, or convulsions."

It thus appears that the cases, accumulated by the industrious researches of Mr. Pearson, are not sufficient to establish the conclusion that any degree of pressure upon a healthy nerve will produce excitement: nor are the arguments or observations of Mr. Swan more satisfactory. The chapter devoted by the latter writer to the subject of compression wants much of his usual clearness, and even contains something approaching to contradiction in the description of its effects. The details upon the subject of compression of nerves are introduced by an account of the effects of "extension," which Mr. Swan appears to think the same or synonymous with pressure. After stating that "a nerve may be extended some way without giving pain or inconvenience," he adds, "but when a nerve is *extended* in any considerable degree, pain is excited; and if the extension be increased, the pain is increased in proportion, till at length the nerve begins to ulcerate; and *if the pressure be not removed*, it becomes almost destroyed by this process." In his description also of the effects of pressure, the statements are either obscure or they are contradictory. Thus "when a nerve is pressed against a bone for a short time, an uneasy sensation is produced, and the parts to which it is distributed feel benumbed. When the pressure is continued longer, these parts entirely lose the power both of sensation and motion; but if it has not been very violent, they will recover;" and yet though impaired sensibility and defective muscular power are thus described as the consequences of the pressure of a nerve against a bone, it is subsequently asserted that "people frequently complain of *pain* in the lower extremities, which is sometimes *very excruciating*. It is often occasioned by the use of tight garters, *which press the nerves against the bones*. But although these two statements appear at the first glance contradictory, yet the contradiction is only apparent, and admits readily of explanation. Both assertions may be

true: pressure upon a healthy nerve produces enfeebled energy, but long-continued pressure, as from tight garters, occasions the nerve to inflame; and it has been already shewn that pressure upon an inflamed nerve is not only painful at the point of compression, but is often also productive of neuralgia in its remote distribution. All the cases adduced or quoted by Mr. Swan, in which pain attended compression of a nerve, will bear this interpretation of the symptoms. The first is an instance of severe pain in the toe, from thickening of the corner of the nail, which had occasioned "an indentation in the flesh about the size of a pin's point." It was in fact, in essence, a corn, only formed by the nail, instead of an inverted cone of hardened integuments, and pressing upon the subjacent sensitive tissues; and it is scarcely possible to doubt, that if the nerve in this case was affected at all, it was either from the continuous mechanical irritation of this "pin's point," or the nerve had become the subject of inflammation from the same cause; just as inflammation was produced by a gooseberry thorn, in the case recorded by Mr. Wardrop; by an angular piece of porcelain, in that related by Mr. Jeffries; by portions of the alveolar process, in those adverted to by Mr. Swan; and by decayed teeth, in the highly-interesting and instructive example detailed by Mr. Mitchell, as well as others alluded to by Swan and Descot. In the second case, a painful affection of the left leg, the fibres of the psoas magnus, and the small psoas mucle, were put upon the stretch by the tumor, with the walls of which "some of the origin of the anterior crural nerve *appeared as if incorporated*, and the body of the second lumbar vertebra was ulcerated; both circumstances rendering it highly probable that the nerves may have been inflamed.

The quotation from Lobstein merely states the facts, that the nerves of the crural plexus may remain uninjured in the midst of lumbar abscesses, but that in cold, scateomatous, and other tumors, the nerves may be wasted, too dry, flattened, applied or agglutinated to the tumors; and that in abscesses situated near the spine, and arising from caries of the vertebrae, the nerves are sometimes destroyed.

In the case of aneurism of the aorta, extracted from Scarpa's work, the pains

in the lumbar region, stretching over the abdomen, were traced, upon dissection, to be owing to "the effused blood, which had formed deep excavations in the substance of the left psoas muscle, so as to *disorganize* the lumbar nerves, and *injure* the anterior crural and obdurator nerves.

In Portal's case, the pain in the great toe of the left foot after eating is referred to the pressure by the last false ribs on the sigmoid flexure of the colon, producing compression of the lumbar plexus. But it must be borne in mind that there was also great curvature of the spine, involving disease of the vertebral column, and in this disease the origin of the lumbar nerves may have been implicated. This is rendered more probable from what was observed in Scarpa's case already referred to, and the instance I have quoted from Ollivier. Besides, I have seen no less than three instances, where the colon was so large and so hard at this part as to have been pronounced to be instances of ovarian tumor. Much pressure upon the nerves must here have been produced, and yet neuralgia attended neither; and the same observation will apply to those examples of minor distention of the sigmoid flexure, which are of every-day occurrence, but are unattended with any pain which can be referred to an affection of the nerves, although numbness, in a greater or less degree, is no uncommon result of pressure under such circumstances.

In the instance of pain from fracture of the glenoid cavity, there cannot be the shadow of a doubt that the nerves in the vicinity were first contused or crushed, then inflamed: and in the case quoted from Mr. Earle, it is expressly stated, as matter of belief, that the same blow which had fractured the clavicle, had lacerated or crushed the axillary plexus of nerves, just as they pass under that bone.

The case of paraplegia only proves that pressure in one degree produces enfeebled nervous energy, and that additional pressure renders the palsy more complete and unmanageable; that of partial paraplegia, from lying on the damp ground, can give no countenance to the notion that pressure upon a healthy nerve occasions pain; and the last instance recorded by Mr. Swan, is one simply of paraplegia, from san-

guineous congestion within the spinal canal.

The very prevailing impression, therefore, that pressure in one degree upon a nerve occasions pain, in a greater degree paralysis, is vague and indefinite, as the difference of degree cannot be made the subject of estimate or description; but it is probably also erroneous, and perhaps, after all, it would be difficult, with all the new lights of modern physiological science, to improve upon the more intelligible, because more perspicuous, statement of Galen upon this point, that "when nerves are compressed by ligatures or the hand, by a phlegmon or a scirrhus, by dislocations or fractures, they *all* become in the first instance torpid, and are afterwards altogether deprived of sense and motion; and such affection of the nerves is called paralysis*": but when a nerve is inflamed, the patient frequently suffers from spasm and alienation of mind, and if he be fortunate enough to fall under the care of an intelligent practitioner, who will divide the nerve, the patient is cured of his spasm and mental disturbance, but the muscle upon which the nerve is distributed loses afterwards its sensibility and power of action†."

But this, after all, is a question to be settled not by authority merely, but by an appeal to experience; and one mode of ascertaining the effects of pressure, which would naturally suggest itself to the mind of one who is engaged in the investigation of these points, is the application of a ligature upon the nerve. The effects of ligatures, however, vary according to so many adventitious circumstances connected with their application, that the inferences deduced from them are unsatisfactory. These effects, for instance, are materially modified by the degree of tightness with which the ligature is drawn, and by its thickness; but it is universally admitted, that if drawn with a sufficient

* Si autem a duro aliquo corpore, quod illi extrinsecus immitatur pressus sit (nervus) ne sic quidem virtutis transitus non morabitur. Proinde nervi, qui vel funiculis vel manibus sunt contracti; et qui ab externo aliquo, quod vel phlegmone sit obsepum velcum sensus nexa duratum, (schirrhum vocant) premuntur; omnes principio quidem torpent, postea vero omnino sensus incutisque expertes fiunt. Et vocatus quidem ejusmodi nervorum vitium, Græce, paralysis, id est (nervorum resolutio.—*De Sympt. Causis*, lib. 1, cap. 5.

† De motu musculorum, lib. i. c. 1, already quoted.

force, and with a string sufficiently small to overcome the protecting influence of the neurilematous covering, the consequences are the same as those produced by a complete solution of continuity of a nerve. The direct and immediate consequences, therefore, of the complete division or removal of a portion of nerve being identical with those of the effective application of a ligature, any observations or reasoning which are legitimate and true as to the one, will be equally applicable to the other; and as the division or excision of a portion of nerve always involves, as its necessary consequence, the annihilation of its function below the seat of injury, so also it may be inferred that paralysis will be the inevitable result of the efficient application of a ligature. Thus, to say nothing of the experiments of physiologists, the surgeon in his operations has, in some instances included inadvertently a nerve in the ligature which was intended to remove a tumor, or compress an artery. An instance of this is related by Morgagni:—A ligature was applied by Valsalva upon the brachial artery, on account of an aneurism produced by a wound in the artery in bleeding. "All the parts below the ligature lost their faculty of sense and motion as soon as it was tied, and the extremity became cold a few hours afterwards*."

But ligatures present to us several sources of fallacy, which rarely influence our deductions in cases of division or excision. If the ligature be thick, or not tied with sufficient force, or the nerve be very large, the medullary fibres protected by the neurilema may not be sufficiently compressed to intercept their function, which in such cases may be only impaired, not destroyed. But even in these cases the immediate consequences are more frequently those of enfeebled energy than excitement†.

* *Frequentia etiam experimenta sunt, quæ, vinculis nervo injectis fiunt. Tunc enim partes omnes musculi qui nervos suos a trunco nervi ligato accipiunt, resolvuntur paralytica neque porro a voluntate in motum eieri possunt.*—Haller, *Elem. Phys.* V. iv. p. 322.

When a nerve has been included in a ligature, the parts to which it is distributed are deprived of sense and motion, in the same manner as if they had been divided.—*Swan on the Diseases of Nerves*, p. 145.

† La liguire d'un nerf, même volumineux, ne produit pas les convulsions, les spasmes, et autres accidens graves que les pathologistes se sont plu à attribuer à ce genre de lésion.—*Descot*, p. 109.

In such cases the function of the nerve is commonly restored at no very remote period, as might be expected, the continuity of the medullary filaments not being completely interrupted. Still the ligature in these cases must have ulcerated the nerve through, to allow of its escape from the wound; but it is not difficult to understand, nor hard to believe, that as the ligature advanced by very slow degrees through the nerve, the part behind may have gradually healed; an opinion rendered the more probable, from the observations of Mr. Swan, that before the ulcerative process commences, and the ligature consequently becomes loose, "immediately the vessels of the injured portion of the nerve begin to enlarge and become more numerous, and coagulable lymph to be effused, and the ligature becomes increased by the lymph" which forms the medium of communication between the portions above and below the ligature. "In an experiment seventy-two hours after the application of the ligature, the separated portions had been united by lymph and the vessels had anastomosed."

There has been considerable discrepancy of opinion, and even some controversial discussion, as to nature's mode of reparation in these cases of re-union, whether after ligatures or division with a knife. All are agreed, however, that the first change is an effusion of lymph which becomes organized, but whether new medullary matter is subsequently deposited has been the matter of dispute. Meckel has marshalled the forces on each side of the question. He represents Cruikshank, Haighton, Fontana, Michaelis, Monro, and Mayo, to be in favour of partial or imperfect reproduction of nervous matter, whilst Arneman decidedly rejects the opinion, asserting that cellular tissue, condensed by inflammation, is the sole mode of communication; the opinion of Meckel himself being, that the last of the series of changes which completes the restoration of the nerve is a conversion of the substance deposited into true medullary matter*. The decision of this question is of secondary importance; it is enough that the intermediate substance performs the office of

* Les expériences rapportées plus haut semblent autoriser à croire que cette substance nouvelle, d'abord homogène dans les plaies de tous les organes, peut finir par se convertir, peu à peu, en véritable substance nerveuse.—*Meckel, Manuel d'Anatomie*, &c. Vol. 1, p. 285.

nervous matter, communicating to the sensorium the impressions from without, and conveying from within the mandates of the will to the muscles influenced by the nerve which has been tied or divided. Mr. Swan is of opinion that not only is the communication carried on through this "new formed substance," but also that "in some instances new nerves are formed to keep up a communication with the brain." But this opinion requires the confirmation of more numerous experiments and observations than have been hitherto collected upon the subject. It appears quite within the bounds of possibility that those described by Mr. Swan may have been minute nerves, now first perceptible in consequence of that enlargement, which is consequent upon greater exertion; enlarged by what Mr. John Hunter would have denominated, in his very peculiar phraseology, "the stimulus of necessity."

[To be concluded in our next.]

INJECTIONS OF THE VESSELS OF THE FŒTUS,

TO SHew SOME OF THE PECULIARITIES OF ITS CIRCULATION*.

By DR. JOHN REID.

THREE fœtuses were injected in the following manner:—A red-coloured injection was thrown up the vena cava inferior, and a yellow-coloured injection down the vena cava superior at the same time, and as much as possible in equal quantity, and with equal force, to endeavour to imitate the currents which flow along these veins during the life of the fœtus. As it is impossible that one person can manage both, it was necessary to intrust the two syringes to different persons; and this must render the success of the injection more precarious. It was principally wished by these injections to try to what extent the Eustachian valve prevented the intermixture of the two currents entering the right auricle by the two cavæ; and, provided that the Eustachian valve really had the effect of keeping the two currents to a certain extent separate,

directing the greater part of the ascending current directly into the left auricle through the foramen ovale, whether these two currents still continued separate in their subsequent course,—that passing along the aorta going entirely to the large vessels of the head and superior extremities, and that through the ductus arteriosus filling the descending aorta.

The first trial was made on a fœtus of four months. By some mistake the injection was not thrown down the cava superior, and that thrown along the cava inferior was in small quantity. On examining the heart, we found that the red injection had passed along the cava inferior; that some of it had passed into the right auricle, but the greater part had been directed through the foramen ovale into the left auricle by the Eustachian valve, so as to fill the whole of the left side of the heart, while not a single drop of injection had passed into the right ventricle.

This experiment, then, was not entirely useless, for it shewed, in this case at least, that a fluid ascending through the inferior cava passed more readily into the left side of the heart than into the right. That part of the injection should have passed into the right auricle, was to have been expected; for though the Eustachian valve when perfect nearly insulates the cava inferior from the cavity of the right auricle, yet it cannot entirely exclude the passage of some of the fluid into the right auricle, when that cavity is not occupied by the column of blood which descends through the superior cava.

The second trial was upon a fœtus at the full period. Upon examination we found, that, though the two currents chiefly passed in the course which we shall fully describe in the third experiment, yet some intermixture had taken place. This was not to any great extent. This intermixture might depend upon two causes. First, the Eustachian valve is supposed to be less perfect at the full time than at an earlier period; and, secondly, the injection was not so well managed as it ought to have been, from the difficulties experienced in two persons commencing and stopping exactly at the same time, and using nearly equal forces.

The third trial was upon a fœtus of about seven months, to judge from its

* Edinburgh Medical and Surgical Journal.

size and the position of the testicles. Care was taken, by a previous course of training, to throw in the two currents as equally as possible. On tracing the red injection upwards, we found that it had passed through the foramen ovale, and filled the left side of the heart, without any intermixture with the yellow, except very slightly at the posterior part of the right auricle. Not a drop of the yellow appeared to have accompanied the red into the left side of the heart. From the left side of the heart it ascended the aorta, and filled all the large vessels going to the head and upper extremities. The injection in all these vessels had not the slightest tinge of yellow.

On tracing the yellow downwards, we found it filling the right auricle, free from intermixture, except slightly at the posterior part of the auricle, as already mentioned. From the right auricle it filled the right ventricle, passed along the pulmonary artery, and filled the ductus arteriosus, and branches going to the lungs. On entering the aorta, it passed down that vessel, filling it completely without any intermixture of red; and thus all the branches of the thoracic and abdominal aorta were filled with yellow. The whole of the red had passed to the upper part of the body. In an experiment of this kind, the injection, after filling the left auricle, passes along the pulmonary veins, but, during the life of the fœtus, these veins must be filled by the blood returning from the pulmonary arteries. Had the injection been sufficiently minute, it would have passed from the pulmonary arteries into the pulmonary veins, and, consequently, we would have had some intermixture of yellow in the left auricle.

Though it may be doubted whether these two currents keep themselves so distinctly separate in the living fœtus as they appear to have done in this last experiment, yet, from the result of these three injections, we may be justified in concluding, that the blood returning from the placenta principally passes to the head and superior extremities, and that the lower part of the body is principally supplied by the blood returning by the cava superior, or, in other words, by blood which has already made a circulation in the body.

REPLY TO MR. RICKMAN'S REMARKS

ON THE

INFANT MORTALITY IN MANUFACTURING TOWNS.

By M. L. H. VILLERMÉ,

Member of the Institut *.

To the Editor of the Medical Gazette.

SIR,

THE high importance of the last "Returns of the Population of Great Britain," the impress of truth which is stamped upon them from beginning to end, the great esteem which I have long entertained for the learned compiler, and the desire of one day seeing those valuable documents made the model of similar ones in France,—all these considerations induced me to draw up that analysis which Mr. Rickman has done me the favour of making some critical remarks upon, in your journal of the 24th January.

I perceive by those remarks that he does not accord with me respecting the duration of life in the manufacturing, as compared with the agricultural, counties. In fact, from his calculations, founded upon the number of marriages, baptisms, and deaths, combined in a certain way, and taken in connexion with the amount of the population in 1831, it would follow that if the number of deaths of children under two years of age were subtracted from the whole, the re-

* [We think it but fair and proper towards M. Villermé, to give the original as well as the translation of his letter.—ED. GAZ.]

"La haute importance des derniers *Returns of the Population of Great Britain*, le cachet de vérité que l'on y aperçoit d'un bout à l'autre, la grande estime que depuis long-temps j'ai vouée à leur savant rédacteur, et le désir de voir ces précieux documents servir de modèle en France pour des recherches sur la population, tout m'en a fait rédiger une analyse que Mr. Rickman a honorée d'observations critiques insérées dans le cahier du 24 Janvier de votre journal.

"Je vois par ces observations, qu'il ne pense pas comme moi en ce qui concerne la durée de la vie dans vos comtés manufacturiers comparés aux comtés agricoles. En effet, selon lui, il résulterait des chiffres des mariages, des baptêmes, et des enterremens combinés entre eux d'une certaine manière et avec le chiffre de la population trouvée en 1831, que si l'on retranche les décès des petits enfans âgés de moins de deux ans accomplis, tous les autres décès sont à la population entière, dans l'Angleterre prise en masse,

mainder would exhibit for all England a mortality of 1 in 75, while in Lancashire (which both of us take as a sample of the manufacturing counties generally) it is 1 in 77. This is the simple question between us.

The consequence of Mr. Rickman's statement is manifestly at variance with my opinion. With regard to the mortality of very young children we are both agreed, and the rather, as I admit, as well as he, that those children having nothing to do with the factories, cannot suffer directly from their influence. But it is surely quite immaterial regarding the present question, whether those children die, as Mr. Rickman says, by the families to which they belong being cooped up in close and confined dwellings in the vicinity of the factories, or by the direct influence of the latter, since the crowding of the habitations is caused by the manufactories themselves, or by the condition in which the operatives are obliged to live. Whether a person be killed by a splinter of rock struck off

by a cannon ball, or by the ball itself, is it not all the same? is it not the cannon-shot that has killed him? Add to this, that every thing I said with regard to the influence of your manufactures was founded, as it should be, altogether on the tables of mortality in the third volume of your returns. Finally, I have not separated that influence (and I said distinctly I did not), from the effects of residence in the chief manufacturing towns, nor that of the rapid increase of population by births becoming more numerous than they ever previously were.

I have just said that I borrowed my facts entirely from the official mortality tables. Now, these tables are far from authorising a smaller proportion of deaths, subsequent to two years of age, in the manufacturing counties (in Lancashire particularly), than in all England beside, more especially the agricultural counties; this the following table, which any body may verify from the documents in question, will prove.

Of 10,000 Individuals born in the Agricultural Counties.	The Survivors of their 10th Year amount to	The Number that die between their 10th and their 40th Year.	
		Reckoning from Birth.	Reckoning from the 10th Year.
Rutland	6816	1847	2711
North Riding of York	7053	2097	2974
Hereford	7199	2025	2813
Wilts	6860	2070	3018
Westmoreland	6876	2069	3009
Berks	6654	2080	3121
Northampton	6574	2095	3187
Buckingham	6549	2097	3202

Oxford	6194	2023	3115
Suffolk	6694	2156	3221
Huntingdon	6257	2053	3281
Northumberland	6691	2132	3187
Norfolk	6118	1893	3094
Devon	6359	1834	2884
Essex	6107	2203	3451
Bedford	6541	2323	3551
Lincoln	6115	1995	3262
Cambridge *	5775	2041	3539

* The high mortality of Cambridgeshire for the ages between 10 and 40, must be imputed to the unhealthiness of the Isle of Ely. As to that of Bedford and Essex, which are both above the mean mortality of the said ages for all England, I know not what to say. I have, I should add, never visited England; and the classification of the counties which I adopt is taken from English authorities, quoted by me in my Analysis of the Parliamentary Returns —L.II.V.

Of 10,000 Individuals born in the Manufacturing Counties.	The Survivors of their 10th Year amount to	The number that die between their 10th and their 40th Year.	
		Reckoning from Birth.	Reckoning from the 10th Year.
Salop	6684	2180	3262

Stafford	5640	2120	3759
West Riding of York	5619	2078	3698
Chester	5917	2272	3840
Lancaster	5148	2111	4100
Monmouth *	6661	2047	3073
Mean for the Agricultural } Counties	6495	2038	3134
— Manufacturing do. } Monmouth excepted	5645	2104	3726
All England proper	6094	2064	3387
In Wales	6728	2013	2992
In England and Wales together	6125	2061	3365

* Monmouthshire here presents a low mortality from 10 to 40; but Mr. Rickman has no confidence in the correctness of the returns for this county. Excepting Monmouth, therefore, there only remain Salop and Durham, in which the mortality from 10 to 40 is below that of all England during the same period.—L.H.V.

Thus it is not merely the *infants* in the manufacturing districts who are subject to a high mortality; those between 10 and 40 years of age are exposed to a similar risk.

But further, on Mr. Rickman's own showing,—notwithstanding the posi-

tion he has more recently adopted, —my statements are fully borne out. This appears from the 43 tables of the English county mortality, which are all reduced to the scale of 10,000, and have each a column headed “In each period of man's life died per cent.” There the

comme l'est à 75, et, dans le Lancastre (que lui et moi prenons comme type des districts manufacturiers), comme l'est à 77. A cela se réduit toute l'argumentation.

“La conséquence est évidente: elle milite contre mon opinion. Quant à la mortalité des très-petits enfans, Mr. Rickman et moi sommes d'accord, et d'autant mieux que j'admets, avec lui, que ces enfans qui ne travaillent pas dans les fabriques ne peuvent en recevoir directement d'influence. Mais peu importe, pour la question actuelle, qu'ils meurent, comme Mr. Rickman l'a dit, par l'établissement des familles dans des habitations trop étroites au voisinage immédiat des manufactures, ou bien par une influence directe de celles-ci, si l'encombrement des habitations est amené par les fabriques elles-mêmes, ou par les conditions dans lesquelles vivent leurs ouvriers. N'est-il pas vrai qu'être tué par une pierre qu'un boulet de canon frappe et lance dans l'air, ou bien par le boulet lui-même, c'est également mourir d'un coup de canon? Ajoutez que tout ce que j'ai dit de l'influence de vos manufactures s'appuyait et devait s'appuyer seulement sur les tables de mortalité du troisième volume de vos *Returns*. Enfin, je n'ai point séparé cette influence, et j'ai eu le soin d'en avertir, de celle du séjour dans les villes ou sont les principaux at-

liers, ni de celle de l'accroissement rapide de la population par des naissances devenues plus nombreuses que jamais.

“Je viens de dire que j'avais pris mes faits dans vos seules tables officielles de mortalité. Or, ces tables sont bien loin de justifier une moindre proportion des morts passe l'âge de 2 ans, dans les comtés manufacturiers et particulièrement dans le Lancastre, que dans l'ensemble de l'Angleterre, et surtout que dans les comtés agricoles. Vous allez en juger par le tableau suivant, de l'exactitude duquel on peut s'assurer, en refaisant les calculs à l'aide des tables dont il s'agit. [See Table in the Text.]

“Ainsi, ce ne sont pas seulement les petits enfans qui éprouvent une mortalité plus forte dans les districts manufacturiers de l'Angleterre, que dans les districts agricoles; les personnes âgées depuis 10 ans jusqu'à 40 l'éprouvent également.

“Mais d'ailleurs, Mr. Rickman a pris soin lui-même, malgré l'assertion qu'il m'oppose aujourd'hui, de justifier ce que j'avance. Car ces quarante-trois tables de mortalité des comtés de l'Angleterre proprement dite, qu'il a ramenées à 10,000 décès totaux, afin de les rendre parfaitement comparables, ont toutes une colonne intitulée *In each period (of man's life) died per cent.*

important fact which I have just stated is expressly set forth, for the several classes of ages comprehended in the tables. For example, we find from

those tables that out of 100 individuals belonging to each class respectively, there died, during the 18 years from 1813 to 1830—

	Throughout all England.	In Lancashire.	West Riding of Yorkshire.	Hereford- shire.	North Riding of Yorkshire.
Before 5 years	31.8	41	39	24	25
From 5 to 9	06.5	08	07	05	05
10 — 14	04.3	06	05	01	04
15 — 19	05.8	08	07	05	06
20 — 29	14.2	17	15	12	13
30 — 39	14.3	18	15	11	11
40 — 49	16.4	21	16	12	12
50 — 59	20.8	25	21	16	15
60 — 69	34.3	38	36	29	27
70 — 79	59.3	63	61	53	52
80 — 89	87.5	88	88	85	81
90 — 99	95.5	94	97	93	95
Above 100	100	100	100	100	100

The obvious inference from all this is, that at every period up to 80, the mortality falls considerably heavier upon the manufacturing counties than on all England in general, or on the agricultural counties in particular. And the same result becomes still more manifest, when we suppose 100 to be the number of deaths of all ages in England, taken collectively, and we reduce by the rule of proportion to this standard the amount of mortality at each age in the agricultural and the manufacturing counties.

I might easily cite a number of additional facts, but those already given may suffice, as I have instanced all England proper, two counties essentially manufacturing, and among the agricultural counties the first two that came to my hand. If I have left out Rutland among the latter, while I have placed its name at the head of the second list,

it is not because the mortality of that county was unfavourable to my position (for it is in reality just the reverse), but because the Rutland table has been constructed on too limited a number of observations.

In short, what better argument could be tendered than that afforded by the data in the last table, in order to disprove the assertion that the mortality for ages subsequent to 2, in your manufacturing districts, is not higher than in others? and please once more to observe that those data are supplied by Mr. Rickman himself; they are given in his tables. The only question, therefore, that can possibly arise, is whether I have cited them faithfully. This being the case, I am either justified in the unfavourable account I have given of the short duration of life in the manufacturing districts, or Mr. R.'s data are incorrect.

où le fait important que je viens de montrer se trouve exprimé pour chacune des catégories d'âges en lesquelles ces tables ont été divisées. On y lit, par exemple, que sur 100 individus des mêmes groupes d'âges, il en est mort pendant les 18 années consécutives de 1813 à 1830, savoir :— [See Table in the Text.]

“Ce qui revient à dire que pour tous les âges, jusqu'à celui de 80 ans, la mortalité pèse notablement plus sur vos comtés manufacturiers que sur l'Angleterre prise en masse, et que sur vos comtés agricoles en particulier. Cela serait encore plus manifeste, si, supposant 100 la nombre des morts, nombre des décès de tous les âges dans l'ensemble de l'Angleterre, on rapportait à ce module par des règles de proportion la valeur de la mortalité de chaque âge dans les comtés agricoles et manufacturiers.

“Je pourrais multiplier ici les faits; mais il suffit, je crois, d'avoir cité avec l'Angleterre propre tout entière, deux comtés essentiellement

manufacturiers, et parmi les comtés agricoles, les deux premiers venus. Si j'ai retranché de ces derniers le Rutland, dont le nom se voit en tête de l'autre tableau, ce n'est point parce que sa table de mortalité n'est pas favorable à ma thèse (elle l'est au contraire beaucoup), mais parce que cette table est fondée sur un trop petit nombre d'observations.

“Que pourrais-je dire, je le demande, qui vaille les proportions des décès aux différents âges données dans le dernier tableau, pour combattre l'assertion que pas-é l'âge de 2 ans la mortalité n'est pas plus forte dans vos districts manufacturiers que dans les autres? Et notez bien que, comme on l'a déjà vu, ces proportions sont de Mr. Rickman lui-même, qui les a écrites dans ses tables. Il ne s'agit donc plus que de savoir si je les ai fidèlement reproduites. S'il en est ainsi, tout le mal que je signale dans vos districts manufacturiers, sous le rapport de la durée de la vie, est vrai, ou bien les chiffres de

There is no further room for discussion, except as to the explanation of the facts; and the following is what I said on the subject in my Analysis, at the end of paragraph vii. :—

“Whether it be to the extension of her manufactures or not, that we are to attribute the excessive mortality among the manufacturing population of England, or whether it be owing to concomitant circumstances, with which I have at present nothing to do, certain it is, that in England, and in the actual state of things, the offspring of the manufacturing part of the community becomes more rapidly extinct, drops off in a much larger proportion, than the issue of the manufacturing population.”

It may be observed, that throughout the whole of this reply I have constantly entrenched myself behind the cyphers in the excellent and noble work of Mr. Rickman. I conclude by requesting him to believe that I am just as free from passion as I am from any interested motive regarding the question which has been raised. Like him, too, I have no aim, no wish, but for the truth; and such is my confidence in his enlightenment and his candour, that I leave it altogether to him to do justice between us.

Your most obedient servant,

L. R. VILLERME.

Paris, February 1835.

P.S.—Mr. Rickman's tables, like all other tables of mortality, assume that every

Mr. Rickman sont faux. On ne pourra plus discuter ensuite que sur l'explication des faits. Or, voici comme j'en parle dans mon analyse des trois volumes de documens officiels sur la Population Anglaise, à la fin du paragraphe VII. :—

“Que ce soit ou non à l'extension des fabriques qu'il faille attribuer l'excessive mortalité des populations manufacturières en Angleterre, ou bien aussi à des circonstances concomitantes, ce que je n'examine point, toujours est il qu'en Angleterre, et dans l'état actuel des choses, les générations des populations manufacturières s'éteignent plus vite, succombent en bien plus forte proportion, que les générations des populations agricoles.”

“On a pu remarquer que, dans toute cette réponse, je me suis tenu constamment retranché, si l'on peut s'exprimer ainsi, derrière les chiffres du grand et beau travail de Mr. Rickman. Je termine en le priant de me croire sans passion, comme sans intérêt, dans la solution de la question soulevée par moi. Comme lui, je ne cherche, je ne veux, que la vérité; et c'est à lui-même que je m'en rapporte pour la trouver et la dire, tant j'ai foi dans ses lumières et dans sa conscience.”

Paris, Feb. 1835.

“Post-Scriptum.—Comme toutes les tables de mortalité, celles de Mr. Rickman supposent que

individual registered in them was born in the locality for which they were drawn up: but emigration, which, it is certain, takes place chiefly at the expense of the agricultural counties, and immigration into the manufacturing districts, necessarily modify the results. The effect of the former is to render the amount of probable life and mean life less than it really is; at least up to those ages when emigration ceases: immigration, on the contrary, causes it to appear larger. Accordingly, when we calculate the amount of probable life and mean life for each county, on the data afforded by Mr. Rickman's tables, we find it very sensibly larger in the agricultural than in the manufacturing districts. This fact, on which Mr. Rickman himself has laid much stress in the Preface to the Abstracts, when comparing the North with the West Riding of Yorkshire, and with Lancashire, were alone sufficient to prove irrefutably that I am not wrong.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Outlines of Comparative Anatomy.

By R. E. GRANT, M.D. F.R.S.E.
Sec. Part I. Baillière.

ALL who attempted in vain to read the heavy course of lectures on Comparative Anatomy, lately reported in the *Lancet*, or who were loath to admit that publication into their libraries, will perhaps be glad to find that the substance,

tous les individus qu'elles comprennent ont pris naissance dans les localités pour lesquelles ces tables ont été dressées. Mais les émigrations qui, assure-t-on, se font principalement aux dépens des comtés agricoles, et les immigrations dans les comtés manufacturiers, en modifient nécessairement les résultats. L'émigration a pour effet de faire paraître la vie moyenne plus courte qu'elle ne le sont réellement, du moins jusqu'aux âges où cette émigration cesse, et l'immigration, au contraire, de les faire paraître plus longues. Or, lorsqu'on calcule la valeur de la vie probable et de la vie moyenne, pour chaque comté, à l'aide des tables de Mr. Rickman, on les trouve très sensiblement plus longues dans les comtés agricoles que dans les comtés manufacturiers. Ce fait, sur lequel Mr. Rickman a beaucoup insisté dans la Préface des trois volumes in folio, en comparant le comté North Riding of York aux deux comtés West Riding, et Lancaster, serait seul la preuve irrécusable que je ne me suis point trompé.”

the really useful part, of those lectures, has been collected by the author, and offered to the public in a more appropriate and convenient form.

We cannot, however, speak positively as to the merits of the present performance, until we see more of it. There are to be *four* parts, it seems; but as yet we have no preface, nor introduction, stating the author's views. The fasciculus now before us is, in fact, the barest specimen of Outlines we have ever seen. There is not a single note given in it; no bibliography; not an intimation, in short, that any body had ever written before on the subject, except Dr. Grant.

Some authors, we are aware, have a trick of never quoting, in order that they may appear to be so much the more original; but, unfortunately for them, it but too often turns out that they are in consequence themselves seldom quoted. In the case of Haller, it may be said that *his* Outlines are without references. But, beside that Dr. Grant is not exactly Haller,—the *Primæ Lineæ* is but a book of reference to the *Opus Magnum*, in which the bibliography and illustrative notes of every description abound. In a work on natural science, it is a great fault not to guarantee the *facts* therein stated by proper authorities. Neither Cuvier, Blumenbach, Carus, Otto, nor any other writer on such subjects, that we are acquainted with, have ventured to put forth their statements in so magisterial a form. Dr. Grant had better think of this in time: though we presume that all that can now be done in the matter is to *append* a bibliography and a posse of notes,—a proceeding much less calculated to give satisfaction than having them at the foot of each page, or at the end of each chapter.

In other respects, the author has acquitted himself with all that ability, which, in addition to his great attainments as a naturalist, render him perhaps the most competent person in England to write a manual on the subject.

This Part contains the comparative anatomy of the bones, ligaments, and part of the muscular system. It is neatly printed; and many of the woodcuts (of which there are sixty-five altogether) are well executed. We shall await the completion of the work with some anxiety for its success.

MEDICAL GAZETTE.

Saturday, March 7, 1835.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri: potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”
CICERO.

THE JOINT-STOCK UNIVERSITY.

ONE advantage, at least, accrues to the public from the actual state of this establishment—namely, that as it is a purely mercantile speculation, in which many and various persons have a pecuniary concern, the accounts must be publicly audited every year: thus the boasting and pretensions of its managers are put to the proof, and no deception can well be practised. At the last general meeting of the shareholders, on the 25th ult., some important points came to light regarding the financial affairs of the year just expired. There was, it seems, an increase in the *receipts* of the school to the amount of 81*l.* 13*s.* 8*d.* But now hear the *per contra*: another mortgage is found necessary for the Valetudinarium; 2500*l.* must be raised forthwith in that way, in addition to the 4000*l.* borrowed not long since. The *ordinary* expenses of the year exceeded the estimate by 107*l.*, while the *extraordinary* expenses prove to be no less than 1218*l.* 16*s.* 9*d.*—of which 480*l.* have been expended in the vain attempt to procure a charter of an exclusive and an offensive description. We must confess we wonder not a little how these things are borne by the trading portion of the proprietary. That many of them are heartily sick of having had any thing to do with the “University,” is abundantly clear; nor is it less evident, from recent proceedings, that they think they have risked quite enough in the good cause of “diffusing knowledge.” A modest proposal made to them at the meeting above mentioned, by the great advocate, or *solicitor* rather, of the institution, put this to the test. Mr. Tooke threw out the suggestion that as

it was a main objection to the "University" that it was a joint-stock concern, and since the chance of getting 4*l.* interest on each share must, by this time, be considered by the majority of the proprietors to be a *desperate prospect*,—that therefore they might as well relinquish their shares altogether, and *endow* the school with the amount!

Some of the shareholders did not fail to characterize this proposition as it deserved. Colonel Stanhope, for one, was highly indignant, and boldly stigmatized it as a most "fraudulent proposal." It was finally scouted.

Yet the same Mr. Tooke who made this proposal is to bring forward another scheme on the 26th. He will make trial whether the House of Commons may not be induced to grant to the Gower-Street proprietary the power of recruiting their finances by the sale of degrees. A desperate effort is suited to a "desperate prospect," and we suppose it is with that impression that the active member is about to bestir himself.

PROPOSAL TO GRANT A MONOPOLY TO THE MEDICAL SCHOOL IN GOWER STREET.

WE beg to direct the attention of all those connected with the medical schools in London and the provincial towns, to the notice given by Mr. Tooke, of a motion to be made by him, in the House of Commons, on the 26th of this month. The proposal of that gentleman is, that Parliament should address his Majesty, praying him to confer a charter, with power to grant degrees in medicine, on the *London University*. If the honourable member succeeds, then may the other schools at once shut their doors, as a monopoly in teaching would be secured by the shareholders in Gower-Street. There is, however, no chance of his succeeding, unless through the over confidence and supineness of the teachers whose interests are at

stake, many of whom think that because the act would be unjust, therefore it will certainly not be perpetrated. This we believe would be a legitimate inference, but that a large proportion of the members of the House of Commons are not aware of the true state of the case, and think that Mr. Tooke's proposal is the only measure by which the dissenters are likely to obtain relief on the subject of academic distinctions; and thus it comes to be regarded by those who are ill informed on the subject as a trial between the ministry and the opposition.

Petitions against Mr. Tooke's motion are already prepared at some of the principal schools; and we earnestly advise that this proceeding (which, by the way, does not, like the Memorial to the Privy Council, entail any expense beyond that of a sheet of parchment), be immediately adopted by all the others. The *Memorial*, which forms a good model for a petition to parliament, will be found in the *MEDICAL GAZETTE* for April 26, 1834; and we further recommend, that every one who is acquainted with a member, particularly on the opposition side of the House, should make him acquainted with the merits of the case, as detailed in the document alluded to. By means such as the above this most impudent demand was thwarted before, and by the same means we have no doubt of its being so again—but *then the means must be used*. The "*London University*," it is to be kept in mind, is represented in the House by numerous shareholders,—the other schools, there is reason to fear, are *misrepresented*.

FRENCH MEDICAL APPOINTMENTS.

THE vacancy left in the *Hôtel Dieu* by the death of Baron Dupuytren has been filled by M. Ronx, while M. Velpeau occupies the place of the latter at *La Charité*.

MR. WAKLEY'S DEBUT IN PARLIAMENT.

MR. WAKLEY, ambitious of attracting a little notice, must needs put some questions to Sir Robert Peel, the other night, touching the College of Physicians. Nothing could be more auspicious than the *début* of the *honourable* member for Finsbury, who contrived to elicit a confirmation of all the statements on the subject which have been made in this journal, and who had the satisfaction to get laughed at into the bargain.

MEETING OF THE MEDICAL STUDENTS IN EDINBURGH,

ON THE SUBJECT OF ANATOMY.

A PRINTED report, in an official form, has been forwarded to this and, no doubt, to the other journals, containing an account of a meeting held on the 7th ult. by the medical students in Edinburgh, for the purpose of petitioning the House of Commons on the subject of the Anatomy Act. It appears that the working of the bill has been extremely defective in Scotland, and that some time ago the various schools remonstrated with the local authorities on the subject; but without procuring any redress, notwithstanding the crying evil of *two hundred* anatomical students having been arrested in their progress, from the want of any means of dissecting. This is certainly a lamentable state of matters, but it is one, we are fain to confess, which we do not expect to see speedily removed, as regards Scotland, owing to the strength of the popular feeling against the objects of practical anatomy.

Suffering under the grievance alluded to, it is natural that the students should exert themselves to obtain relief; nor is it to be wondered at, that in a meeting of seven hundred young men, the whole of their proceedings should not have been marked by absolute wisdom.

The first resolution which was passed on the occasion is unexceptionable—viz.

“That this meeting considers the present Anatomy Bill defective, inasmuch as it places no restraint on parochial authorities regarding the disposal of their unclaimed dead, and leaves them quite at liberty either to dispose of them as may best serve their own interest, or bury them if they choose to do so; and suggests that it should be made imperative on all parochial authorities, superintendents of hospitals, infirmaries, charities, &c. to forward a notice to the Inspector of Anatomy, of their district, whenever a dead body lies in their possession, under such circumstances as are pointed out by the Act.”

Nor have we any thing to object to the second resolution, except that it was introduced with a good deal of frothy flummery about the “meridian splendour” of science, the “blackening effect of corruption,” and all that sort of thing; which last, considering that the subject related to dead bodies, was coming rather too close to reality to be quite agreeable. After an exhortation to the young gentlemen present, to “concentrate their energies to overthrow and destroy corruption wherever she *rears* (?) her diminished head, the following resolution was put and carried:—

“That this meeting deem it most unjust, that there should still exist an unequal distribution of subjects among the students attending the legally recognized classes of this town; and, moreover, urge the adoption of the principle acted upon in London and elsewhere, that subjects should be distributed according to the number of students attending each class.”

Here, we regret to say, our commendation of the proceedings must terminate; and it is to be lamented that the parties had not the good sense and discretion to content themselves with what had been done. The next resolution was a censure upon the late Secretary for the Home Department; and various others equally foolish were subsequently proposed, some of which were adopted,

and others rejected. The business of the day was closed by an animated discussion between two gentlemen named Fidler and Potts, both of whom seem to have played their parts extremely well, as we are told that they excited "shouts of laughter." Unluckily we are not favoured with any of the good things, except one; but from it some idea of the scene may be gathered; while, at the same time, it will be rendered apparent on what sufficient grounds we have above expressed our regret that the meeting went beyond the second resolution.

"One spirited remark from Mr. Potts (says the official report), deserves being rescued from oblivion. It was in answer to the question, What use such a resolution could be of? 'I do not care about the use; what I want is, for this meeting to throw all its moral influence over the managers of the Royal Infirmary. (*Great laughter.*) It is no use laughing, gentlemen; those who know me are aware that I hold it as nought; while, for those that do not, I don't care a straw.' Mr. P. here dexterously (suited the action to the word) *turned his body half-way round!* at the same time snapping his fingers, which feat elicited tremendous laughter."

We most earnestly hope that redress will be afforded; but what are we to think of the discretion of those who, in printing a copy of these proceedings for circulation, have included in their account the above piece of low, stupid, and coarse vulgarity, as "deserving to be rescued from oblivion!"

FORCIBLE SURGERY.

OUR disinterested and impartial contemporary details, in his last number, the alleged particulars of a case in which a clergyman and surgeon are said to have conspired to subject a lad to the operation of lithotomy against his "urgent entreaties and reiterated remonstrances." The story is evidently trumped up for a purpose; but let that pass. We have here recorded, in black and white, the just horror of the virtuous Editor at any thing like force on such occasions. Suppose now that a case were to occur nearer

home—in the very limited field of hospital practice which is open to his inspection;—suppose the operation forced upon the party did not involve life and health, as in the above, but merely touched a deformity, and afforded an opportunity for surgical display;—suppose that the party was not a young man, but a poor girl;—suppose that she struggled, and entreated—that she escaped, and was brought back by force;—suppose she declared that she was there unknown to her parents;—suppose she exclaimed that "*the money would be of no use to her*;"—suppose that, nevertheless, the operation was performed "against her urgent entreaties and reiterated remonstrances";—suppose but one tithe of this occurring, when and where it suited the purpose of our contemporary to denounce it, and how abundantly would the phials of wrath be opened! But suppose, on the contrary, it should occur when and where it did not suit his purpose to expose it?—why he would then do just what he has done—say not a syllable about it;—and if now, by our allusion, the subject be forced upon him, we dare be sworn he will declare that nothing of the kind ever took place. Such is the nature of some people's impartiality!

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, February 24, 1835.

THIS evening the society met for the first time in their new apartments, in Berners-Street. The meeting was very fully attended. The appearance and accommodation of the new *locale* seemed to give much satisfaction: the library is large and handsome, and the whole suite of rooms, when well lighted, not a little imposing.

After the usual routine business, a paper was read by the President, entitled,

"*Observations on the Medicinal Properties of Kreosote*," by JOHN ELLIOTSON, M.D. F.R.S., President of the Society.

It contained the results of various trials of kreosote in several kinds of intractable disease—in phthisis, cholera, diabetes, neuralgia, epilepsy,—made partly in St. Thomas's Hospital, partly in private practice, in the course of the last eight or ten months; and possessed much interest, when considered as the first introduction to the British public of a new remedy, which is likely to prove an important acquisition to our Pharmacopœia.

After some prefatory observations on the importance of attention to the medicinal properties of drugs and chemicals, as a source of light and power in the cure of diseases, the author stated, that having his attention called, early in 1834, to the therapeutic properties of kreosote by reports from foreign sources, he had begun his experiments by administering it to patients whose cases were ascertained to be unmanageable by other means. He first tried it in phthisis and epilepsy, and afterwards proceeded with the inquiry in cases of neuralgia, cholera, diabetes, &c. He usually began with two or three drops suspended in watery mucilage, and gradually raised the dose to ten, twenty, or more drops, until the stomach would no longer tolerate increase; over-dosing producing nausea, vomiting, headache, vertigo, heat of tongue, fauces, and œsophagus. He found the remedy quite powerless in phthisis, in whatever form, or dose, or mode exhibited. When res-pired, however, he occasionally observed temporarily increased facility of respiration and expectoration, as, indeed, might be expected; for it cannot be doubted that tar fumes have in some instances proved useful, as in the hands of Crichton and others. He mentioned that in some instances of bronchorrhœa, or chronic catarrh, he had obtained excellent effects from its inhalation from a solution of five to fifteen drops in about a pint of water, repeated several times daily.

In epilepsy he found little effect of any kind; but from an apparently tranquillizing power which he thought he observed in it in that disorder in some instances in irritable subjects, he extended the use of kreosote to hysteria, neuralgia, and other forms of morbid excitability.

CASE I.—A young girl, labouring under acute pain in the hypogastrium and pelvis, with various other nervous symptoms, and habitual obstinate constipation. At first the pain, &c. recurred irregularly, but at length every morning between seven and eight, and lasted till night, after which she lay comatose until morning. Her face, gestures, &c. expressed extreme suffering. The evacuations healthy; bladder free of calculus. Every known remedy had been tried before her admission into St. Thomas's. Three grains of morphia relieved her a little every morning, but was soon discontinued as unavailing. July 22d, ordered a drop of kreosote three daily. The dose was gradually increased to seven drops. She improved rapidly, and left the house well in a month, having meanwhile regained her flesh and looks.

CASE II.—A man, ill of neuralgia of the nares and palate three months, suffered

dreadfully from pain, with sympathetic contortion of the features. He had been ill three years previously, and recovered without remedies. He began with three drops of kreosote three times a day, August 22d. On the 28th he was taking six minim doses, and was better, the pain recurring less frequently, and his sleep being much less disturbed by its paroxysms. The dose was raised at length to eighteen minims, and he soon got well enough to wish to leave the house.

The author noticed two other cases still under treatment, in which the disease seems nearly cured.

During these experiments the cholera broke out in the hospital, and it occurred to Dr. E. to try the tranquillizing power of kreosote in that *opprobrium medicorum*. In two cases it was exhibited with the effect of stilling the vomiting completely, but without other advantage; these cases likewise proved fatal. They suggested, however, further trial of its anti-emetic power; and the result of his experience was, that he knew of no medicine at all to be compared with kreosote in arresting vomiting, against which he had repeatedly known it succeed after prussic acid had failed. It has proved in his hands equally powerful to arrest vomiting when present, and to prevent it when threatening. In dyspepsia also, characterized by pain, acidity, nausea, &c. he has found it very useful; but he has observed flatulence aggravated by it.

He was led to try it in diabetes, from having accidentally read an account of a case in which it had been successfully administered.

CASE VII.—A country gentleman, of 60, ill four or five years with foul tongue, excessive thirst, and very saccharine urine, was ordered kreosote. On the 10th of September he was making water but seven times in twenty-four hours, instead of fifteen times as in August; his urine contained scarcely any sugar, and he felt himself quite well.

CASE VIII.—A medical man (Nov. 8), ill eight months, made twelve quarts of urine, of specific gravity 1038, per day. Stomach excessively acid; bowels costive. He took kreosote. November 25th, spirits, strength, and general health, greatly improved, and his amendment altogether surprising.

CASE IX.—A gentleman of 60, six months ill, making six quarts of water in twenty-four hours, of specific gravity 1037, took kreosote. Nine days after seen again; his health much improved. In December his thirst had disappeared, his urine come down to three pints, with proportional

general amendment; but the urine still of specific gravity 1037. He has since been heard of, and continues to improve.

Such were the facts of the paper, the incompleteness of which, to a certain extent, the author pointed out, but accounted for satisfactorily from the rarity of some of the diseases, and the novelty of the whole inquiry.

Annual Election of Officers.

On Monday last (24 instant) the officers of the Society for the year 1835-6 were elected. The following is the list:—

President.—Henry Earle, Esq. F.R.S.

Vice Presidents.—H. S. Roots, M.D.; John Howship, Esq.; Robert Lee, M.D. F.R.S.; Herbert Mayo, Esq. F.R.S.

Treasurers.—John Bostock, M.D. F.R.S.; J. M. Arnott, Esq.

Secretaries.—John Clendinning, M.D.; Richard Partridge, Esq.

Librarians.—John Thomson, M.D.; William Coulson, Esq.

Members of the Council.—Sir James Macgrigor, Bart. M.D.; John North, Esq.; Sir Astley P. Cooper, Bart.; John Yelloly, M.D.; John Elliotson, M.D. F.R.S.; Neil Arnott, M.D.; Sir Benjamin C. Brodie, Bart.; Edward Stanley, Esq. F.R.S.; J. F. South, Esq.; Sir Matthew Tierney, Bart. M.D.

ST. GEORGE'S HOSPITAL.

OPERATIONS, WITH CLINICAL REMARKS, By MR. CÆSAR HAWKINS.

CASE I.—*Contraction of the Fingers.*

THOMAS COFFEE, *pt.* 30, was admitted into St. George's Hospital, January 14th, under the care of Mr. Hawkins, in consequence of a deformity of the left hand, which seriously interfered with its use. The little finger was kept permanently contracted in the bent position, so that the back of the first phalanx was always presented to any object which he wished to grasp, the joint being directed towards the root of the thumb. There was a broad thick piece of skin and subjacent substance running from the centre of the palm of the hand half way down the first phalanx, and partially towards the second, the base of which in the palm seemed, when the finger was stretched, to have a narrow band, looking just like a flexor tendon in shape and size, running up towards the wrist, the extension of which caused a good deal of pain. The ring-finger was also partially contracted in the same way, but nothing like a tendon from this finger could be perceived connected with the palm.

This contraction had gradually taken place during the last five years; during which time nothing of any consequence had been done for him, and the inconvenience being now considerable, he wished it, if possible, to be relieved.

Mr. Hawkins ascertained, by moving the fingers in different ways, that there was no adhesion of the tendons, and that the contraction was in the fascia only, and determined to divide the contracted parts. Before operating, however, he gave the patient two doses of calomel and haust. *semae*, to prevent the inflammation which would otherwise probably ensue; and on the 22d he performed the operation, which he explained afterwards to this effect:—

The little operation which you have just seen, is one which, perhaps, you have not before witnessed, as it is very seldom done; partly because the disease seldom produces so much inconvenience as to induce the patient to submit to it, and partly because its nature is not well understood; for it is generally supposed to be a contraction of the tendon of the flexor muscle, and that its division would be very troublesome, from inflammation of its sheath, or that it would render the finger useless afterwards. It is an affection which I have, however, repeatedly seen, and it is remarkable that it almost always selects the little and ring-fingers, and consists in a slow inflammatory action in the fascia of the palm of the hand, going on for many years (in this instance for five years) before it produces very great contraction, and arising (as in this patient) without any known cause. The only description of it with which I am acquainted, is one by Dupuytren, who seems to have frequently operated for it on the principle which I have adapted here. The portion of fascia affected was that which comes from the annular ligament and divides near the base of the fingers, so as to embrace the sides of the little finger and one side of the ring-finger; and what I did for it was this. I first made an incision, about three-quarters of an inch long, in the centre of the palm, across the base of that portion of fascia which went to the fingers, and which started up when it was stretched, so as to look like a tendon. This being divided, a good deal of room was at once gained, and you saw the fat and nerves of the fingers at the bottom of the incision. I next made a semicircular incision more than half way down the little finger, at the fold which joins it to the palm of the hand, down to the tendinous sheath in the centre, and just avoiding the artery and nerve on each side. I next divided, in the same way, the side of the ring-finger next to the little finger; so that by these incisions the portions of

the fascia inserted into the fingers were divided, and the fingers could be extended almost to their natural length, allowing only for the shortening of the flexor muscle and tendon in five years, and which will, no doubt, soon yield. I also made an incision, in a longitudinal direction, through the thick substance formed by the skin and fascia together, which was there more than half an inch thick, thinking that this might, perhaps, allow more easily of extension. I gained nothing, however, by it, unless it facilitates, by suppuration, the removal of this hard substance which has been formed by the continuance of the disease. I have placed (as you saw) a little lint in each cut, and have directed it to be placed on a splint, to keep the hand at rest, as there will perhaps be some inflammation from opening the fascia, and to keep the fingers stretched; which it will be necessary to do, even after the wounds have healed, for some time each day, or at night.

Jan. 27th.—The wound being dressed, was found to be suppurating well; and there was no inflammation or swelling, such as might reasonably have been anticipated.

Feb. 20th.—The incisions have quite healed and the fingers are perfectly straight; so that there is every reason to suppose that he will regain the perfect use of his hand, all the fingers of which are a little stiff at present, from the use of the splint. The last few days, however, the splint has been left off, and the flexion of the fingers is improved. Almost the whole of the thick mass formed by the contraction has disappeared, and he has as much power over the fingers which were operated upon as any other.

CASE II.—*Large Navus of the Cheek.*

Frederick Yeo, æt. 18, admitted Jan. 14th, under the care of Mr. Hawkins, in consequence of a large navus of the left side of the mouth and cheek, which produces so unsightly an appearance that he has never been able to procure a situation as a servant. The tumor began at his birth, but has lately increased a good deal.

The tumor forms a thick dark-blue mass, which, if pressure be made upon it, or the breath be retained, projects considerably at the left angle of the mouth. It is chiefly seen through the mucous membrane, which is extensively implicated; and just at the angle the outer skin has lately begun to have a red appearance, from diseased vessels forming in it, to the extent of nearly an inch. The tumor, when examined on the inside of the mouth, is seen to be about four inches long by two broad, and when the vessels are full, it is nearly two inches thick, and gives a sensation of a great number of

varicose vessels under the membrane. It has no pulsation, and does not seem to have occasioned any increased action in the vessels around.

Jan. 22d.—A method of cure was commenced, which was explained to the students present, by Mr. Hawkins, to this effect:—

After mentioning the nature of the disease, he observed that the most effectual method of treatment was to remove such tumors completely, which was done either by the knife or by the ligature. Either plan was possible in the present case; but I have not thought it right to employ them. I might have cut out the whole tumor, but it is so extensive—reaching even to the gums at its lower part—that there would have been great danger from hemorrhage, as the vessels composing it, being in a diseased state, and having no contractile power, bleed to an immense and fatal extent if not cut across; and if I had succeeded in avoiding this by completely getting around the tumor, yet so much of the cheek must have been removed, that the edges could hardly have been brought together, or at the best, not without very great deformity. On account of its danger, then, the knife is scarcely ever used; and whenever it is practicable, the tumor is removed by ligature,—an operation which you frequently see in the hospital. I might have used the ligature in some form or other, so as to have destroyed this tumor, but the deformity produced by it must have been very great—more, perhaps, than by the knife.

For similar reasons I have not attempted to destroy so large a tumor with caustic, which is sometimes used for this purpose; besides which, there is some risk of hemorrhage from this method, and it is very painful and tedious.

If such a tumor is not removed, another method of treatment, which is sometimes used with success, is the obliteration of some of the diseased vessels by the production of inflammation. In some situations this can be done by constant pressure; but of course this is out of the question on the cheek, or indeed with any large tumor. Sometimes inflammation is excited in a young child, by making a number of punctures to inoculate the surface with vaccine matter; the method occasionally succeeds; yet it seldom answers with large naevi. Another plan which has been recommended is the use of a seton running through the tumor; and lastly, the production of inflammation, on the principle which I have just employed, and which you have seen me use also for the treatment of common varices of the ankle. You saw me use a narrow-pointed knife, cutting on its edge: an iris knife in shape, but a little larger, answers the purpose.

This I passed through the skin at one margin of the tumor, and ran it under the skin to the angle of the mouth. I then drew it forcibly towards me, turning the edge towards the month; my fingers in the month regulating the force of the incision, so as not to cut through the inner membrane. By this I endeavoured to cut through the vessels which form the tumor, and I repeated the same incision in eight or ten other directions. You saw that no blood escaped externally, but the tumor became larger, from effusion within its structure; and I hope that by the coagulation within it, and the inflammation excited by the operation, the increase of the tumor may be checked, if it does not disappear. I conclude that the incisions will have to be frequently repeated before much good can be effected. If it fails to do any good, I shall probably pass a seton through it; but as the seton hanging out of the mouth, to avoid a scar, would be a dirty and disagreeable plan, I have first tried the present incisions.

Some little inflammation and pain took place; but the coagulum appearing to be nearly absorbed, Mr. Hawkins made some more incisions on the 31st, and again on the 10th and 17th of February, the effect of which has been an apparent diminution, to a small extent, however, and chiefly at the upper part of the tumor. During the incisions the vessels seem to be very tough, and to escape sometimes from the edge of the knife; but some appearance of bruise, and of swelling, shews that some of them are cut across each time.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

At a meeting of the College, held on Thursday, February 26, Dr. H. Maunsell, (author of the Dublin Practice of Midwifery,) was elected Professor of Midwifery and the Diseases of Women and Infants, in the room of Dr. Johnson, resigned.

COLLEGE OF SURGEONS.

LIST OF GENTLEMEN WHO RECEIVED DIPLOMAS IN FEBRUARY 1835.

J. Thomas Harland, Ashbourne.
M. David O'Connell, Kilmarnock.
Rich. Inaffatt, Monaghan.
Wm. Deakins, Bristol.
R. Sturley Munn, Colchester.
John Hawkins, Peckham, Surrey.
Alexander Montgomery, Belfast.
F. Hutton Hill, Bath.
Jas. Rodgers Williams, London.
Jas. Morris, Vincent-Square, Westminster.
Maurice Dyle, Houndsditch.
Wm. Herbert, Army.
J. Nicholls Stevens, Penryn, Cornwall.
C. Burton Dushwood, Yarmouth.
Brook Fishley, London.
Wm. Henry, Hull.

Henry Davenport, Egham.
Robert Barker, Rochdale.
T. Lewen Marsden, Leeds.
John Chapman, Stoneleigh, Warwick.
John Baird, R.N.
H. P. Lewis Drew, Gower-Street, London.
T. Caverhill Jordan, E.I.
H. Foote Ling, Stogumber.
A. E. L. Webber, Wellington.
R. Chas Bidden.
Chas. Lingen, Hereford.
A. F. Carpenter, New Ross, Wexford.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

February 26, 1835.

Edward Joseph Staples, Bristol.
George Connolly Cone Lunn, Tiverton, Devon.
John Gorham, Tunbridge.
Alfred Loche.
George Tomkins George, Bath.
Thomas Chandler, Devizes.

March 5th.

John Lower Clark, Devonport.
Parker Margetson, Kirkby Stephen.
John Jackson, Whatton, Notts.

LECTURES
ON THE
DISEASES OF THE CHEST,

In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE XXIV.

DISEASES OF THE PERICARDIUM.

THE pericardium is a fibrous membrane enclosing the heart: it is lined by a fine serous membrane, which is afterwards reflected over the surface of that viscus, and the origin of the great blood-vessels arising from it. This serous membrane secretes a limpid fluid for the purpose of lubricating the inner surface of the pericardium and the external surface of the heart, by which the movements of these parts upon each other are facilitated.

The diseases of the pericardium bear a great analogy to those of the pleura; for, like the latter, they almost all have for their results an alteration in the nature of the serous fluid secreted. These diseases are as follows:—

Pericarditis {Acute.
 {Chronic.
Hydro-pericarditis.
Pneumo-pericarditis.
Adventitious deposits.

Pericarditis.

By pericarditis is meant an inflammation of the serous membrane lining the pericardium and covering the heart: it is divided into two forms—*acute* and *chronic*.

Acute Pericarditis.

Morbid anatomy.—This part of our subject may, like pleuritis, be considered in 380.—xv.

reference to the following stages:—1st, redness; 2d, effusion; 3d, formation of false membrane; 4th, conversion of false membrane into cellular tissue, or fibro-cartilage.

1st Stage.—Redness.—The redness of the serous membrane is rarely considerable; it generally appears irregularly disseminated in spots, points, or stains upon its surface; but, as I have mentioned in speaking of the red stage of pleurisy, these forms are probably mere post-mortem results, depending upon the partial transudation of blood through the inflamed vessels, so that during life the red colour was more universally diffused. The serous membrane itself is not thickened during this stage.

2d Stage.—Effusion.—Soon, probably a few hours after the red stage has commenced, effusion takes place from the inflamed surface. This effusion is limpid, of a slight fawn or straw colour; sometimes it is slightly reddened; occasionally a few fragments of half-concreted albumen float within it, but these are rarely sufficient, in the early period of the disease, to produce a milky or troubled appearance. The quantity of fluid varies; it may be but very small, or there may be a pint or more. Corvisart once met with as much as four pints.

3d, Formation of false membranes.—A semi-concrete albuminous false membrane is soon deposited after the effusion has commenced. It usually covers the whole surface of the heart, the origin of the great blood-vessels, and the inner surface of the proper pericardium. This pseudo-membrane rarely presents a smooth appearance, although there are two or three preparations on the table which are of that character; but it is usually reticulated, irregular, unequal, or papillated.

The consistence of the albuminous deposit is slight at first—it is scarcely that of half-boiled white of egg; it afterwards becomes more concreted, and finally ac-

quires a greater firmness and thickness than the false membranes which form upon an inflamed pleura; it adheres also with great tenacity to the serous membrane beneath. Its colour varies from a light whity-brown to that of pus.

The comparative quantities of serum and false membranes vary considerably; generally there is infinitely less serum, in proportion to the false membrane, in pericarditis than in pleurisy or peritonitis. Often in intense pericarditis there is scarcely any serous fluid, whilst there is a large quantity of thick and concreted albuminous matter occupying the space between the heart and pericardium. In this case, it is probable that the thinnest portion of the serum is absorbed, and that the albuminous substance with which it is charged becomes deposited.

When pericarditis occurs, it generally attacks the whole surface of the serous membrane lining the proper pericardium, and covering the heart and its great blood-vessels. The disease is rarely partial; when it is so, the anatomical characters are nearly the same; the serous effusion is then occasionally as considerable as when the inflammation is universal; usually, however, it is less abundant. The false membrane generally covers the inflamed parts only.

Ath, Conversion of false membranes into cellular tissue, or fibro-cartilage.—Nature frequently effects the cure of this disease in precisely the same manner as she does that of pleurisy. If the opposed membranes be thin, they gradually approximate as the serum between them becomes absorbed; films of concrete albuminous matter then pass from one false membrane to the other: these films gradually become vascular and organized, being at first soft and opaque, and finally firm and transparent, assuming altogether the anatomical and physiological characters of cellular tissue. If, on the other hand, the pseudo-membranes be thick and firm, then also, as the interposing secretion becomes slowly absorbed, their surfaces approach, unite, and form, in the same manner as in pleurisy, a single fibro-cartilaginous membrane, of a thickness proportionate to the elementary membranes which by their union have formed it.

Chronic Pericarditis.

Morbid anatomy.—This form of the disease always affects the whole surface of the serous membrane, which is then highly reddened in the form of small spots, or stains, closely approximating to each other. Laennec considers that chronic pericarditis is rarely accompanied by pseudo-membranous formations, or that when they exist, they are softer, and similar to a layer of thick pus. There is always a lactescent

secretion present, which ultimately becomes puriform. He believes, also, that the intimate adhesion of the pericardium to the heart is the result of chronic pericarditis, while the cellular union depends upon the acute disease.

But it would be, perhaps, more correct to consider the red stage of pericarditis, when accompanied by acute and sudden symptoms, as the *acute* form alone; and the disease would be more properly called chronic soon after the serous effusion has occurred, or at least when the albuminous matter separates to form the false membranes; for after that period, the changes in the colour, consistence, &c. of the serous fluid, and of the false membrane, and the mode of their union, vary exceedingly: sometimes they will present all the appearances described under the head of acute pericarditis, sometimes all those mentioned of the chronic disease. It appears to me that Laennec has erred, in considering the above characters as conclusive of pericarditis originating in the chronic form, when they are, perhaps, almost as frequently the consequences of acute inflammation. I have already made some observations upon this subject, in describing acute and chronic pleuritis. I have there also detailed some opinions relative to the formation of false membranes upon the serous surfaces: the same observations apply here. I shall not recapitulate them, but refer you to the lecture on Pleurisy.

In many cases of pericarditis, particularly when it has arrived at the chronic form, the substance of the heart itself becomes discoloured and whitened, as if it had been macerated for some time in water. This appearance is often united with a softening of its tissue. This discolouration and softening has been attributed by some authors to inflammation of the muscular fibres; but pus has never been seen among them, and therefore this opinion remains problematical.

White stains on the surface of the heart.—Those who are frequently in the habit of making post-mortem examinations, often find upon the surface of the heart, not otherwise affected, substances of a whitish colour, opaque, and varying in size from a shilling to that of the palm of the hand; they are about a line in thickness, and have somewhat the consistence of soft cartilage. It appears they are placed upon the surface of the serous membrane investing the heart, for they may be removed without destroying it. It is a question whether this appearance depends upon a partial pericarditis forming a false membrane, afterwards converted into condensed cellular tissue, or not: Laennec inclines to the former opinion; but why are not these bodies found also subsequent to inflamma-

tion of the serous membrane lining the fibrous pericardium, or on the pleura and peritoneum?

Signs of pericarditis.—*Acute pericarditis.*—This disease is almost always accompanied at its commencement by severe inflammatory fever; but its local and functional signs are certainly more irregular and equivocal than those of any of the diseases of the heart, for sometimes they may present themselves in their exquisite form, and yet the pericardium be intact; in other cases, the disease may be perfectly formed, and yet produce no symptoms.

When the symptoms present themselves, they vary also exceedingly in their duration, intensity, and succession. Sometimes the disease runs a rapid course, and death is the consequence after the most agonizing distress; at other times the symptoms may be slight and chronic. The symptoms also do not, as in pleuritis, indicate the particular anatomical stages of the affection with any certainty, nor are they the measure of the degree of lesion to which the pericardium is subjected. Let us, however, examine these signs.

Pain often takes place in the region of the heart, and it is increased by inspiration and coughing. Dr. Hope observes, that it is aggravated by pressure on the precordial ribs, and by forcing the epigastrium upwards on the left side: these latter circumstances occasionally may be produced, but certainly not invariably.

Palpitations most frequently occur, consisting of impulsive ventricular contractions, succeeded often at intervals by shorter and feebler pulsations: this sign is often accompanied by syncope or lypothymia. The *pulse* usually bears a relation to the regularity or irregularity of the beatings of the heart, but frequently none to the force of its movements: thus it may be full, hard, and jerking, conveying a thrilling vibration to the finger, or it may be very feeble. Corvisart believed that the pulse gradually increased in irregularity from the commencement of the disease; but there is no doubt that, at the earliest period of the affection, it is often as intermittent, irregular, and thready, as towards the termination.

Dyspnoea is rarely absent; it is often extremely great, so that patients can scarcely breathe in a horizontal position, but you find them generally in the upright posture. I have seen them in this state of orthopnoea for many days, and even weeks. If this sign be severe, the uneasiness, distress, and jactitation, become incessant; the face assumes a livid hue, and swells; the extremities and trunk even become cedematous; the cerebral functions are also disturbed; slight delirium or constant sleepiness takes place, although positive

repose is rarely obtained. A slight dry cough occasionally co-exists with the dyspnoea.

The patient sometimes complains of heat and weight about the heart, but these signs are frequently absent.

Upon the application of the stethoscope to the region of the heart, the impulse of the movements of the organ are almost always felt to be increased: that impulse is not regular, for after them feebler movements frequently follow, to be succeeded by stronger. The *bruit de soufflet* is also frequently heard during the contractions or dilatations of the ventricles.

When I first met with the *bruit de soufflet* in a case of pericarditis, I confess I was much surprised; for I saw no relation between the causes which usually produce that sound and inflammation of the pericardium. The known causes of the *bruit* are obstructions at the orifices of the heart to the current of the blood, and what are called nervous causes: the first being distinguishable from the second, by organic lesions rendering the bellows-sound permanent, and the nervous of temporary duration.

Finding, however, that in many cases of pericarditis there was no *bruit de soufflet*, I was led to suppose that in those cases of the disease in which it was permanently formed, it was probable that organic lesions of the valves, or dilatations and contractions of the aorta, with their consequences upon the structure of the heart, might have existed before the pericarditis; and upon a most minute inquiry into the history of the patients thus affected, I found that the greater number of them, particularly children, were never considered by those around as perfectly healthy individuals, but that they had always been subject to dyspnoea or palpitations upon that degree of active exertion or movement which upon healthy persons of the same age would produce no such effects. It is probable, therefore, that if these individuals had been examined before the pericarditis had occurred, the *bruit de soufflet* would have been found.

I examined not only all my own preparations of inflammation of the pericardium, but also, by the permission of my excellent friend Mr. Langstaff, all those, and they are numerous and complete, contained in his museum. I divided them into two series; in the first I placed all the cases of pericarditis in which the heart was of its normal proportions; in these the valves were not diseased, and I presume there had been no bellows sound; in the second series I arranged all the cases of inflammation of the pericardium in which the hearts were of large proportions; and in all these there were obstructions at

the mitral orifice, or diseases of the aortic valves, or enlargement or diminution of the ascending aorta. In these cases a permanent bruit de soufflet must incontestibly have been present.

I would consequently infer, that when a bellows sound exists throughout the progress of pericarditis, that it arises from the organic causes which usually produce that sound, and not from inflammation of the pericardium. I may add, also, that it is extremely probable that enlargements of the heart, by compressing the pericardium, must strongly predispose that membrane to inflammation.

To elucidate the cause or causes of the bruit de soufflet when it co-exists with pericarditis, I propose to you the investigation of the following points.

1. To ascertain, post-mortem, when the bruit has been permanent through the course of the pericarditis, whether the heart or its orifices are of the normal proportions, because if they are, then the sound must have depended upon the inflammation of the pericardium; if they are not, it was the consequence of disproportion.

2. To determine in those cases of pericarditis in which the bellows sound is not heard, whether the heart and its orifices are of their natural size, because if they are, the absence of the bruit is explained by the absence of its usual organic causes.

3. To examine whether, after all the signs of pericarditis have disappeared, the bruit de soufflet continues; if it does not, we must infer that it was caused by that disease only; if it does, that it depends upon obstructed cardiac orifices.

4. The bruit de soufflet sometimes coincides with the diastole of the ventricle, and sometimes with the systole. There is no reason at present known why this irregularity should occur, if it depended merely upon pericarditis; examine, therefore, post-mortem, whether these variations are not found to correspond with the lesion of a particular set of valves only.

When the union of the false membranes has been so effected as to cause, by their intermedium, adhesions between the pericardium and the heart, it has been supposed by Meckel that the pulse is then habitually small, and by Laennec and Vieussens, that palpitations are the constant results. Dr. Sanders supposed, also, that a depression or hollow was formed at the epigastrium under these circumstances. None of these signs are to be depended upon as indicative of adhesions. I have seen the pericardium united with the heart by a thick and cartilaginous false membrane, without any lesion of the functions of the organ.

There is no single sign which can be

considered as pathognomonic of any stage of pericarditis; nay, the union of them all is insufficient to express the certain presence of the disease; yet by the examination of the abdominal organs and the lungs, certain negative circumstances tend to render the diagnosis more certain.

Thus the most certain symptom of pericarditis is dyspnoea. Now dyspnoea can only arise from diseases of the lungs and pleura, from affections of the heart and pericardium, or from lesions of the organs contained in the abdominal cavity preventing the free play of the diaphragm. Examine, then, the abdomen, and you will readily detect any intumescence sufficiently great to prevent the descent of that muscle; next, examine the lungs most carefully, and note whether there is sufficient disease there to account for the dyspnoea. If there be no abdominal or pulmonary disease, or the latter be so slight as to bear no proportion to the dyspnoea, then it must be inferred that the cause of the difficulty of breathing arises from some disease either of the heart or pericardium. The question will now be to determine whether the heart be diseased or the pericardium inflamed; the latter affection may be affirmed to be present when the attack is sudden, when there is inflammatory fever, when the pain and burning sensations occur in the cardiac region, when there are sudden palpitations of the heart, and especially when these signs have supervened upon a general attack of acute rheumatism. After all, gentlemen, you must not consider this accumulation of symptoms as *perfectly* diagnostic, as affections even of the head have been seen to simulate this disease; yet I have most commonly found that they have been sufficient to establish a correct diagnosis.

Treatment of pericarditis.—During the first few days, when inflammatory fever and pain exist, the disease should be treated precisely after the plan proposed in the first stage of pleurisy; bleeding, leeches, and cupping, should be employed proportionate to the intensity of the disease and the power of the patient. Mercury is also a most important remedy, and should be freely given from the commencement; and the antiphlogistic plan is to be strictly enforced. I refer you to the treatment of acute pleurisy, as it is unnecessary to recapitulate it here.

When, however, some days or weeks have passed, so that the disease assumes the chronic form, your indication is to cause absorption of the effused fluid; but that is rendered difficult, from the inorganic nature of the false membrane by which that function has to be performed. Mercury, carefully administered in this stage, so as not to excite salivation, but

rather to keep the mouth tender for two or three weeks, is the most efficacious remedy. I would recommend you to use the same method, with the precautions I have given in using mercury, for the treatment of chronic hepatization of the lungs. You will find, also, that counter-stimulants and exstortives are often of great service; as blisters, setons, &c.

Hydro-pericarditis.

By hydro-pericarditis we mean an accumulation of serous fluid, in greater or less quantity, in the bag of the pericardium. This disease, like hydrothorax, may be symptomatic or idiopathic; the latter form is, however, rare; the preceding very common. Slight serous effusion is often a mere cadaveric result, or it is a consequence of the agonies of death. Symptomatic hydro-pericarditis is usually combined with general infiltration in the serous cavities and cellular tissue of the rest of the body. In the idiopathic form, the effusion is confined to the pericardium.

The effused fluid is sometimes colourless, but most frequently it is of a slight fawn, straw, or ruddy tint; it rarely presents a reddish aspect. Its quantity varies from an ounce or two to two or three pints; Corvisart had seen as many as eight pints. The heart and pericardium are usually free from any alteration in this disease.

Signs of hydro-pericarditis.—Various signs have been given of hydro-pericarditis, although none of them are pathognomonic; thus, according to Lancisi, there is an enormous weight at the precordial region; others have stated that the patient has felt his heart as if swimming in a fluid; Senae mentioned that he had seen the movements of the fluid in the intercostal spaces between the third, fourth, and fifth ribs; and Corvisart asserted that he had felt its fluctuation. The last author gives the following signs of this disease:—Sensation of weight at the precordial region, which region gives a dull sound on percussion. The beatings of the heart are felt to a considerable extent; they are to be distinguished at certain moments better at one point than at another, and this point varies every instant, being sometimes at the right side, sometimes at the left. These movements are also tumultuous and obscure, and seem to arrive at the hand through an interposed soft body; the pulse is frequent, small, and irregular; the extremities, and the integuments over the region of the heart and the trunk, are infiltrated with serum; the patient cannot bear the upright posture for an instant; he experiences frequent syncope, but rarely palpitations.

These signs are as uncertain as those of pericarditis. Much assistance may be given in determining this disease by observing the state of the lungs, to ascertain whether they present sufficient disease to account for the great dyspnoea.

Treatment of hydro-pericarditis.—The treatment of this disease should be precisely the same as that for hydrothorax and oedema pulmonum; I refer you, therefore, to those subjects. It has also been proposed to puncture the pericardium, for the purpose of evacuating the fluid; but I have so little confidence in the signs of this affection, that I have never ventured to recommend that operation.

Pneumo-pericarditis.

By this expression is meant an acriform effusion developed in the pericardium. This effusion is often found at the examination of bodies in whom the process of putrefaction has commenced; but it is occasionally also found when it must have existed during life. In the latter case, it is accompanied by liquid secretions, although sometimes the pericardium is found distended by air alone. Laennec asserts that air and liquids may be developed in the pericardium a short time before death, and that he has been enabled to announce that event by the sound on percussion being clearer and louder over the cardiac region, or by a fluctuation corresponding to the beatings of the heart, or to a strong inspiration. He believes, also, that when the pulsations of the heart are heard at a distance from the patient, that it depends upon a sudden disposition of air in the pericardium, which is as suddenly absorbed, producing no distressing symptoms. I have met with several instances in which these pulsations were heard at a distance, but the patients presented no signs of disease either of the heart or pericardium.

Accidental productions developed in the thickness of the parietes of the pericardium.—Bonetus, in his *Sepulchretum*, mentions instances of the development of tubercles, cysts, and cancerous tumors, in the pericardium. Mr. Langstaff has a preparation shewing a number of tumors presenting the characters of medullary sarcoma, placed upon the serous membrane covering the heart. Ossific deposits have also been seen formed between the membranes of the pericardium; these ossifications vary considerably in thickness and extent.

Polypi.

Before we proceed to the consideration of the diseases of the large blood-vessels, let us first study the characters of the sanguineous concretions that are frequently found in the cavities of the heart, and which have been called polypi.

Upon making an anatomical examination of the heart, you will often find that its cavities contain coagula or concretions, varying in size, colour, and density. These coagula were supposed to give rise to symptoms which we now know to depend upon hypertrophy or dilatation of the organ. Similar concretions are occasionally found also in the large blood-vessels. These polypiform substances form either during life, or during the last moments, or immediately after death.

The left carotid artery, and the left internal jugular vein, have been seen obstructed by coagula by Haller. I have seen coagula extending considerably up both carotids. Haller had seen the inferior cava similarly obstructed, between the giving off of the renal and iliac veins. Laennec saw the inferior cava contracted and obliterated to the breadth of four fingers, by a whitish, fibrinous concretion, completely filling the vein; its external layer, strongly adherent to the internal parietes of the vessel, was exactly similar to the inflammatory crust of the blood, but of a firmer consistence. The internal layers were of a yellowish colour, perfectly opaque, and like the decomposed fibrine sometimes found in large aneurismal sacs. Other concretions have been observed more or less red coloured, especially in their interior; and these have not so completely filled the vessel but that the blood has been enabled to flow, although with difficulty.

These coagula must have formed during life; and it is extremely probable that the same thing takes place in the heart, especially in individuals who are struggling with death for a considerable period, and in whom the circulation is carried on with irregularity. Many authors have noticed these facts, and have recorded them, as Bertin, Bonilland, Laennec, Burns, Velpeau, &c. It is now generally admitted that some of these concretions are formed before, and some after death.

The polypus which forms in the heart after death, and is consequently the most recent, consists of a slightly whitish, or yellowish, opaque and semi-transparent layer, like the inflammatory crust of the blood, enveloping a coagulum of blood; this layer is never complete, but only partially surrounds the clot. It does not adhere to the parietes of the heart, or to the vessel in which it may be inclosed. This concretion is sometimes firmer and thicker, and forms an isolated mass. When the blood is very thin, it is semi-transparent, less firm, and trembles like jelly; it has no fibrous texture, and appears infiltrated with serosity.

The polypi which form during life are much firmer than the preceding, having

nearly the consistence of muscular fibre. They adhere more or less to the parietes of the heart; and that adhesion is often considerable when they form in the sinuses of the auricles, or in the ventricles, in consequence of their interlacement with the *carneæ columnæ*, which latter are often even flattened by their pressure. These concretions are opaque; their texture is fibrinous; they are of a pale, fleshy, or violet colour, different shades of which often exist in different parts of the same concretion. Sometimes an isolated clot of blood is found in their centre, and stains of that fluid upon its surface are seen plunging more or less deeply within. Laennec believes that these polypi may become organized, and that the vegetations I have already described are the forms which they then assume. These polypi are most commonly found in the right auricle and ventricle.

There are other concretions occasionally found, which must have formed some time before death. They are adherent to the parietes of the heart, and can be generally detached only by scraping them with a scalpel. Their consistence is less than that of the preceding species; they are not fibrinous, but are somewhat similar to a dry paste, or to the decomposed layers found in aneurismal sacs. These have been discovered only in the auricles and their sinuses.

Signs of polypi.—The signs of polypi of the heart are very obscure. Laennec believed that, when they had arrived at a certain volume, they would be indicated by the following symptoms:—

When, in an individual whose heart has hitherto pulsed regularly, its beatings become suddenly anomalous, confused, and obscure, so that they no longer admitted of analysis, a polypus may be suspected. If this derangement occurs only on one side of the heart, its presence may be considered as almost certain. Thus, when in exploring the heart at the inferior part of the sternum its beatings are found to be confused and tumultuous, whilst they were regular a few hours before, a concretion may be suspected to have formed in the right cavities, especially if the movements of the left side of the heart are still distinctly heard.

DISEASES OF THE LARGE BLOOD-VESSELS.

1. *Inflammation of the Inner Membrane of the Heart and Arteries.*

I shall, in the first instance, describe the various appearances which occur on the inner surfaces of the heart and arteries, and which have been supposed by some authors to arise from inflammation of their lining membrane, although denied by others.

1. *Redness of internal membrane of heart and arteries.*—The interior of the aorta and pulmonary artery is often found uniformly reddened, as if tinted by the blood they contained: this redness may be of a scarlet, or brown, or violet shade.

The scarlet colour is usually confined to the internal membrane of the heart, aorta, and pulmonary artery, but sometimes it penetrates through the fibrous even to the cellular coat of the arteries. This tint is uniform, some points being only deeper coloured than others; there is no arborescent appearance of injected capillaries. Sometimes the colour gradually diminishes in its intensity, from the origin of the vessel to where the tint is lost; at others it ceases suddenly, forming irregular, although strictly defined, edges. Occasionally, in the midst of a red surface, a circumscribed white spot is seen, as if the blood had been pressed out by the point of the finger. When there is but little blood in the aorta, the red colour exists only where that fluid is in contact with the vessel. The origin and arch of the aorta are most frequently reddened; the whole of the arteries are rarely so. The mitral and aortic valves appear as if they had been plunged into a red tincture, and their colour is generally deeper than that of the arteries.

When the pulmonary artery is thus affected, its valves and the tricuspid are generally in the same state.

The valves are occasionally coloured when the internal surfaces of the heart are not; but when the latter are also affected, the aspect of the valves presents a still deeper hue. Sometimes these surfaces are tinted of a deep red, whilst the valves remain of their natural appearance; in that case the heart has always been found filled with blood, and the arteries emptied.

Does this redness depend upon inflammatory action? Frank, Bertin and Kreyzig, and Bouilland, have adopted this notion; but the colour is never attended by thickening of the membrane lining the heart and arteries, and its sudden, abrupt, and irregular termination, would seem to indicate that it was caused by the irregular flowing of a coloured liquid upon the surface, and which, by the smallness of its quantity, could not touch all its points. Finally, this state of the heart and vessels has not only not been found to correspond with any specific symptoms, but it occurs in diseases of a very opposite character.

The second species of redness, or that which has a brown or violet tint, is also found in the aorta, pulmonary artery, valves, auricles, and ventricles; and sometimes it appears in them all at the same time.

This colour is often of unequal intensity,

but it is always particularly marked where the blood has been most in contact with the parts: it generally penetrates through the internal membranous lining of the heart and arteries, and more or less into the textures beneath it. This redness is commonly found in those who have died of typhoid fevers, of emphysema of the lungs, of diseases of the heart, or whenever the agonies of death have been of long continuance, and accompanied by sensations of suffocation; it has been found especially when the blood is very liquid, and when the putrefactive process has commenced: thus it is seen most in the summer time, and when the body has not been opened before twenty-four hours after death. The redness is frequently attended by a certain degree of softening of the tissue of the heart, and humidity of the parietes of the arteries. Does this colour depend upon inflammation? It appears not, but that it is caused by the blood tinting the parts with which it comes in contact. The redness may also be produced artificially in a day or two, by introducing this blood into a portion of an artery separated from the body.

Inflammation of the internal coats of an artery may be suspected, if, in addition to the red colouration, they are swelled, and their capillary vessels injected.

Pseudo-membranous condensation from the internal surface of the heart and arteries.—The formation of a false membrane may be considered as an incontestible proof of the pre-existence of inflammation of the lining membrane of the heart and arteries. Several instances of this plastic formation have been observed: Bayle had seen the tricuspid valves inflamed and covered by lymph; Dr. Farre saw the aorta lined by it; Burns, Bouilland, Bertin, and Laennec, have described similar instances of this deposit adhering to the internal surfaces of the heart and arteries.

Ulceration of the membrane lining the heart and arteries.—The internal membrane of the heart and arteries is so thin, that it is difficult to conceive its ulceration without that also of the tissues beneath it; yet there are many evident proofs of it, as may be seen in the works of Hodgson and Kreyzig. Small pustules are also occasionally found projecting into the cavity of the aorta. These are probably formed upon the surface of the fibrous coat of the artery, or in the fine cellular tissue uniting that coat with the internal membrane.

Ossous, calcareous, and cartilaginous incrustations of the aorta.—Ossous and cretaceous deposits are always placed, when present, between the internal and middle coats of an artery. These substances are usually irregularly flattened, and of unequal thickness. Their internal surface is

generally rough, and imbedded in the fibrous coat of the artery, upon which they not only leave their impression, but gradually destroy its texture, so that when these concretions are removed, the vessel is semi-transparent where they had been deposited. Their internal surface is usually smooth, and covered by the internal membrane of the artery; sometimes, however, they are rough, and destroy that membrane, so that the phosphatic matter is exposed to, and bathed by, the blood. These incrustations form at first in small points, which gradually increase and unite, until they have been seen so completely to surround the artery, as to form an osseous coat around it.

Cartilaginous deposits often precede, and may be considered as the rudiments of, the ossific formations. These cartilages are softer than their analogous tissues. The phosphatic matter is at first deposited in them in small points, which increase in number, unite, until the whole of the cartilage is converted into bony matter.

The phosphate of lime is sometimes secreted in a pulverulent form; it is then found between the internal and middle tunics of the artery, mixed with a certain quantity of fluid, so that it presents the appearance of mortar, or putty, of greater or less fineness. The phosphate is occasionally found beneath the cartilaginous deposit, of the same putty-like appearance.

These osseous incrustations often break through the internal membrane of the artery, and separate it to a certain extent at their edges, forming projections into the cavity of the vessel. The blood then insinuates itself behind these projections, which fluid being placed out of the direct current of the circulation, coagulates, and still further destroys the fibrous coat, so as to become the most common cause of false consecutive aneurism. The fibrine thus formed has been called atheromatous matter, and the parts from whence the osseous deposits have been separated, have been considered as ulcers, although they are really not so; it is true that the edges of the internal membrane which has been ruptured are seen red and swollen, but these are the effects of the separation, and not the causes.

It is still a contested point whether the deposits I have just described are the consequences of inflammation or not. My time does not permit me to enter into the various hypotheses of different authors upon this subject; but I believe they are no more the results of inflammation than the calcareous deposits in the lungs.

You thus, gentlemen, perceive that the redness of the internal coats of the arteries depends most commonly upon mechanical causes, and not upon inflammation; and

that the latter cause can only be admitted when the colour assumes an arborescent form, combined with a certain degree of swelling of the membrane, or is followed by an exudation of plastic lymph, or by ulceration.

Have we any signs of this inflammation when it really exists? None that are certain; but the following have been mentioned:—Pulse hard, quick, and full; pain and heat in the course of the aorta. Frank and Pinel have supposed arteritis to be the organic cause of synocha, from whence the latter author has denominated that affection “fièvre angiolénique.”

OBSERVATIONS

ON THE

PATHOLOGY OF NERVES.

By HUGH LEY, M.D.

Physician-Accoucheur to the Middlesex and the General Lying-in Hospitals.

[Concluded from p. 803.]

OTHER modes of compression, as might well be expected, produce similar results*, and this in whatever part of its course from its origin to its distribution the nerve may happen to be subjected to pressure. The positive evidence upon this point is so abundant and conclusive, that I might almost content myself with referring to the familiar examples, to which I have already had occasion to advert, of pressure during sleep upon the sub-occipital branches of the upper cervical nerves, or upon the ulnar, the radial, or sciatic nerves, which invariably produces a diminution or negation of nervous influence, whatsoever may be the degree of compression from the chair or table.

Many other causes also within the body may compress a nerve in its

* Eadem fiunt si pro vinculo alia quæcunque causa nervum compresserit.—Haller, *Elem. Phys.* V. 4, p. 322.

Quidquid ergo vel nervi continuitatem solvit, vel comprimendo ejus cavum delet paralytin faciet illius musculi, cui talis nervus prospiciebat.—Van Swieten, *Comm.* V. 3, p. 358.

La propagation des impressions externes ou internes est interrompue quand la continuité ou les connexions viennent à cesser entre la partie centrale et les organes en général. De là la perte du sentiment, du mouvement, et de la faculté sécrétoire, aussitôt que le nerf d'un organe vient à être coupé ou comprimé, soit par une ligature, soit par une tumeur voisine, dans son trajet, à son origine ou à son entrée dans l'organe.—Meckel, *Manuel*, V. 1, p. 263.

course, and by obstructing the communication of nervous influence, paralyse the parts upon which it is distributed, and if the nervous cord be minute and thready, a very slight degree of pressure may suffice. An instance of this occurred to me in a fatal case of crowing inspiration, in which an inflammatory effusion at the base of the brain, near the foramina leading from the cranium to the orbit, although it produced no sensible effect upon the optic nerves, or the common trunk of the *motores oculorum*, was yet sufficient to paralyse the separate filaments which supply the superior recti muscles of the eye. This effect of the thickening of surrounding parts from inflammatory deposits around a nerve, is amply illustrated in those cases of facial paralysis which are of frequent occurrence, and only of late years well understood. A very interesting example of this has been detailed by Dr. Percival, and is not of the less value that the facts were recorded before the ingenious researches of Sir Charles Bell upon the peculiar functions of the fifth pair, and the *portio dura* of the seventh, were generally known to the profession. It occurred in an unmarried female of seventeen, of fair complexion, of sensitive and irritable habit, but robust form, in consequence of exposing herself, whilst overheated and perspiring from exercise, to a current of cold air which passed from an open window chiefly over her head and neck. On the following day she experienced some uneasiness from stiffness of the muscles in the parts which had been exposed; pain and swelling gradually supervened, and were followed in the course of a week by torpor and paralysis of the entire left side of her face, scalp, fauces, and neck. At the end of another week Dr. Percival first saw her, when "he found her face considerably swelled, her head drawn to the right side, her articulation very imperfect, and her power of deglutition and swallowing so much impaired that she could suffer only small portions of liquid, and by great effort, to pass down her throat." The inflammation was in this case confined to the textures surrounding the nerve, without implicating the nerves themselves. Had it been otherwise, the inflammation would have manifested itself in the production of the symptoms of excitement, and as the nerves affected were motor nerves, convulsive move-

ments would have occurred; as in a well marked case of inflammatory affection of the same nerves, which in the same volume of the *Medico-Chirurgical Transactions* immediately succeeds the communication of Dr. Percival. This patient, fifty years of age, was seized suddenly with an affection in which *she felt* something drawing her tongue and mouth to the left side; it took her speech away, and her face shook very much. She had afterwards, in the progress of her complaint, twitchings of the occipito-frontalis and orbicularis muscles, her tongue was drawn forcibly in a curved direction towards the left molars, the teeth were clenched, and the lower lip much distorted by a strong spasm in the left depressor anguli oris, and depressor labii inferioris; the eyes also became affected, as did also the muscles of that side of the neck, so as to draw the head "round to the left shoulder, occasioning an appearance as if the left ear and chin were about to recline on the point of it." It was suggested by Dr. Thomas, in consultation with Mr. Mitchell, who narrates the case, that some local irritation on the nerves of the mouth might produce the complaint. Upon examination it was found that all the teeth on the upper and left side of the mouth were in a decayed state, and highly sensible when touched with a probe, and the gums inflamed and irritable. The symptoms gradually ceased as these sources of irritation were removed, and eight days after the extraction of the last of seven teeth the gratifying report is first recorded, that "the patient has lost all spasmodic action."

These two cases, thus placed in juxtaposition and contrast, are so interesting in themselves that it is scarcely necessary to invite attention to them. The same set of muscles were implicated in both cases. In the first they were paralysed by being, to use an expression of Mr. Swan, "strangled" in their course by the compression of surrounding inflammatory deposits; but this not until a week had elapsed from the period of exposure, when active inflammation had subsided, and when intumescence alone remained. As the swelling disappeared the nerves recovered their energy. In the latter case inflammation at the roots of numerous teeth upon the side affected, of the gums, and probably of the alveolar processes themselves, had extended to the contiguous nerves of the

fifth and seventh pairs. These were morbidly excited, and associated in their disordered function those muscles of the neck, the shoulders, the chest, and probably the diaphragm, which are largely supplied with energy from the respiratory system of nerves.

Such instances of paralysis of the muscles of one side of the face, from exposure to a current of cold air, are by no means uncommon. Three cases have been recorded in the fifth volume of the Medical Transactions, and Mr. Shaw, and subsequently Sir Charles Bell, have multiplied instances of the same kind; so that the point is at length proved, by an extent of cumulative evidence which is perfectly irresistible, that paralysis may be induced by the accumulation and confinement around nerves, so as to occasion pressure, of the products of inflammation. Nor does it appear less clear that if the inflammatory affection of surrounding textures extends to the same nerves, spasm may be expected; at least it occurred in the case related by Mr. Mitchell; in one referred to by his associate in the consultation; and a third mentioned by M. Descot, which was also cured by the extraction of a carious tooth. If any additional proof were required of both these propositions, it will be found in a case already briefly noticed, in which Sir Charles Bell draws the distinction between the effects of pressure upon one nerve, and of inflammation in another produced by the same malady. The patient suffered from an ulcer of the character of "*noli me tangere*" or "*lupus*," which extending into the orbit, completely displaced the eye. "The swelling of the parts within the orbit compressing the fifth nerve caused insensibility of the part of the face to which these branches were distributed, without affecting the motion. When the tension and swelling subsided there was returning sensibility; but more than this, the inflammation affecting the nerves in their passage through the orbit gave the sensation of excruciating pain perceived as if in the face. An inflammation of a nerve does not give perception of pain in the proper seat of the disease, but in the part to which the extremity of the nerve is distributed."

That tumors of various kinds pressing upon healthy nerves in their course, will produce paralysis in the parts which they supply, is so well known as scarcely to require proof, and an appeal, therefore,

to a few of the numerous cases which are upon record will suffice to verify the assertion. Amongst those about which there can be the least dispute, as both the cause and effect are abundantly obvious to the senses, are the paralytic affection of the portio dura of the seventh pair. The first in the series of admirable pathological illustrations of the views of Sir Charles Bell, contained in the appendix to his work upon the Nervous System, is of this kind. The local palsy was produced by a gland situated between the angle of the jaw and the mastoid process, and enlarged from mercurial irritation within the mouth. In a second instance, communicated by Dr. Malden, in whom I recognize a cotemporary who has not disappointed the expectations formed of him when in Edinburgh, the paralysis of the face is said to have been "produced by a hard, fixed, and indolent tumor, lying between the ramus of the lower jaw and the mastoid process of the temporal bone." "In a fortnight the tumor disappeared, and with it gradually the paralysis of the face." In a third, transcribed from the Pathological and Practical Researches on the Diseases of the Brain and Spinal Marrow, by Dr. Abercrombie, it arose from a tumor under the ear, of the size of a small bean, very firm, and of an ash colour. It lay directly above the facial branch of the portio dura, and there was considerable appearance of inflammation in the cellular membrane surrounding the nerve; but "*without any deviation from the healthy structure in the nerve itself.*" In a fourth, an enlarged gland, tender on pressure, just between the mastoid process and the upper portion of the lower jaw, produced the same effect. In a fifth, the paralysis was the result of an enlargement with induration of the parotid gland. Upon other causes of pressure affecting these nerves it is unnecessary to enlarge; but amongst them may be mentioned mechanical injury and subsequent inflammation: abscess, especially if with a hardened base; tumor embedded in the substance of the parotid; and inflammatory thickening within the bony canal, through which the nerve has to pass before it escapes by the stylo-mastoid hole to be distributed upon the muscles of the face. The number and variety of causes which thus produce paralysis of the respiratory nerves of the face occasion this to be amongst the most frequent of local pal-

sies, and afford us ample opportunities of investigating its phenomena.

Illustrations of the same pathological principle—that simple compression upon a healthy nerve impairs or annihilates its function, according to the degree of pressure—may be derived from the numerous causes which are capable of producing amaurosis, amongst which are enumerated, by the highest authorities upon such subjects, turgescence of vessels, especially of those which constitute the circle of Willis; thickening of the membrane surrounding, or in contact with, the optic nerves; encysted or other tumors compressing the same nerves; caries of the os frontis trenching upon the optic foramina; deposits of serum or other fluids; induration, or other disease of the thalami; a gorged state of contiguous parts of the brain. In general these causes are slow in their operation, and the amaurosis proportionally gradual in its progress; but upon other occasions the cause of pressure is more speedy in its influence, when the effect is in proportion rapid, the loss of sight being even sometimes instantaneous, as I have known in more than one instance of puerperal convulsions, and even in that state of sanguineous congestion of the vessels of the head which sometimes occurs in advanced gestation, and a melancholy example of which I have recently had an opportunity of seeing in the family of a professional friend.

Many other causes of pressure might be enumerated and illustrated, but it is unnecessary to adduce them, as the principle is too well understood and universally conceded to require such additional confirmation. I shall conclude, therefore, this abstract of the pathology of nerves by inserting the masterly sketch of their morbid conditions by an eminent French pathologist, who says—“Nerves, as well as the parts whence they derive their origin, may be compressed, indurated, softened, enlarged, attacked with inflammation, suppuration, gangrene; they may be contused, wounded, compressed at their origin, together with the brain or spinal marrow, in their passage through the foramina of the cranium or of the vertebral canal, and along the rest of their course, whether in the cellular tissue or in the viscera, and in fact in every part of the body exposed to congestions and causes of compression.” And again—“Nerves may be compressed

by tumours in general; by distention of vessels; by the violent contraction or displacement of muscles; by dislocations, fractures, exostoses; by foreign bodies, shot, and balls; by pointed instruments; (?) by the wadding of fire arms; sometimes by the displacement of certain viscera; by the effect of violent contusions, by a fall, by a violent blow*.” This account is evidently the result of minute observation and industrious research, is in the main accurate, and is given in reference to his great distinction of the diseases of nerves into those of “painful and convulsive stretchings of the medullary fibres, and into that kind of compression which renders the nerves insensible†.”

In this sketch of the pathological history of nerves, the imperfections of which I am bound to acknowledge, it will be observed that I have not availed myself of the experiments of physiologists, repeated as they have been, from the time of Galen, *ad nauseam usque*, or the observations of pathologists upon the *par vagum*. I have sedulously avoided this, as I was solicitous, by examining minutely the facts connected with other nerves, to deduce such general principles as might be applicable to the injuries and morbid conditions of the eighth pair. Had it been consistent with my present object to enter upon that subject, I should have found abundant evidence of the truth of those general propositions which I have ventured to enunciate and endeavoured to illustrate. But this subdivision of the subject has relation to another inquiry which has much engaged my attention, and upon which it is my purpose to enter at another time and in another form‡.

* Portal, Anat. Med. V. 4, p. 142.

† Whether the terms “*tiraillemens douloureux, convulsifs*,” has been properly rendered in the text, may be questionable. French writers frequently employ these terms without intending to convey the notion that the fibres are actually put upon the stretch, and I believe the expression in this instance means merely the combination of pain and spasm, implying no more than what ancient writers meant to convey, when they used the terms “*distensio*,” or “*convulsio nervorum*,” the former being perhaps the more classical expression of the two.

POISONING WITH ARSENIC.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case of poisoning with arsenic worthy of insertion, it is quite at your service.

I am, sir,

Yours respectfully,

P. H. HOLLAND, Surg.

Chorlton-upon-Medlock Dispensary.

Manchester, Feb. 20, 1835.

C. S.—, a middle-sized woman, between 30 and 40 years of age, was taken ill at midnight on Tuesday the 17th inst. Mr. Partington, surgeon, was sent for; his assistant, who went, found her dead. It was impossible to obtain a satisfactory account of her previous indisposition, but it appeared in evidence, at the subsequent inquest, that she had been a servant with a surgeon in this neighbourhood, who had discharged her for misconduct. She had been observed, after receiving notice, to be very low-spirited, and unwilling to go, while he was determined that she should. On the evening of Tuesday, at half-past six or seven, she was slightly sick and faint, and declined going then. As it was quite necessary that she should go that night, her master procured a coach. She refused to answer any questions as to her illness; she continued faint and sick till midnight; refused to take the aromatic draught, or the brandy and water which her master had prepared for her, but requested cold water. Did not complain of any pain; did not appear seriously ill; got into the coach, and rode to her friends, about four miles off. The young man who went with her says that she made no complaints; did not appear to be in pain, only sulky, as he thought, but was sick. She did not speak, except to give directions as to where she wished to be taken. On arriving at the house, she was unable, but as was thought at the time unwilling, to walk unassisted. She sat down on a chair, and the people of the house thought she was intoxicated, and sick in consequence, but she did not vomit then: very shortly afterwards, however, she was seriously ill, became very faint, looked cold, and the skin became blue; her eyes fixed. She slipped off her

chair, but did not fall to the floor. Mr. Partington was sent for; his assistant found her in a semi-reclined position, her head resting on the table, and quite dead. This was a little past one on Wednesday morning; between six and seven hours after the sickness was first observed.

A person dying so unaccountably, without apparent severe illness, called for judicial investigation. Mr. Partington was directed by the coroner to conduct the examination; which was made, in the presence of Mr. Hargreaves, surgeon, and myself, thirty-one hours after death.

The body remained very sensibly warm fifteen hours after death. The countenance was placid, but sunken, and very slightly contracted. The abdomen was sunken; no tympanitis or material discolouration of the integuments; there was slight lividity where the dress had pressed, and decided blueness of the fingers and nails. The intestines externally, and peritoneum, were more vascular than usual; no effusion, no opacity, no mark of inflammation. The colon was contracted to the size of the finger through its whole length, except near the cæcum.

Stomach.—Vessels injected externally. Mucous surface of the pyloric half intense purple-red, darker than raw meat, and softened. The stomach contained about two or three ounces of bloody mucus, with numerous grey, yellowish, gritty particles. The cardiac extremity and œsophagus were comparatively free from injury. Could not find any particles imbedded in the mucous membrane. The whole surface near the pylorus seemed equally acted upon.

In the duodenum, the mucous surface was softened, mottled, and corrugated. Throughout the first third of the small intestines there were patches of inflammation of about an inch in diameter, but in only some few instances did we find any of the grey particles actually on the spot, though in all some were found close by. The ileum was free from these patches, except about three feet from the cæcum, where the whole mucous surface, for some inches, was congested, softened, and nearly destroyed. Colon contained no feculent matter (she had been purged while in the coach). There was no feculent smell. The

bladder was quite empty. The uterus had the appearance of menstruation.

There was no effusion in the chest. Lungs were gorged with purple blood; most so behind. No disease of lungs, heart, or pericardium. Veins and sinuses of dura mater distended with blood; arachnoidal vessels injected; no opacity, no effusion whatever. On cutting through the medullary substance, spots of blood appeared. Substance of the brain neither hardened nor softened.

It was now evident that the deceased had been destroyed by some irritant poison; it only remained for the medical examiners to ascertain what that poison was. The slow appearance of the symptoms, and the morbid appearances being principally seen towards the pyloric extremity, shewed it to be some slowly soluble substance; the appearance of the powder led us to suspect arsenic.

I took $\frac{1}{4}$ or $\frac{1}{2}$ a grain of the suspected substance, mixed it with charcoal, put it at the bottom of a small tube, which I heated cautiously by a small spirit flame. We presently perceived the arsenical odour, while a ring of iron-grey formed half an inch from the bottom of the tube; above that, some white sublimate. On cutting the tube, the grey crust appeared decidedly a metallic surface, of octahedral crystals; the triangular facets, set at right angles to each other, were easily seen with a lens. I placed the broken tube in a test tube, and heated it, when a dense white cloud formed, and settled on the side. I dissolved this white substance in solution of potass, mixed two drops of the solution with four of ammoniaco-sulphate of copper, in a watch-glass: bright green arsenite of copper was immediately formed. I then mixed two drops of the solution with one of liquor ammonia, touched this with a stick of lunar caustic, which was directly coated with a yellow crust of arsenite of silver. A portion of the grey-white powder was subjected to the two liquid tests, shewing decidedly that it was arsenic, though less satisfactorily than by the reduction of the metal, which admits of no possibility of error.

Note.—The quantity of arsenic taken in this case must have been very considerable: there could not have been less than ten or twelve grains found in the stomach, besides what had been re-

jected by vomiting and what passed to the intestines. This, together with the large extent of surface acted upon, may account for the symptoms being those rather of stupor than of intense irritation.

TREATMENT OF FRACTURES OF THE HUMERUS.

To the Editor of the Medical Gazette.

SIR,

THE treatment of fractures of the humerus is often very troublesome, from the extreme retraction of the one portion of bone upon the other, particularly where the fracture is oblique, and situated below the insertion of the deltoid muscle; for then the upper portion of bone is drawn outwards and forwards by its action, while the lower is drawn upwards by the muscles that pass from the scapula down to the elbow. This retraction is often produced by the obliquity of the fracture alone, the deltoid remaining relaxed and inactive.

The common mode of treating this kind of fracture, and by which the retraction is prevented, is without making any extension on the muscles, but merely applying pressure by means of a bandage carried circularly round the arm, and four lath splints to prevent displacement of the ends of the bone. This in almost every case is found to be the simplest and best treatment that can be adopted, being sufficient to obviate the retraction, and to keep the fractured portions of bone in proper apposition.

There are, however, some cases where the obliquity of the fracture is so great, or the action of the muscles so strong, that this treatment by lateral pressure only succeeds with difficulty in preventing displacement of the bone, rendering a repeated application of the splints necessary, as the slightest loosening of the bandages relieves the pressure upon the muscles, and allows them to act, and draw the portions of bone from their line of apposition. These cases, if not difficult to treat, are often very troublesome, and require great care to prevent deformity in the limb.

A case of this kind occurred lately at

the Middlesex Hospital, in which retraction existed to a great extent, the bone being fractured below the insertion of the deltoid, and in a very oblique direction, there being no apposition of the ends of the bone. The ordinary treatment was tried; but so great was the tendency to displacement, and the difficulty of preventing it so great, that it was found necessary to re-apply the splints every day; the ends of the bone forming an angle with one another, however tightly the limb was bandaged.

Having seen this case, it appeared to

me that this great retraction and displacement of the ends of the bone might be more easily prevented, and the treatment facilitated, if counter-extension could be employed in this, as in some other kinds of fracture. With this view I had the following kind of splint made, and with the permission of Mr. De Morgan, the house-surgeon, I had an opportunity of employing it in the above case.

The annexed drawing represents the splint.

FIG. 1.

FIG. 1.

- a a*, The crutch.
b, The slide, to elongate or shorten the splint.
c, The screw, to fix the slide.
d, The splint.
e, The curve for the elbow.

The instrument consists of a thin bar of iron, extending from the axilla down to the elbow, curved at its inferior extremity, that it may pass under the elbow, and turn up as high as the outer condyle. The upper end is perforated with a vertical groove, to admit a sliding bar, to which is attached a kind of crutch, formed by a narrow bar of iron, curved to press upwards in the axilla. This crutch allows of being raised or depressed, by means of a small screw which fits into teeth in the sliding bar,

FIG. 2.

- f*, Hook for the bandage, which with *g g*, fix the elbow.

FIG. 2

- Represents the apparatus when applied.
a, The crutch. *b*, The curve under the elbow.

so that it can be elongated or shortened at pleasure. It is applied as follows:—

The splint is to be made of the proper length by means of the sliding bar, measuring it with the opposite limb, and making it rather longer, to allow of the thickness of the pad upon which the elbow has to rest. The limb is then to be extended to the utmost, by drawing down the lower portion of bone, and keeping the arm as near to the side as possible. The splint is to be placed upon the inside, fitting the elbow into

the curve, and pushing the crutched extremity under the axilla as high as it will go. The elbow is then fixed by a few turns of bandage carried across it, and fastened round two small lateral pegs on the inner side of the splint, and round the curved end upon the outer side. Counter-extension is now produced; for the elbow is fixed to the inferior extremity of the splint, and retraction upwards prevented by means of the crutched extremity that presses in the axilla. The limb is then confined by three splints, placed on the outer, fore, and back part of the arm, with three straps, which can be moved to make pressure on one part more than another, as may be required. The fore-arm and hand should be evenly rolled before applying the splint, and the bend of the elbow well padded, to guard against unequal pressure of the bandage. Pressure on the superficial veins is prevented by putting the fore-arm into extreme pronation, causing the bandage then to press on the outer rather than fore part of the joint, where the veins are situated.

It is not my intention to recommend the treatment of fractures of the humerus by counter-extension as a general practice, it being much more complicated than the ordinary method, and in the majority of cases quite unnecessary, the simple lath splints and lateral pressure answering every purpose required; but in the above case in which I tried it, the treatment was certainly facilitated, by preventing the extreme retraction that existed. I have since tried it in another case, and with the same result; from which I am inclined to think, that where the fracture is very oblique, and the apposition of the ends of the bone difficult to preserve, counter-extension may be employed in this, as in other kinds of fracture, with advantage, and the treatment thereby be facilitated.

If you can insert the above in your valuable journal, I shall feel obliged.

I remain, sir,

Your obedient servant,

EDWARD LONSDALE.

8, Berners-Street, March 2, 1835.

ACTION OF IODINE UPON GUAIAECUM.

To the Editor of the Medical Gazette.

SIR,

I BEG to offer to your consideration the following remarks, which, if deemed worthy of insertion, it would oblige

Your obedient servant,

J. BRETT.

General Dispensary,
March 6, 1835.

In trying the effects of various reagents on guaiacum resin, I noticed the following curious fact. On the addition of a very minute portion of free iodine to a small quantity of an alcoholic solution of the powder of guaiacum, I obtained a very fine blue colour, varying in its different shades, according to the quantities used. The decomposition of iodine which here takes place, bears so close an analogy to that effect which is produced by starch, that all I feel surprised at is that it has not been mentioned before. The circumstances that are necessary for the success of the one experiment hold good in the other; and the modifications also are in a great measure alike. I am induced to advance these brief remarks merely by the consciousness that this circumstance is of a curious and interesting nature; indeed the action of several reagents towards guaiacum is of so particular a kind, as to merit a much closer attention than has, perhaps, been as yet paid to it.

INJUSTICE OF THE GRATUITOUS PROFESSIONAL ATTENDANCE OF MEDICAL MEN.

To the Editor of the Medical Gazette.

SIR,

I HAVE often been tempted to address you, and through you the profession in general, on the subject of the minor medical charities of this great metropolis; but have hitherto deferred it, with a hope that the subject might have been taken up by some one who could do it more justice. In this I regret the torpor of the profession has disappointed me. A circumstance has lately occurred at one of those institutions, which induces me to trouble you with the follow-

ing observations. Should they merit a place in your journal, they may not be without their effect.

At the Welbeck-street Dispensary, the office of physician became vacant. Five candidates commenced a warm canvass. Upon the day of nomination, a motion was made, that in future no physician should receive any salary, the senior physician and surgeon having always received 60*l.* a-year. The motion was made by a solicitor, and carried *unanimously*. The number of candidates in this instance, with the example of professional meanness exhibited some time back at the Marylebone Infirmary, doubtless suggested this *saving* clause. In every other profession, the labourer is worthy of his hire; but with us the case is different. Yet, if Adam Smith's doctrine be true, "that the wealth of a nation consists in her population," the science of medicine, which is so essential to its well-being, is not unworthy of general support.

It would be a waste of time to analyse the motives which prompt three-fourths of the subscribers of those charities in giving an annual guinea. Many of those who profess the widest philanthropy, very prudently commence operations at home, by quartering their domestics, in all states of illness, upon those institutions, thereby receiving ten times the amount of their subscription, by the attendance of a physician and medicines from the charity. It is not an uncommon thing for the subscribers themselves to be attended in this way; I have attended them repeatedly. These are the men who refuse the smallest remuneration for the public services of medical men. If we find a merchant lavish of his stock in trade, do we not consider him a foolish, imprudent man? If we see a barrister who takes briefs without a fee, do we not see him immediately sent to Coventry? Yet physicians, whose stock in trade consists of time and a modicum of brains, are expected to be lavish of their capital, and at the same time to be sensible and well-meaning men. How charitable!

It is a curious question, and one not unworthy the attention of the philosopher, why, of the three learned professions, medicine is the only one in which there is no common tie. This is the more surprising when I consider the wide field of medical erudition. The

philosophers of old tell us, that "*didicisse fideliter artes*" humanizes even savage nature; but the medico-philosophers of the present day give us another reading of this maxim. We profess ourselves—nay, call ourselves—members of a liberal profession, and belie ourselves in the very first act of our calling. For a notable instance of this, we need not travel far from the sound of Bow bell, where talent, reputation, and integrity, were superseded by the servile tools of a trading sect. Can we wonder, then, that we have sunk in public respectability—that our services are unrequited—when we ourselves, by a gratuitous offer of them, have stamped them as valueless?

It is still, however, in our power to make ourselves not only respected, but remunerated. Let the medical officers of all charities unite, and demand a remuneration for their services. The principle of self-preservation, so powerful throughout nature, would be seen to manifest itself here; and the dread of having our streets the haunts of disease, would bring back the public to a sense of justice.

In proposing such a measure as this, I am sure I am consulting the interests of the unhappy beings who are objects of those charities, more than the miserable traffickers of guinea subscriptions, whose affected charity is a libel on humanity.—I am, sir,

Your obedient servant,

MEDICUS.

Feb. 26, 1835.

WEIGHTS AND MEASURES FOR THE NEW PHARMACOPŒIA.

To the Editor of the Medical Gazette.

SIR,

ALLOW me, very briefly, to recal the attention of your readers to the subject of an alteration in the weights and measures employed in pharmacy, to which your correspondent, Dr. Barham, has referred in a recent number of your valuable publication.

As it is intended to bring the "Weights and Measures Act" of last session before parliament, very shortly, for revision, and as a committee of the College of Physicians is now engaged in revising the Pharmacopœia, it ap-

appears extremely desirable that the present opportunity of introducing the necessary alterations should not be lost. Every day's experience proves that a change of some kind is required. The confusion necessarily arising from the application of the same denomination to weights of different value, particularly in establishments where both troy and avoirdupois weights are employed, is too obvious to need illustration. The same confusion exists with respect to measures, with this additional anomaly, that the Pharmacopœia still prescribes the old wine gallon and its divisions, the employment of which is illegal, and subject to severe penalties.

The adoption of the imperial pound as the standard both of weights and fluid measures, as proposed by your correspondent, would obviate many inconveniences; and his suggestions as to minims and grains appear to me to deserve consideration. I would further suggest the introduction of the *fluid pound* as a substitute for the present pint and gallon.

If the old gallon be still employed, a clause should be introduced into the new act to legalize it; but the introduction of either the old or imperial gallon into the new Pharmacopœia appears to be unnecessary.

If the above proposition respecting fluid measures should be found objectionable, the cubic foot (equivalent to 1000 imperial ounces of distilled water) might be adopted.

I merely throw out these hints to draw the attention of your readers to the subject, and hope it will be taken up by some person more qualified to do it justice than, sir,

Your obedient servant,

B. Y.

March 6, 1835.

OBSERVATIONS ON THE

CURATIVE PROPERTIES OF HY- DRIOATE OF POTASS

IN PERIOSTITIS AND CHRONIC ARTICULAR
RHEUMATISM.

By JOHN CLENDINNING, M.D.

Physician to the St. Marylebone Infirmary, and
to the Western Dispensary, Westminster, &c.

WHATEVER may be the disadvantages of our great establishments for the relief of diseased poverty in a moral or poli-

tical point of view, they certainly and greatly benefit the public in the otherwise unattainable facilities they afford for the advancement of the science and art of physic. In the absence of such laboratories for the analysis of the signs and causes of health and disease, it were difficult to conjecture how much more slowly we should have advanced in the prevention and cure of physical suffering. Our great hospitals have two principal advantages over private practice, as sources of professional improvement. Not to dwell on minor but very important points (1, such as compulsory attention to rules as to drugs, diet, and regimen—2, accurate registration of symptoms, &c. without distraction to the physician—3, greater facilities of post-mortem investigation, &c. &c.), I would say that the hospital physician occupies a position more advantageous than the private practitioner, in that—1, with a full supply of all useful agencies, medicinal, dietetic, &c., he has at the same time a control, as complete as may be, over the use of those agencies—every person and object about the sick being under his authority; 2, that he is as nearly as possible unfettered by any considerations of selfish interest, and is at liberty to employ the most gigantic remedies that the cases of his patients may seem to him to require or admit of, without any other restrictions than such as are imposed on him by his own sense of right, and his obligations to the often acute and inquisitive youth that attend his practice. It is, therefore, to the physicians of our medical charities principally, if not exclusively, that British medicine must look for improvements in Semeiology and Pathology; while, with regard to the *Materia Medica* and Therapeutics, the claims of the art on the official practitioner are peculiarly strong, on account of his almost exclusive privilege of exemption from the inconveniences arising from private fastidiousness, timidity, or caprice, and from the dangers of professional envy or malice. For my part, I have in private practice but rarely, and if at all, timidously ventured on the exhibition of any remedy not already current with the stamp of authority; and I have no reason to believe that I am by any means singular in that respect. As an official physician, however, I have not been insensible to the superiority of

my position ; and, when opportunity offered, have endeavoured at least to turn it to useful purposes. To state the results of experiments lately made in an official capacity principally, on the powers of iodine in diseases as a remedy for which it is as yet little known, is my present object.

In the course of last summer, a very interesting paper was read before the College of Physicians, from the pen of my friend Dr. Williams, of St. Thomas's Hospital, in which Dr. W. stated that he had found the hydriodate of potass a very certain and speedy remedy for periostitis. On the occasion on which that important paper was read before the College, I had not the good fortune to be present ; so that previously to its publication in the Medical Gazette, I knew nothing of the virtues of iodine as a remedy for periostitis and other chronic inflammatory affections of the hard membranous tissues. My first practical acquaintance with the subject I owe to the late distinguished president of the Royal Medical and Chirurgical Society.

CASE I.—Not many weeks after the publication of Dr. Williams's paper, a case occurred in my practice at the Western Dispensary, which, after foiling every remedy I could think of, and exhausting, as I supposed, the resources that a dispensary can command, I succeeded in having transferred to the abler hands of Dr. Elliotson, in St. Thomas's Hospital. It was a case of a young woman, of about 21, enjoying apparently excellent general health ; her uterine, intestinal, and pectoral functions were in perfect order, but she constantly complained of dull pain usually either in the back or front of the head : it was of some years standing, and sometimes alternated for a time with a pain in the left hypochondrium, with which it also sometimes coincided. This pain I treated at different times by cupping, blistering, setons, purgatives, &c., and by steel, bitters, aromatics, ammonia, and other stimulants, and by anodynes and narcotics of various kinds, also by mercury to pyralism ; but none of these means proved *remedies*, and some did less good than mischief. After several months of fruitless endeavour, I had her placed under the care of Dr. Elliotson, with a view to procure for her the benefit of the superior resources of a great

medical establishment, and lost sight of her for two or three months.

CASE II.—In the meantime another young woman, who proved afterwards to be a sister of the former, applied to me. She complained of a pain similar to her sister's in character and duration, and in like manner enjoyed apparently good general health ; the headache, however, was, like her sister's, sufficiently constant and distressing to prevent her doing any thing to earn her bread. At first I tried the depletive plan, and afterwards other remedies, but without deriving any important result from any thing but from venesection ; after which she always enjoyed days or even weeks of ease. Venesection, however, is not a remedy for frequent repetition, where there is no urgent danger and no plethora ; and after having pushed it as far as her constitution would suffer it, I was forced to east about for other means.

About this time I learned that her sister had returned home from St. Thomas's quite well ; and, on inquiry, ascertained that, after having failed with many other remedies, Dr. Elliotson had succeeded in relieving her by large doses of the hydriodate of potass. I then commenced the use of that salt with the sister under my own charge, and soon found it produce excellent effects ; the pain yielded, and the patient at length returned thanks. Before finally losing sight of these two patients, I had an opportunity of ascertaining that the first-mentioned had had an apparently periostitic affection of the temporal bone, above and behind the left ear (I think, for my notes have been mislaid), which, if it existed during my treatment of the case, was certainly not complained of, so as to draw my attention to it ; and when I examined it, the node was easily detected, and rather tender on pressure.

I learned also that Dr. Elliotson had attributed her headache to the node, and her relief to the remedial power of iodine in periostitis. I then strictly examined her sister's head, but failed in eliciting any thing from personal inspection, or minute inquiry, to warrant the inference that she had ever laboured under periostitis in any part of the skull. Both these young women were afterwards obliged occasionally to use the hydriodate, but continued, when I last

heard of them, to enjoy greater ease than they had experienced from any former remedy.

CASE III.—In the course of last summer, a seafaring man, of about 25, was admitted at the Western Dispensary, having, along with other traces of venereal taint, nodes on his shins disabling him from labour. His constitution was good, and vital and natural functions undisturbed. In this case I employed the hydriodate, in doses of five grains, four times a day, in compound decoction of sarsaparilla; and in the course of ten days or a fortnight the swellings had disappeared, and he was soon after discharged convalescent.

CASE IV.—About the same time with the last patient a woman was admitted at the Western Dispensary, who had long suffered from a venereal taint contracted from a profligate husband, which had attacked the interior of the nose, and, in addition to other symptoms, had produced tenderness of the scalp, dependent on a palpable periostitis of the frontal bone. This woman was altogether long under treatment, but got quickly rid of her periostitis and tender scalp, and headache produced by it, after the commencement of a course of hydriodate of potass in compound decoction of sarsaparilla.

CASE V.—In July last a gentleman between 30 and 40 years of age was suddenly attacked with headache, vertigo, double vision, flashes of light, and other signs of cerebral disturbance. He had also, for the first week or ten days thereafter, rather singular illusions of vision; not only were objects changed variously in shape, size—viz. halved, doubled, &c., but he had also a succession of spectra, visible nearly equally distinctly in light and darkness; sometimes whole figures, sometimes single limbs, generally men and women, whether in whole or part; sometimes brute creatures; occasionally clouds or other vapour like appearances. The spectra, when most constant, appeared and disappeared alternately at very short intervals, and seemed called into existence by the stimulus of the arterial blood, being often, if not invariably, synchronous with the pulse, and disappearing with the subsiding and swelling of the

blood-vessels. This combination of symptoms was combated by leeching, purging, low diet, rest in bed, &c. These symptoms were in some respects new to the patient; but there was good reason to attribute them to sympathetic cerebral irritation, arising from periostitis of long standing on the vertex and right side, in front of the ear, causing tenderness of the scalp over the whole of the right half, or rather more, of the head.

He had for years past been subject to periostitis of various bones, viz. the sternum, clavicle, acromion, and cranium—sometimes in one part, and sometimes another, and all consequences of an inveterate rheumatism of the scalp and neck, which originated from a practice of wrapping wet cloths round the head during the night, as a remedy for troublesome headaches, attributable to defect of exercise and excess of study. The antiphlogistic means above mentioned as first employed, produced little effect. On former occasions, leeches, and other means of like tendency, had always given relief; but from frequent use their power appears to have been abridged; they had ceased to be any thing more than palliatives. Additional advice was wished for, and Dr. Elliotson's aid requested.

Under that gentleman's direction the hydriodate of potass was exhibited in small doses, to be cautiously augmented. The dose was rapidly raised until it reached ten, fifteen, twenty, and at one time for a few days thirty, grains of the salt thrice a day. After about a fortnight's use of the remedy he was free from headache, visual defects, and every other important inconvenience, except the weakness produced by the antiphlogistic measures employed before the attendance of Dr. Elliotson.

The use of the remedy was persevered in for some weeks, and at length suspended, owing to the unpleasant cardialgia, flatulence, &c. produced by such large doses; but he had still occasional slight and transitory tenderness of the scalp, sternum, &c.; he had frequently momentary cold pricklings about the forehead, cheek, &c. with sense of fulness in the head, giddiness, &c. The crackling sound, also, noticed by Dr. Johnson, in a recent number of the *Medico-Chirurgical Journal*, as attending the contraction of

muscles affected with chronic rheumatism, was more than usually distinct at the insertion of the cervical muscles into the occiput, and was heard even by the patient himself.

In October, consequently, he was again suddenly attacked with symptoms, such as those just described, and for which Dr. Elliotson had ordered iodine. This attack also was combated by the hydriodate, and in due time completely subdued; and from that time to the present he has had slight returns, but no attack of periostitis, or its effects, and is now in better health than for years past.

CASE VI.—In the interval between the first and second attacks of the patient last noticed, a gentleman was brought to me for advice, by my friend Mr. Kelly, of Pinner. He was between 40 and 50, of originally sound constitution, and had suffered for years from rheumatism in one form or other. For a considerable time before I saw him, the complaint had advanced to the periostitic stage. He complained principally of nocturnal pains of the long bones, or *osteoepi*, which required large doses of opium for their alleviation. He had latterly as much as two or three grains of morphia at a dose, without other effect than relief from pain. On one of the tibiae there was a hard swelling, visible at a considerable distance, extremely tender, extending longitudinally over the greater part of the anterior surface of the tibiae, and obviously a periostitis or node of the hard kind. From the history of the case, I have no doubt it was of purely rheumatic origin. All the usual remedies had been tried without permanent advantage. On detecting the node, I at once thought of the hydriodate of potass, and accordingly prescribed it, in doses of three grains, thrice a day. The dose was increased gradually, and the result was very satisfactory. After a few days he abandoned the opium altogether, and in less than a month Mr. Kelly called to inform me that he was quite well. This patient never, if I rightly recollect, took so much as is recommended in Dr. Williams's paper.

Mr. Kelly has informed me, that in two or three other cases of periostitis, in which he has since used the hydriodate, he has had the same success as in Mr. M.'s case.

CASE VII.—Nearly six months since, a lady, resident in Lincoln's-Inn-Fields, requested me to see one of her servants, who was disabled from doing her work by pains in the head, neck, and back. On examination, she was found to be possessed of an originally sound constitution, but to have suffered for some time from rheumatic pains, extending from the occiput to the loins and sacrum through the whole length of the *longissimus dorsi*, and other elongated muscles that fill up the grooves between the spines of the vertebræ and shafts of the ribs. There was likewise extreme tenderness of the occiput, owing obviously to periostitis, and some pain also at the lower end of the muscles just referred to, owing apparently to a rheumatic inflammation of the fascia. The exercise of the muscles that support the head, and of the *ligamentum nuchæ*, as in stooping, sneezing, coughing, was distressing; and she had difficulty of lying on her back in bed, from tenderness over the occipital bone. She had likewise a complaint of the uterus, owing to hard labours, of which further notice is unnecessary. This woman I put under the influence of iodine, in the same manner as Mr. M., and with the same result. In about a fortnight, her tenderness of scalp and pain on stooping were gone, and she soon abandoned the use of the remedy.

CASE VIII.—In the course of the last autumn, a young gentleman consulted me respecting circumscribed and tenderswellings on his head, at the highest part of the frontal bone; and arising, there was reason to believe, from sexual indulgences. He had had his head shaved, and worn a scalp, for the use of blisters with less inconvenience, and had used sarsaparilla and other means, but without permanent advantage. This was obviously a mild case of the class so successfully combated, at St. Thomas's, by Dr. Williams, with the hydriodate of potass, and I at once recommended that medicine. In a few days the swellings were sensibly less, and in ten or twelve days there was no longer any need of remedies.

Perhaps the cases already mentioned will suffice at present on the subject of periostitis—that is, the disease respecting which the efficacy of Dr. Williams's (I believe I may say) discovery is best

made out. I could, however, easily swell the number from my own resources, without borrowing at all from my friends. Since my appointment to the great parochial hospital of Marylebone, more particularly, I have had greatly increased means of observing the operation of the hydriodate, and have from that source collected the particulars of three or four other very satisfactory examples of the utility of iodine in the form of disease in question.

A second class of cases, in which Dr. Williams does not appear to have employed the hydriodate, and in which I, led by analogies that I need not point out, have very lately been induced to try it, and with very satisfactory results,—viz. chronic articular rheumatism—I shall now proceed to notice and to exemplify.

[To be concluded in our next.]

DEATH BY HANGING,

Unattended with any of the usual characteristic Lesions.*

By M. ALBIN GRAS.

WHAT is remarkable in the present case is the absence of every sign by which it might be determined (had the body been found under suspicious circumstances), that death had been produced by suspension. There was the mark of the cord, indeed, round the neck, but nothing to shew that the body had not been suspended *after* death.

Josephine, aged 27, was admitted into the Salpêtrière on the 21st December, 1834. In the course of a few days she attempted to strangle herself with a handkerchief; then with her stocking. A strait-waistcoat was put upon her; but this was subsequently removed on her giving a promise not to do herself mischief. On the 3d of January she was questioned as to her history, when she gave an extraordinary, but rather incoherent, account of herself. She did not know whether any of her family had ever laboured under mental derangement, and she had never had any malady

to signify, except, perhaps, some *nervous attacks*, or *vapours*. At the age of 14 she left home, and went to service; and since then, as she described it with deep repentance and remorse, she had lived a very disorderly life. After many changes and chances she formed a connexion with a man who quitted her when she proved with child. Her grief caused her to miscarry. This was in January, 1834; after which she came to Paris, and lived with her sister till the month of September. She then became *femme de chambre* in the family of the Marquis de R—. It was after her arrival in Paris, she said, that she began to *look inward* upon herself, and applied to a confessor, who frightened her extremely by telling her that she was lost. Her melancholy was aggravated from that moment, and she was the victim of religious terrors. She did not, however, neglect her service, nor give any dissatisfaction to the family she lived with; but beyond the door she could not go, though aware that it was her duty sometimes, and though she wished it. Soon after it became necessary to send her to the Salpêtrière.

At her admission, she was observed to be of a moderately full habit of body, dark complexion, and of a bilious temperament. The expression of her countenance was that of melancholy. She spoke little, and when she did it was only to say how very wretched she was; that she did not know what would become of her soul; that she deserved to be starved. When visited afterwards, she requested to be put to death: she said she should never get well; but she complained of no bodily ailment, except some slight pain at the pit of the stomach. The only medical treatment she received was some slight purgatives: twice, indeed, she got croton oil. She also had some baths; but she ate little, and only when pressed to take food. Three days before her death, she seemed on the whole better. But on the 20th, she asked me, at the visit, if I thought she should live; and that evening she several times struck her head against the wall. On the 22d she arose at four in the morning, went down to a cellar where there were several cords, which she had, no doubt, secreted there some days before, and hung herself from one of the rails of the staircase. She was not cut down till an hour and a half af-

* From the *Annales d'Hygiène*, No. xxv.

terwards, when all efforts to restore her to life proved vain.

Upon examining the body, at eight o'clock A.M., there was no distortion about any part of it; the features and lips were pale; the mouth and eyes partially open. At ten, although the mean temperature of the weather was at the freezing point, there was still a slight moisture on the surface. At four in the afternoon, the elbow and knee-joint were still flexible, but the jaws were firmly closed.

The autopsy took place thirty hours after death. At this time there was cadaveric stiffness; the skin generally was pale, but there was no tumefaction any where observable. The tongue lay within the alveolar processes, and there was no froth in the fauces. On opening the head, much blood was found on the exterior of the dura mater; but this effusion was partly, if not entirely, owing to the blows of the hammer used in breaking open the cranium. The substance of the cerebrum was injected; the optic thalami, the corpora striata, the cerebellum, the protuberance, and the cortical substance, less so. No adhesion of the meninges. The whole brain firm, and the cranium tolerably thick.

The skin of the neck presented a furrow, which ran in an oblique direction from left to right, and from below upwards; the most elevated part of it corresponding to the angle of the jaw on the right side. At this part there was a depression, caused by the knot of the cord. The furrow passed in front of the os hyoides; so that only the vessels of the left side of the neck were compressed. *Beneath* the furrow on the left side, the external jugular vein was distended with air. Along the track of the depression the skin was yellowish, like parchment; it adhered strongly to the subcutaneous tissue, but there was no ecchymosis, no fracture or injury of the os hyoides, nor of the cartilages. There was no trace of the furrow on the subjacent muscles; no rupture of the coats of the vessels, either of the jugulars or the carotids; nor was there any luxation of the vertebral column.

In the lungs there was very little blood; their colour was pinkish, and in their upper portion some tubercles were observed. The parietes of the heart were thick; they contained but little

blood; and what was remarkable, the left cavities more of that little than the right. A very small quantity of blood in the inferior cava.

The stomach appeared shrivelled; slightly red in some places. Of the small intestine, the colour was an uniform light rose-pink. The liver seemed to be of a somewhat deeper red colour than ordinary. Spleen and kidneys normal. The uterus and vagina presented no unusual appearance; but the ovaries were very large, and had on their surface four or five little serous cysts, each about the size of a vetch. One of them, smaller than the rest, was embedded in a little clot of blood, with a yellowish tinge.

Above the left knee there was some slight excoriation. The fingers of both hands were gently flexed; the thumbs not so.

It will be perceived that there is a strong analogy between this case and some of those which were published in the *Archives Générales*, in the year 1823, by M. Esquirol: but, at all events, it proves that suspension *may* take place during life, and leave on the dead body no sign of mortal lesion,—no bloated face, no protruded or swollen tongue, no ecchymoses on the neck, no rupture of vessels or their coats, no luxation; no more than a simple furrow, where the skin is yellowish and crisp, and the subjacent tissue somewhat condensed; nothing, in fact, to enable us to say whether suspension has been effected on the living body or on the dead.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

A Practical Compendium of Diseases of the Skin; with Cases, &c. &c. By JONATHAN GREEN, M.D.

THE work before us is a condensation, judiciously made, of the present state of knowledge of cutaneous diseases in our own country, and in France.

We do not intend to enter into the consideration of certain unimportant changes which have been made in the mode of arranging these diseases, because it is upon other grounds that the

value of the book rests; it is upon the application of certain energetic therapeutical agents—baths of various kinds.

The importance of medicated baths as remedial agents in the treatment of cutaneous diseases, has long been established. In their employment, however, no system has been adopted; they have been indiscriminately used in all forms and in all stages of these affections, whilst they were, perhaps, only applicable to particular diseases, and only to certain stages even of these diseases. We hail, therefore, with great satisfaction the work before us, embodying as it does the extensive experience of the author in the application of every variety of these agents, to almost every variety and stage of skin diseases.

The doubt we entertain is not as to their general value, but whether the author is not rather too confidently impressed with their universal applicability. This circumstance, however, cannot be made a ground for reproach; there are few men, either medical or other, who are not influenced to a greater extent than they would like to confess, by some favourite idea.

The author has done his part; the public will decide whether they can go with him to the full extent of his commendation of these agents. We are of opinion, that in spite of the alleged infallibility of the remedy, we shall still have to endure the reproach which will attach to our inability to suggest a remedy for many cases of diseases of the skin. Whether subsequent experience shall reject or confirm some of the author's data regarding them, this much is certain—that the profession must be largely indebted to him for communicating the results which he has obtained from an extensive administration of the remedy during a period of "fourteen years."

We earnestly recommend those who are interested in the subject, not only to read this book, but to put the efficacy of the agent to the test.

Sketch of the History of Medicine, from its Origin to the Commencement of the Nineteenth Century. By J. BOSTOCK, M.D. F.R.S. &c. 8vo. pp. 240.

WE have here, probably, as good a sketch of the history of medicine as the

space allotted to it could allow. Dr. Bostock has arranged his materials, and drawn on the ample stores which were open to him, with ability and success. He has produced a very superficial work, no doubt; but we believe it to be a correct one, so far as it goes. The facts, at least, are honestly stated. As for the opinions (especially many of those relating to recent times) we deem not a few of them to be extremely open to controversy; and while we thus express our general approbation of the performance, we reserve to ourselves the right of calling to account, at some future period, certain assertions which we here and there met with, and marked as matter for animadversion.

Lectures on the Means of Promoting and Preserving Health. By T. HODGKIN, M.D.

A GREAT deal of useful popular information connected with medical subjects is contained in this small volume. The dietetic precepts are very good, and sometimes curious. Some political hints, interspersed in the notes to the third lecture, we could wish had been omitted: they are ill timed, and on the whole, we think ill judged. The lectures were delivered at a mechanics' institute five years ago, but of course have been so revised as to be properly adapted for present purposes.

MEDICAL GAZETTE.

Saturday, March 14, 1835.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE PROPOSED TRAFFIC IN DEGREES.

MONEYCHANGERS, we believe, were never proverbial for their modesty; nor those involved in ruinous speculations remarkable for the moderation of their efforts to extricate themselves, when thoroughly awake to their danger. Drowning men are known to catch at straws: too often, however, they do worse—they lay hold of their good-

natured but unwary neighbours who venture too near them, and the safety and very existence of the whole party is at once thrown into imminent peril.

We cannot think of the state of things in Gower-Street, nor of the desperate efforts meditated and being practised by some of the shareholders of the joint-stock school there, without having some such image as this present to our minds. The report relating to the financial concerns of the establishment we noticed briefly in our last number: the particulars which we added respecting the proceedings at the meeting—the proposal of one of the proprietors to abandon the “shares,” as affording only a “desperate prospect,” and the indignant refusal with which that proposition was received—must have prepared our readers for hearing of any other forlorn attempt on the part of the speculators to meet the emergency in which they are placed; and such is the purpose of their approaching appeal to parliament.

We could pity, and perhaps lend a hand to relieve them in their necessity, but that their efforts to keep afloat are not of the most virtuous or praiseworthy description: we see them wilfully diverging from the plain, straight-forward, and, in the end, the most practical and safe course, which people of upright minds would endeavour to persevere in; we discover them grasping not only at things beyond their reach, but at what it would be highly improper for them to possess; and, beholding this, can it be wondered at that we spurn them from us, and leave them to the advocacy of their hirelings?

From the very first we had our doubts of the good intentions of the Gower-Street proprietary. There were, indeed, among them, we were aware, many worthy individuals, really desirous of procuring for their fellow-citizens of

more limited means, as well as for their own families, the opportunity of a cheap and good education, and willing to contribute funds liberally for the attainment of so desirable an object; but we could not help observing the large number of Jews and Gentiles who had got amongst them, persons whose main object was of a very different nature, and who, in short, were more frequently to be met with about 'Change than in the halls of philosophy or religion. Our apprehensions were justified ere long. The money-seeking proprietors went on cautiously for a time; but not succeeding according to their wishes, or rather, their speculation becoming utterly desperate, off went the mask of decency, and behold them intent upon the scramble. Nothing now can check their eager anxiety to retrieve their losses, at whatever risk of repulse or exposure. Not content with their defeat, upon being deliberately and patiently heard by the Privy Council, on which occasion *Lord Grey's cabinet, after the pleadings had been heard, were unanimous against them*, they would fain avail themselves of the “crisis” in the political world to work up their pecuniary concerns into something resembling a party question. It remains to be proved whether parliament and the public will suffer themselves to be imposed on.

Can any thing be more preposterous and barefaced than the humbug of this mere medical school, calling itself a “University?” A charter it might have had long since, like any other trading company, founded and supported, as it is, by money subscribed in shares: but, no—this would leave it to work its way too slowly for those who calculated on a quick return for their outlay. The charter is disdained, unless it can be procured together with a privilege of trafficking in degrees; the parties well knowing that with such au

instrument in their hands, they may laugh at all their metropolitan and provincial rivals, and instead of being simply a school of medicine—one of the many—become at once *the* school of medicine of the metropolis, setting at defiance the competition of all other similar establishments.

Yet if the grounds of these claims for monopoly be inquired into, none other can be assigned save those of gross presumption combined with sharp necessity. The project was started in the report for 1833, in which, after stating the embarrassments of the institution, and the utter inability of commencing another session without some new source of relief, it was explicitly avowed that “the first *scheme* which presented itself to the council as favourable for the support of the institution, was, if possible, to obtain a charter enabling it to grant degrees in subjects not theological.” So that by their own shewing it is no zeal for the promotion of literature or science that induces them to persevere in seeking for exclusive privileges, but confessedly the main object is by this “scheme” to prop up the declining fortunes of the establishment.

But suppose, for a moment, that through some infatuation, or factious resistance to the dictates of reason, a majority in the House of Commons should be found to support Mr. Tooke’s motion on the 26th, who are the parties on whom this important privilege is to be conferred? Who *are* the influential persons that constitute the chief portion of the proprietary in this, or in any other joint-stock concern? Without doubt, those who have most shares in the speculation—the most monied shareholders, whether they be Jews, pettifogging lawyers, or quack-doctors. The shares are for sale on ‘Change at prices more than 75 per cent. below their nominal value; and if Morison, of

quack-pill-notoriety, choose to be a purchaser to a considerable amount (if, indeed, he be not so already), *he*, along with any other spirited and monied charlatans about town, may become the rulers of the destiny of the new joint-stock - medical-degree - conferring establishment; and the rising generation of practitioners in London will have the satisfaction of deriving their professional powers and privileges from a body, of which Messrs. Morison, Eady, and Co. may be the head!

There is no alternative. As long as the school in Gower-Street, which now sets forth its extravagant and impudent pretensions, is a joint-stock speculating company, with shares transferable and purchasable in the market, so long will it be dangerous to commit to it the power of qualifying by a diploma practitioners either in law or physie for the public service. Were the place endowed with landed property—not chargeable with the ruinous practice of borrowing money on mortgage—in short, possessed of any stability (nay, we might say respectability) in the eyes of the community—there might then probably be some shadow of a pretext for entrusting it with certain limited powers for the conferring of honorary titles; but even then, the idea of giving it any privilege not shared by the other schools could not for a moment be entertained. But nondescript and tottering as this unchartered *soi-disant* University is at present, every body, except perhaps the disappointed shareholders involved in the concern, must see the propriety of not burthening it with *any* privileges, which could only prove at once a mockery to itself and a mischief to the public.

FORCIBLE SURGERY.

THE almost incredible story to which we alluded last week, of a clergyman and surgeon having forcibly sub-

jected a lad to the operation of lithotomy, has, we find, some foundation in fact, and is to be made the subject of legal proceedings against the parties. We shall lay the particulars before our readers at the proper time; to do so at present might interfere with the course of justice. When we first heard of it, presuming that no one could have been guilty of so insane a proceeding, we took it for granted that the story had been trumped up, and palmed off on our contemporary, as a quiz upon his proverbial appetite for slander; but we have ascertained that the account in the *Lancet*, though infinitely beyond the truth, was not altogether without foundation;—an acknowledgment which candour induces us to offer even to the most thoroughly dishonest opponent that ever journalist had to deal with.

As this sheet was passing the press, we received the *Lancet* of this day, by which we perceive that the other instance of "forcible surgery" to which we alluded last week, has not been lost upon it. Our worthy and veracious contemporary has been pleased to inform the public that the anecdote was given on the authority of Dr. Macleod, and referred to an occurrence at the North London Hospital: the former assertion is not true; and the latter, (we mean the application he has thought fit to make of the story), be it remembered, is entirely his own.

ADDRESS TO HIS MAJESTY,

FROM THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

To the King's Most Excellent Majesty.

WE, your Majesty's most loyal and dutiful subjects, the President and Fellows of the ROYAL MEDICAL AND CHIRURGICAL SOCIETY OF LONDON, beg leave to offer to your Majesty our most grateful acknowledgments for the high honour which your Majesty has been pleased to confer on us, by granting to us your Majesty's Royal Charter of Incorporation; and for your Majesty's gracious condescension in becoming the Patron of our Society.

It has been our earnest endeavour, during a long series of years, to sup-

port, in our publications and our meetings, that character for liberal and useful acquirements which the medical profession has always possessed in your Majesty's dominions.

In the sanction and encouragement which your Majesty has been graciously pleased to give to our exertions, we view the means of augmented stability and usefulness; and we venture humbly to assure your Majesty, that, as the best mode of evincing our grateful sense of your Majesty's favour and protection, we shall at all times continue to keep steadily before us, as objects of manly and honourable emulation, the successful efforts of the great scientific bodies of the country, which, under the fostering and invigorating influence of your Majesty, and your illustrious predecessors, have so largely contributed to render your Majesty's kingdom pre-eminently distinguished in every department of human knowledge.

That your Majesty may long live in the affections of your subjects, the indulgent promoter of whatever is conducive to their welfare and happiness, and the benignant encourager of every worthy exertion, is our ardent and anxious wish.

Sealed with the common seal of the society, and signed by the authority of a general meeting of its Fellows, on the 18th day of February, 1835.

BY SIR B. C. BRODIE, BART.

LECTURE II.

HEMORRHOIDS—OPERATION.

DIFFERENT methods have been proposed for destroying hæmorrhoids by operation: some surgeons have practised and recommended that by excision, while others have preferred the removal of them by ligature; others speak of the ill consequences attendant on each of these modes of operating.

It appears to me that the question respecting the operation and the proper rule

of treatment has been very distinctly and correctly laid down by Sir Everard Home, in a paper on that subject, at the end of his work on Ulcers of the Legs. He states the matter thus:—"That external piles which are covered by the skin ought not to be removed by ligature; if they are removed at all, it ought to be by excision. On the other hand, internal piles which are covered by the mucous membranes, ought, *for the most part*, to be removed by ligature. In short, the ligature is applicable generally in cases of internal piles, and excision to those which are external. The grounds of this distinction are as follow: The application of a ligature to external piles gives the patient extraordinary pain at the time, and afterwards excites much inflammation, swelling, and disturbance of the general system; whereas, if they be removed by excision, these ill consequences are avoided. After the excision of *external* piles, there can be no danger of hæmorrhage, because the parts are entirely within your reach, so that the bleeding vessels can be easily secured; and though some little inflammation may supervene on the operation, yet it is not sufficient to be of any real consequence. If, however, you remove large *internal* piles by excision, there may be copious and even dangerous hæmorrhage, since the parts which bleed are out of reach, above the sphincter muscle, where you cannot expose the cut surface, so as to be enabled to take up the bleeding vessel. On the other hand, the application of a ligature to internal piles in general causes but little pain, and only a slight degree of inflammation follows, for the mucous membrane has nothing like the sensibility of the skin, and does not resent an injury in the same manner. With respect to internal piles, then, there is no objection to the use of the ligature, while there is the greatest objection to their simple excision. This is the doctrine which I was taught by Sir Everard Home in this hospital when I was a student. But I met with a copy of Mr. Cline's Lectures on Surgery, in which he stated that he removed internal piles by excision; and this observation was added—"a timid surgeon removes them by ligature." Knowing Mr. Cline to be a very cautious practitioner, I thought that in what he recommended there could be no kind of danger, and for some time, therefore, I was led to follow his suggestion. In the first one or two cases I found no inconvenience to arise from my altered practice; but then a case occurred in which the patient lost a great deal of blood; in another case, the hæmorrhage was so great that the patient nearly died; and then a third case occurred, in which also

the patient lost an enormous quantity of blood—so much, that I now only wonder that he did not actually die. Since then I have never removed large internal piles except by ligature.

The removal of external piles is very seldom necessary: they are generally complicated with internal piles; and if you cure the former, the latter, which are a continuation of the same veins, will be cured also. However, there are cases in which it is right to remove external piles by incision. For example, where they are enlarged and inflamed, so that it will take a great deal of time to subdue the inflammation, and the patient is all the while suffering pain, he may be relieved at once by two or three snips of curved knife-edged seissars. Or if an abscess has formed in an external pile, which bursts, discharges, and closes at the orifice, then bursts and discharges again, it may be worth while to cut off the pile and the abscess with it.

The excision of external piles is easily accomplished by means of the seissars which I have just mentioned. You take hold of the pile with a double tenaculum, elevate it a little from the base, and then snip it off. If there be a little artery bleeding considerably, you take up the vessel as you would on any other cut surface.

I have said that internal piles are to be removed principally by ligature. You will observe I do not say they are *never* to be removed otherwise. The fact is, that when internal piles are small, it is not worth while to tie them; and they may under these circumstances be excised with perfect safety. Such a case as this will frequently occur:—a patient complains of symptoms of internal piles; he has always pain about the anus, and a discharge of mucus. You examine the parts, and find a pile, not larger than the end of your little finger, covered with the mucous membrane of the bowel, protruded, and, as it were, sticking in the orifice of the anus. You take hold of it with a double tenaculum, apply the seissars to the base, and no kind of inconvenience follows the operation. But whenever there are large internal piles, which protrude either constantly or occasionally, you ought not to venture to remove them except by ligature. In performing the operation by ligature, the first thing is to get the piles well protruded. For this purpose, you may make the patient sit over a pan of hot water, which will relax the sphincter muscle, and at the same time cause the veins of the rectum to become filled with blood. If this be not sufficient, let the patient have a pint or two of warm water

thrown up as an enema; and when that comes away, the piles will probably descend with it. The piles having been by these means brought properly into view, you may let the patient lean over a table, or lie on one side in bed, with his knees drawn up, the nates being held apart by an assistant. Each separate pile must be separately tied. If the pile be of a very small size, you may just take it up with a double tenaculum, draw it out, and tie a ligature round its base. But if the piles be of a large size, you should proceed in the following manner: have a large curved needle, armed with a strong double ligature; pass the needle, carrying the ligature after it, through the base of one of the piles, and then cut off the needle. The double ligature is now divided into two single ligatures, which are tied round the base of the pile, one on one side and the other on the other side, with a single knot. Treat all the piles in this manner; and as the ligatures are applied, let your assistant draw the several threads out of your way, holding them over the nates. When each of the piles is secured in this manner (and there may be two, three, four, or five, to be thus treated), you then proceed to another step of the operation: cut off the convex portion of each pile, so as to make an opening into the cavity of the convoluted vein which forms it. Thus you take off the tension produced in the pile by the blood which it contains, and are enabled to draw the ligature tighter than before. It should be drawn as tight as possible. As the ligature is tighter, so there is less pain afterwards; so also the slough separates sooner, and the more expeditious is the cure. You have now only to complete the double knot upon each of the ligatures, and cut off the threads close to the knots, returning the piles, ligatures and all, into the rectum. It is a very simple operation; and except when the piles are in a state of inflammation, attended with but little suffering. You are to take care, in performing it, to keep all the ligatures clear of the external parts; for if they include any of the skin, the patient suffers a great deal of pain, and much inflammation will supervene. I generally give a pretty active dose of rhubarb the day before the operation, so that the bowels may be well emptied, and that the patient may afford to go for two or three days after the operation without having an evacuation.

It very seldom happens that inflammation or fever follows the use of the ligature, and the threads generally separate at the end of a week,—not that I look for their separation, for it is of no consequence whether they come away a day sooner or a day later. I never trouble my head about

the ligatures after they have been once applied; but if you choose to look for them, this is the time at which you will find that they usually come away.

But the patient must now take measures to prevent a recurrence of the disease. For this purpose, when there has been time for the sores left after the separation of the ligatures to have healed, I recommend him to take some lenitive electuary and sulphur every night, so as to keep the bowels gently open, and to use a lavement of cold water every morning.

I conceive that this is not only one of the most effectual, but one of the safest operations in surgery. I should think I must have performed, or seen it performed, between 200 and 300 times. I saw one patient who died after the operation, in consequence of diffuse inflammation of the cellular membrane running up on the outside the gut as high as the mesentery; but that was a patient whose constitution was broken down by long-continued hæmorrhage, and in whom any slight accident might have produced equally bad consequences. I saw another patient, who, a week after the operation, and having been quite well in the interval, had an attack of pain in the abdomen, and shivering attended with fever, and died. I was not allowed to examine the body after death. I could not make out at the time that the symptoms had any connexion with the operation, nor do I believe that they had; but I mention the case because, as the body was not examined after death, I have no certain knowledge on the subject.

With the exception of these two cases, out of all the 200 or 300 patients whom I have known treated in this manner I never knew any ill consequences to arise. I contend, then, that the operation is as safe as any operation can be expected to be. You are not to suppose that even the slightest operations in surgery are absolutely, in all cases, free from every particle of danger, any more than the slightest accident. I have known two patients die after the extraction of a tooth, and I have known several die in consequence of venesection at the arm, or an accidental prick of a finger. The chance of danger from this operation at any rate is so trifling that you need not calculate upon it. If you were to calculate upon so small a chance as this, you would scarcely be able to do any thing in the common affairs of life.

Supposing a person has piles which come down when he walks, which are constantly teasing him in this way, and yet he cannot make up his mind to submit to an operation, or that there are any circumstances that lead you to think it better not to have recourse to it, still you may

do something for his relief. There is a machine made for the purpose of supporting the bowel, and preventing the protrusion of the piles. It is sold under the name of a truss for the *prolapsus ani*, the makers of it confounding, as I have told you is often done even by surgeons, internal piles with prolapsus of the rectum. It is made with a spring which fits round the pelvis, and so far resembles a spring truss for a hernia; but at the back part, fixed at right angles to the circular spring, there is another spring which descends behind the sacrum, taking the course of that bone, and terminating below in a pad, which rests on the anus. The elasticity of the spring supports the pad, keeps it pressed against the anus, and prevents the protrusion of the internal piles.

PROLAPSUS OF THE RECTUM.

I have just observed, that it is very common to confound *prolapsus of the rectum* with internal piles. This error is committed not only in common conversation, but by surgical writers; and hence it is that no good account, so far as I know, has ever been published of the first-mentioned disease. But the difference between internal piles and real prolapsus of the rectum is this: in the protrusion of the former, the mucous membrane covering them descends, and may be seen below the anus; but it is only the mucous membrane, there is no descent of the muscular tunics; whereas, in the latter, the whole of the rectum comes down, and sometimes as much as twelve inches in length. I have never dissected a case of prolapsus of the rectum; but it is impossible to examine a genuine instance of this displacement in the living person without being satisfied that the muscular tunic is protruded, as well as the mucous membrane. There being such a marked difference between prolapsus of the rectum and internal piles, nothing can be more absurd, or unscientific, than to confound these two diseases with each other.

It is not remarkable that the whole of the tunics of the rectum should sometimes protrude in this way. Look at what happens to the bowel above. Do you not find one portion of it slipping into another in the case of *intro-susceptio*? and prolapsus of the rectum is just the same thing. If one portion of bowel slips into another, why should not the rectum slip out at the anus?

Prolapsus of the rectum occurs most frequently in children, and especially in those with large tumid bellies and costive bowels, where the whole mass of the intestine becomes too large for the cavity which contains it. Simple dissection will inform

you why children are more liable to this disease than grown-up persons; it is because the prostate gland, urethra, vesiculae seminales, and all these parts, are not so much developed as in the adult. The attachment of the rectum to the surrounding parts does not extend so high in children as in persons of mature age, while the reflection of the peritoneum takes place lower down, and hence the rectum is more liable to be pushed out.

In adults prolapsus of the rectum sometimes occurs as a consequence of piles. The patient having been liable to the protrusion of internal piles, and the sphincter muscle having been thus continually dilated, the rectum is more liable to slip out, as you may well suppose, than it would be if this dilatation had not taken place. However, in grown-up persons the disease is comparatively rare. I see it every now and then, but very seldom; and where you meet with it in the adult, it has generally begun in early life.

When prolapsus of the rectum is combined with internal piles, you will see the latter at the upper part of the prolapsus—that is, close to the orifice of the anus, forming a zone around the gut; and the colour and appearance of the mucous membrane covering the protruded piles is altogether different from that of the membrane covering the rest of the gut.

The inconvenience which the patient suffers from prolapsus of the rectum varies very much in different cases. Sometimes it comes down occasionally after a costive motion only, and is easily pushed up; and when pushed up it remains in its place till some accidental circumstance brings it down again. In other cases you return it, but the moment the patient begins to walk about, down it comes again; and in instances of long standing, the bowel becomes so fixed in its unnatural position, that you cannot return it by any means, and then other inconveniences follow. The rectum having been constantly protruded, becomes inflamed from friction, ulcerated, sore, tender, painful; and where the protrusion has existed for a long time, you will find it covered by a kind of entele.

Treatment.—When you are called to a child labouring under prolapsus of the rectum—and these are the cases that you most frequently meet with—you will almost invariably relieve him in the following manner:—Purge him with calomel and rhubarb occasionally; be very careful about his diet, that he does not eat a great quantity of vegetable substance, which tends to fill up the cavity of the bowel, while it affords but little nourishment; and every morning let some astringent injection be

thrown up. The injection which I have generally used is a drachm of tinct. ferri muriatis, in a pint of water; and two or three ounces, or more, of this, according to the age of the patient, may be injected into the rectum every morning, the child being made to retain it as long as possible. I never saw a case of prolapsus of the rectum in a child, which was not cured in this manner.

If you are consulted about an adult labouring under this disease, and it has been consequent on a protrusion of piles, the first thing to be done is to destroy the piles. Let the patient sit over a pan of hot water, and the sphincter muscle being relaxed and the parts distended with blood, the piles and rectum will all protrude together: you must then tie the piles, which you can easily do, your assistant holding the rectum on one side, while you apply the needles and ligatures on the other. Having tied the piles, you return the rectum into its proper place; and you will probably find, that in curing the piles you have also remedied the prolapsus of the bowel. But if the patient neglects himself afterwards, as the piles return so the prolapsus returns with them.

Where the disease is not complicated with piles, in those cases which occur occasionally in which prolapsus of the rectum has begun in early life, and has continued to adult age, the cure is very difficult, and perhaps impossible. The patient must be retained in the horizontal posture, for then the rectum is much less likely to protrude than when he sits up: he ought not to sit up even for an evacuation, but should have a bed-pan. Whenever the rectum protrudes, it should be pushed up again; an astringent injection should be employed daily, and the patient should be put through a course of Ward's paste. This plan affords him the best chance of a cure which he can have, but I will not say that it will always be successful. I remember trying it for a great length of time in a woman in the hospital, and, after lying many weeks in bed, when she got up the rectum came down as before; nay, it came down sometimes when she was in bed, even in the horizontal posture. In these cases, however, you may employ with advantage the truss for prolapsus of the rectum, which I mentioned as applicable chiefly to bad cases of internal piles. There was a patient in the hospital (a soldier) who had, I suppose, eight or ten inches of the rectum constantly protruded, and it could not be returned. After trying various means for a length of time, he left the hospital as bad as when he came in, and I do not know what became of him. It occurred

to me afterwards, that in such a case as this it might be advisable to apply ligatures, and then cut off the protruded gut; for though the disease is not immediately dangerous, yet it must be regarded as ultimately so; and it might be worth while for the patient to run some risk at the time, for the chance of subsequent cure. I do not know that such an operation has ever been performed; but is it not deserving of consideration whether we ought not to have recourse to it in certain cases? There is a natural cure of bad cases of intro-susceptio, the analogy of which is in favour of the practice which I have just suggested. In the cases to which I allude, one portion of gut being protruded into another, the protruded portion is constricted by the edge of that into which it has passed; the circulation in it is stopped, and it sloughs away as if a ligature had been put round it. In this manner a portion of gut, eight or ten inches in length, has sometimes come away, and the patient has lived and done well afterwards. Several cases of this kind are on record; and I once had an opportunity of dissecting a patient who died when the sloughing process was taking place. If such an operation as I have proposed were to be had recourse to, the gut must be included in several ligatures, so that the orifice of it may not be obstructed, as it would be by a single one.

EXCRESCENCES OF THE RECTUM.

Excrecences of various kinds take place on the inner surface of the rectum, which patients are very apt to mistake for piles. Here is one [presenting a specimen]—a sort of polypus. It is, as you see, of a small size, but I have seen them as large as the finger. It seems to be of the same structure as the polypus of the uterus. This kind of excrecence is by no means uncommon. Sometimes there is a single one; at other times there are two or three growing from the mucous membrane. In some instances they occasion the patient scarcely any inconvenience, while in others they give rise to the most extraordinary suffering. What is it that makes this difference? The patient suffers in those cases in which the excrecence comes down when the bowels act, and gets pinched by the sphincter muscles. Under these circumstances it is liable to become ulcerated, and then the pressure of the sphincter and always induces excessive pain, which continues not only till the excrecence recedes, but for some time afterwards. A lady sent to me, complaining of what she called very bad piles. On examining the rectum, I discovered a little polypous excrecence, in a state of ulcera-

tion, sticking in the sphincter muscle. I took hold of it with a pair of forceps, and snipped it off with the scissors. She felt hardly any inconvenience from the operation, but, to her surprise, though she had been enduring a great deal of pain, and had been miserable for months, from this moment she was well. A lady, not long since, came to my house, from a distance in the country, in whom most severe sufferings were occasioned by one of these polypi being ulcerated and entangled in the sphincter muscle. I immediately snipped it off; she was completely relieved; went home, I believe, on the same day, and I have no doubt has been quite well ever since.

Excreescences of the rectum sometimes take place, of a large size, which are not of a malignant nature, such as you see here [exhibiting a preparation]. This I removed from an old lady, 80 years of age. She sent to me, complaining of pain about the rectum, and hæmorrhage. I thought there were probably internal piles, and that it was not worth her while, at so advanced an age, to go through any operation, and I prescribed her some trifling medicine. She sent to me again, to say that she had lost a great deal of blood, and could not pass an evacuation from the rectum without the greatest difficulty. I introduced my finger and found a large excreescence, of which this specimen is only a portion. It seemed to be a matter of necessity that something should be done for the patient's relief: I therefore introduced my fingers into the rectum, gradually dilated the sphincter muscle, took hold of the excreescence, pulled it down, tied a ligature round its neck, and then snipped it off below the ligature. No harm followed the operation; the patient was perfectly relieved, and lived some two or three years afterwards. I believe the excreescence returned before death, but still she suffered no inconvenience from it.

These excreescences [presenting a fourth preparation] were, I believe, originally external piles, and they are not very uncommon. I mentioned in the last lecture, that when the cavities of external piles become obliterated, they generally form flaps of skin, which gradually waste; but sometimes diseased action takes place in them, and they become converted into excreescences similar to those which grow from the nymphæ of women. They are generally connected with dirty habits: the parts get irritated by the dirt, and so the piles become converted into these excreescences, into which they would not be converted in a more cleanly person.

SUPPOSED ANTIDOTE FOR ARSENIC.

M. BOULEY, junior, has presented a paper to the Académie de Médecine, containing an account of no less than eighteen experiments which he performed, in order to test the reputed efficacy of the hydrated protoxide of iron as an antidote for arsenic. The paper is to be published in the forthcoming fasciculus of the *Memoires* of the Academy. But it may be stated, that nothing can be more decisively negative than the evidence given on the subject by the author. The hydrated protoxide is of no more use as an antidote than so much charcoal powder.

EFFECTS OF KREOSOTE.

SEVERAL physicians of Munich have put to the test the antiseptic, desiccative, and styptic properties of this substance; and, if we may believe the journals, it has been used with the happiest effects in indolent, carcinomatous, and syphilitic ulcers, ring-worm, itch, and caries. It is usually employed externally, pure, or in a state of solution, prepared by diluting kreosote with eighty parts of water. To obtain a more concentrated water of kreosote, a gros (59·1 Troy) of this substance is dissolved in two ounces of alcohol, and a few drops of the solution added to the water, till it becomes opaque. It is highly useful in arresting caries of the teeth. Internally, it has been used in dysentery by Reichenbach, who is of opinion that the inhalation of the vapour would be advantageous in suppurations of the trachea and bronchial tubes. From the experiments of several physicians at Munich, it would appear that its action is only topical, and that it is not absorbed. In one experiment, the carotid artery of a dog was cut through, and the bleeding was stopped by pressing it with the finger. The blood did not flow, and the wound healed in a few days without a bandage. Is this credible?—*Edinburgh Medical and Surgical Journal*.

A SURGEON ASSASSINATED BY HIS PATIENT.

A VERY shocking occurrence of this kind happened on the 19th ult., at St. Antonin, in Guyenne. M. Prestat, of Caylux, had trephined a patient who a few days previously had suffered a severe fracture of the skull from a violent blow. Mania of

a masked character supervened; nobody had the least suspicion of it, much less the unfortunate victim, M. Prestat, who, on approaching the bed to dress his patient, received from him a deep and deadly wound in the abdomen. The fatal mischief was done with a knife which had been incautiously left within the reach of the patient, and secreted by him for the purpose. M. Prestat expired after lingering in much torture for eight hours. The wound measured six inches in length along the linea alba, and was inflicted from below upwards, beginning a little above the navel, involving more or less all the viscera in the upper part of the abdominal cavity.—*Gaz. des Hôpitaux*.

BARON DUPUYTREN'S POMATUM,

FOR PREVENTING THE FALL OF THE HAIR.

Of Tincture of Cantharides, 10 parts.
Hogslard, 90 parts.

To be well mingled together, and rubbed into the roots of the hair.—*Gaz. des Hôp.*

It should be observed, that the tincture of cantharides here prescribed is much stronger than that used in this country: it is made with one part of cantharides powder to eight of alcohol, carefully filtering the mixture after it has stood for some time.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

March 12, 1835.

Pelham Aldred, Stowmarket.
William Cass, Liverpool.
Esquire Dukes, London.
George John Marris Wilson, Greenhithe, Kent.
Joseph Charles Shelton, Bromyard.
Daniel Barker, Bransdale, Yorkshire.
Lewis Redwood, Boverton, Glamorganshire.

LITERARY INTELLIGENCE.

Mr. Swan is preparing for publication, *Illustrations of the Comparative Anatomy of the Nervous System*. The first fasciculus, containing eleven quarto plates, beautifully executed on steel, by Finden, will be ready about next Christmas.

NEW MEDICAL WORKS.

Outlines of Comparative Anatomy, by R. E. Grant, M.R. Part I. 8vo. 7s. sewed.
Chemical Attraction: an Essay. By G. L. Hume. 8vo. 5s. bds.
Practical Compendium of the Diseases

of the Skin. By J. Green, M.D. 8vo. 12s. boards.

Consumption; why so Fatal? By John Tyrrell. 8vo. 5s. bds.

Manual of Experiments illustrative of Chemical Science. By John Murray. 4th edit. 12mo. 5s. bds.

Treatise on Headaches. By G. H. Weatherhead, M.D. 12mo. 3s. 6d. cloth.

Human Physiology. By Dr. Elliotson. Part I.; containing General Physiology and the Organic Functions. 8vo. 10s. 6d. sewed.

LECTURE XXV.

DISEASES OF THE LARGE BLOOD-
VESSELS.

ANEURISM OF THE AORTA.

WE now arrive, gentlemen, at the consideration of one of the most important diseases which affect the animal economy; I mean aneurism of the aorta. Such is the admirable description of this affection given by Laennec, that I can do no better than follow it; exemplifying it, as I shall be enabled to do, by a series of preparations, illustrative of almost every point of the morbid anatomy of the disease, described by that great pathologist.

By aneurism, we mean the dilatation of an artery, or its communication by an opening, more or less large, with a sac formed by its external coat, and occasionally also by the organs immediately surrounding the diseased vessel. The first species is called *true aneurism*; the second, *false consecutive aneurism*. A combination of the two species often also exists—that is, a true aneurism may be surmounted by a false consecutive one.

True aneurism.

Morbid anatomy.—True aneurism of the aorta is not an uncommon disease, particularly in the ascending portion of the arch of that vessel. The disease commonly extends from the origin of the aorta to its

descending part: the centre of this space, often presenting the breadth of three or four fingers, is usually the most dilated. The convexity of the arch and the anterior part of the artery are generally more enlarged than its posterior parietes. When the dilatation occurs in the descending aorta, it forms an ovoid or fusiform tumor, and sometimes there are several of these tumors in the course of the same vessel. [Specimens shewn.] When the dilatation occurs at the space from whence the innominate arises, that vessel, and often also its primary branches, are similarly affected: the left subclavian artery, however extensive the aneurism may be, generally preserves its natural caliber. Occasionally, especially in old persons, the descending aorta, to its iliac divisions, becomes double its ordinary breadth; the ascending aorta and its arch are then also somewhat dilated.

Other arteries are subject to this species of simple dilatation: thus the carotid, at its emergence from its canal in the temporal bone, and the temporal artery to its minutest ramifications, have been seen in this state. Sometimes the arterial capillaries are also found enlarged, forming the principal part of erectile tumors: these have received various denominations—as *nævus*, *fungus hæmatodes*, *varicose tumors*, and aneurisms by *anastomosis*.

Slight dilatations of the aorta have rarely received the name of aneurisms, that expression being reserved for larger dilatations: yet the disease in both cases is the same, the difference being only in degree. The largest true aneurisms form at the ascending portion of the aorta and its arch: they have been seen of various sizes, up to that of the head of a full-grown foetus. When a true aneurism becomes large, a false consecutive aneurism often forms upon it, thereby augmenting its volume. [Specimens shewn.]

The internal membrane of the aorta is often affected in this disease; red points

and slight cracks are seen upon it, and numerous incrustations are often placed between the internal and fibrous coats: these cracks, or fissures, correspond with the edges of the incrustations, and the internal surface of the vessel becomes therefore rough and unequal. On examining the parietes of the artery by a transmitted light, it will be seen to shew various degrees of transparency, from the thinning of the fibrous coat produced at different points, in consequence of the action (probably mechanical) of the phosphate of lime upon it. In some cases these rough surfaces entangle portions of the blood, which then conerete; this matter accumulates, and occasionally forms a series of layers of fibrine, similar to those we shall describe as contained in the sacs of false aneurisms. [Specimens shewn.]

False consecutive aneurism

Is defined to be a tumor placed along the external surface of an artery, and communicating with it by an orifice of greater or less diameter.

The sac of a false is generally more unequal in thickness than that of a true aneurism. It is formed by the cellular coat of the artery, and is occasionally increased in its strength at different points, by cellular tissue, and by the organs around it. In other cases it is almost as thin as a sheet of paper. Its internal surface is very rough, but the orifice of communication is almost always smooth.

False aneurisms are formed most commonly in the descending aorta. When they are placed in the ascending part of that vessel, or its curve, they are generally superadded or attached to a true aneurism. The descending aorta, however, is rarely dilated at the point from which the false aneurism springs; it is often, indeed, contracted.

Causes of aneurisms.—The simple dilatation of an artery, or true aneurism, is no doubt formed by the impulsion of the blood against the parietes of the vessel, already weakened by disease, as by osseous or cartilagenous deposits; and we find that the dilatation is always greatest where the force of the impulsion is more particularly directed. Thus the ascending aorta and the anterior part of its arch are always most enlarged, whilst the posterior parietes of the arch rarely enter into the aneurismatic dilatation, in consequence of the greater resistance they afford to the impetus of the blood, from their being placed against the unyielding dorsal vertebrae.

Although the formation of a true aneurism can easily be explained in this manner, yet many opinions have been entertained as to the modes in which a false membrane originates. Thus some have

supposed, in consequence of the smoothness of the orifice of communication, that the internal membrane of the artery formed a hernia through a rupture of the fibrous coat of the vessel, and lined the whole of the aneurismal sac as it gradually extended and increased in volume; so that the sac was formed of the external cellular investment of the artery and of its internal tunie. Such was the opinion of MM. Dubois, Dupuytren, and many others: but it is impossible to trace the smooth internal membrane beyond a few lines within the sac, except the aneurism be very small—no larger than a nut, for instance. In all probability, as the aneurism enlarges, the internal membrane breaks at a short distance from the orifice of communication; the internal part of the sac then becomes rough and irregular. An aneurism supposed to be formed in this manner, was called *aneurisma herniosum*, *aneurisma herniam arteriae sistens*, or *mixed aneurism*.

Scarpa believed that no aneurism took place without the rupture of both the middle and internal tunics of the artery, and that the sac was formed of the cellular coat of the vessel alone. He went so far as to say that the true aneurism of authors had no existence—that the dilatation of the aorta near the heart could not be called an aneurism, and that that dilatation was never to be found in the remaining part of the course of the vessel. It is singular that the latter opinion should be held by so great a pathologist. You see before you, on the table, preparations of dilatations of the descending aorta and of the primitive iliaes—dilatations containing layers of fibrine as distinct as those we shall presently find existing so commonly in false aneurisms.

But that the opinion of Scarpa is correct, as to the mode in which false aneurisms originate, is most probable: that is, that it is caused by a rupture of the middle and internal coats of an artery, through which the blood insinuates, and gradually, by its accumulation, dilates the distensible cellular coat of the vessel so as to form a sac.

The rupture of these two coats may, though very rarely, be distinctly seen. M. Ambroise Laennec has detailed a singular instance of this state. The arch of the aorta was encircled with osseous deposits, and was also dilated to the volume of a moderate-sized apple. The descending aorta, at about two inches from its origin, presented a transversal slit through its internal and fibrous coat, occupying about two-thirds of the contour of its cylinder; the edges of this slit were thin, unequal, and torn; the cellular coat was healthy, but separated from the fibrous, from the

point of rupture to the primitive iliaes, so that the cavity of the artery was divided into two parts by an intermediate partition. This separation of the fibrous coat was not complete; it occupied about one-half or two-thirds of the surface of the vessel, and turned in some parts around its cylinder. The space between the separated fibrous and cellular coats was filled by clots of blood, or by fibrinous or poly-piform concretions. Mr. Guthrie has met with two cases analogous to this, and Mr. Hodgson mentions a similar instance.

I present you, gentlemen, with two beautiful specimens of this sudden rupture of the internal and fibrous coats of the aorta; for the one I am indebted to Dr. Langmore, of Finsbury-Square; for the other, to Mr. Bennett, of the Commercial Road. The first occurred in a woman, who, during a slow convalescence from typhus fever, became from some cause suddenly alarmed; she instantly fell into a state of syncope, from which she shortly rallied, but died in about twenty hours after.

On examining the aorta, you perceive that at about an inch from its origin, its internal and middle coats, to nearly one-half of the circumference of the vessel, are ruptured transversely, the edges of the torn membranes being thin and unequal; the blood passed through the rupture, and completely separated the cellular from the fibrous tunic, and formed a continuous clot between them; the clot, you see, is preserved, and forms a fourth coat completely round the vessel. The artery must have remained in this state for many hours; at last, the blood, by continually distending the cellular coat, ruptured it also nearer to the origin of the aorta, so that that fluid poured into the pericardium, filled it, and prevented the further movements of the heart. The second specimen was from a man who suddenly fell in the street in a state of syncope; he recovered for a short time, but died five hours afterwards. The pericardium was found filled with blood, and the same rupture was found as in the preceding case; it was, however, not in a transversal direction, but extremely irregular, and the bursting into the pericardium was by a number of small orifices. You observe also in both these preparations the internal surfaces of the aorta are diseased, in consequence of cartilaginous deposits between their internal and fibrous coats.

In these cases the ruptures were too large, and the effusion of blood too sudden, to dilate the cellular coat into an aneurismal sac; but solutions of continuity are effected slowly in the internal membrane from the artery, either by small pustules,

slight ulcerations, and above all, by the partial separations of osseous or cartilaginous incrustations from the fibrous coat. These separations form cracks on the internal surface of the vessel; small coagula are lodged within them, by which the fibrous membrane becomes still more diseased, and finally perforated; the coagula increase, gradually press upon the cellular coat, and distend it; the pressure of the circulating blood increases that distension; the cellular coat still farther enlarges, and finally, though very slowly, forms a sac, the original diseased part of the vessel being the point at which the orifice of communication ultimately forms.

This is the mode in which the false consecutive aneurism is commonly formed, although it is probable that when the sac is very small, and its internal surface is smooth, the internal membrane may have perforated the fibrous coat, distended with and lined its cavity.

Concretions of blood in aneurismal sacs.—In all false, consecutive, and in many true aneurisms, the internal parietes of the aneurismal sac are lined by a series of layers of coagulated blood, evidently deposited at successive periods, and presenting different appearances, according to the date of their formation; thus, those which are nearest to the orifice of communication with the artery are formed of blood more or less coagulated; a little farther, the clots are drier, and mixed with a large proportion of fibrin; deeper still, the layers are of a purer fibrine; they are then white or yellowish, firmer, less humid, and more opaque; below these, layers of a similar colour are often found, which have a certain degree of brittleness, are of the consistence of dried paste, and may easily be broken down by the fingers; the last described layers are in contact with and adhere to the parietes of the sac. Sometimes they are softened to the consistence of "bouillie," and they are formed of fibrine, more or less advanced into a state of decomposition.

These are the characters of the fibrinous layers usually found in false consecutive aneurisms [showing them], but there are also occasionally found others, which, when cut in fine slices, are semi-transparent; they are of a greyish-brown colour, having whitish veins ramifying within them. This substance is like horn softened by heat; it is very compact, easily cut, and leaves no moisture upon the scalpel; its thickness is frequently very considerable, especially in large aneurisms.

The blood often insinuates itself between these fibrinous layers, and separates them from each other, so that fresh coagula are frequently found between deposits of older formation. The blood often also

separates the external layers from the parietes of the sac, penetrates it at its weakest point, and occasionally destroys life in a moment by the quantity that is poured out.

These layers are generally numerous, in proportion to the size of the sac. False consecutive aneurisms are usually entirely filled by them, but that nearest to the opening into the artery often consists of a mere clot of blood, probably formed after death. In moderate dilatations of the aorta these concretions are rare, their formation being prevented by the rapid current of blood passing through the vessel. I have occasionally, however, seen the aneurismal dilatation so nearly filled with coagulated layers of blood, that the passage of that fluid was considerably obstructed. You perceive, gentlemen, that that was the case in this preparation, in which there is a true aneurism of the descending aorta, and one smaller one in each of the primitive iliaes.

The effects of aneurisms upon the surrounding organs.—When the aorta is simply dilated, it rarely produces any serious effects upon the surrounding organs, except the dilatation be very considerable; but the smallest false consecutive aneurism, or even a true one, in which the dilatation is confined to one side of the vessel, forming a projecting tumor, may occasion the most serious consequences.

The effects of the aneurismal tumor, as it increases in volume, are to compress the organs in contact with it. When the tumor is very large, or when, by its position, it becomes a cause of very considerable pressure, it often changes the position of the surrounding parts, which then apply themselves to it so as to form its external parietes. Thus, in an aneurism placed at the extremity of the thoracic portion of the aorta, or at the origin of the celiacartery, the distended and flattened pillars of the diaphragm cover the lateral and even the anterior part of the tumor; the vessels, nerves, and cellular tissue, spread over the sac, as well also as the pleura or peritoneum.

The next effect of the compression of the aneurismal swelling is to attack the structure of the organ with which it may be placed in contact; thus, it may alter and destroy a portion of the pulmonary tissue, so that the aneurism may burst into the air vesicles. [A specimen of this ruptureshewn.]

Aneurisms of the ascending aorta, or of its arch, often compress the trachea, or one of the bronchial tubes, and flatten them; the cartilaginous rings of these vessels become finally destroyed, and aneurisms, by bursting into them, cause a fatal hæmoptysis. [Specimens of these accidents were shown.]

The œsophagus has been similarly compressed and perforated, producing a fatal vomiting of blood. [Specimen.]

The heart may alter its position, if the aneurism be large; thus, if the disease be situated above it, that organ is pushed downwards; if below it, upwards; or it may be forced to the right or to the left, according to the position of the compressing cause. Aneurisms have been seen to burst into the pericardium; but these cases are rare.

I present you with a rare specimen of aneurism of the ascending aorta, destroying the coats of the pulmonary artery, into which vessel it ultimately burst.

When an aneurismal sac ruptures into the pleuritic cavity, it is generally into that of the left side; it is very rare to find it open into the right.

Aneurisms have been seen to compress the thoracic duct, and occasion engorgement of the lacteals. Corvisart saw an aneurism of the ascending aorta compress the superior cava, so as to prevent the free return of blood from the head. The patient died in a sub-apoplectic state.

Aneurisms produce the most singular effects upon the bones,—they seem to destroy them as if by attrition; thus the false consecutive aneurisms of the aorta destroy the bodies of the dorsal vertebræ, leaving the intervertebral cartilages intact, and forming incomplete partitions traversing the back part of the aneurismal sac. It is needless to state, that the posterior portion of the sac has in this case been previously destroyed. True aneurisms have also occasionally produced the same effects upon the bones.

Aneurisms of the abdominal aorta rarely destroy the bodies of the lumbar vertebræ, probably because of the greater freedom with which the sac can develop anteriorly.

True or false consecutive aneurisms often also corrode the sternum, perforate it, and form tumors, projecting beyond the surface of the chest. These tumors sometimes acquire a volume equal to that of the head of a full-grown fœtus, as you observe in these casts and preparations [shewing them.]

Aneurisms of the arch of the aorta, or the innominata, sometimes project above the sternum, or force their way under the cartilages of the ribs on the right side. The bones in these cases are destroyed, although their cartilages are scarcely at all affected. [Preparations.]

It is singular that it is not the largest aneurisms which thus destroy the sternum and form external tumors. Sometimes those of the size of an egg will produce this effect, and very large ones remain hidden in the cavity of the chest, although the anterior face of their sacs be closely

compressed against the posterior surface of the sternum.

General signs of aneurism of the aorta.—Perhaps there is no certain sign of thoracic aneurism except the pulsating tumor which it occasionally forms when it penetrates through the parietes of the chest. The signs of this disease are generally derivable from the effects it produces upon other organs by compressing them. Sometimes the very first evidence we have of the disease is a fatal hemorrhage from its rupture. The general signs I am about to detail may be considered as equivocal.

There is not infrequently a difference in the state of the pulse in the radial arteries; this takes place when the aneurism compresses the left subclavian artery or the innominate, or when coagula fill the opening of either vessel, or when the tumor, by its pressure, changes the angle at which these vessels arise, and renders it more acute. When an aneurism compresses the trachea, a peculiar sibilating sound is heard, and the larynx and trachea are felt by the patient to be drawn downwards; there is also a sense of oppression and dyspnoea, which, however, diminishes when the tumor projects outwardly. Occasionally, also, when an aneurism of the descending thoracic aorta is destroying the bodies of the dorsal vertebræ, a sensation of terebration is produced in the back, as if a gimlet were perforating the bones.

All these symptoms form, however, but doubtful signs; for inequality of the force of the two radial arteries is frequent in many healthy persons; and the difference of the rhythm in these vessels might depend upon obstructions caused by clots of blood in the origin of the subclavians, as well as from an aneurism. The signs from compression may be derived from a variety of other causes; even the terebrating pains may be mistaken for rheumatic or neuralgic sensations. Laennec has seen the pulsating tumor itself confounded with an elongated cerebriform swelling, which, after destroying the first bone of the sternum, projected through it.

Local signs.—The most certain stethoscopic sign we possess of this disease is that of the strong pulsation of the aneurism, a pulsation which is isochronous with that of the ventricular contraction, but stronger than it. This impulsion is frequently coincident with the *bruit de soufflet*, and the *frémissement cataire*. The sound on percussion is dull also over that part of the chest which corresponds to the situation of the aneurism.

Laennec lays much stress upon the aneurismatic pulsation being simple; by which he means that it is not accompanied by the second sound, as in the beatings of the heart; but it has occurred to

me frequently to meet with the second sound in aneurisms of the ascending aorta and its arch, although not so loudly as at the heart itself. No doubt this arises from the noise caused by the ventricular dilatation being communicated through the sac, which is often placed, and reposes, upon the heart itself. I have never heard the second sound in aneurisms of the abdominal aorta.

Laennec has stated, that when the ascending aorta, or its arch, are dilated, a pulsation is felt isochronous with the beatings of the pulse, and stronger than that of the heart, beneath the sternum, or below the right clavicle. Dr. Hope observes, that then there is a constant pulsation above both clavicles, at their sternal extremities, which is stronger on the right side if the ascending aorta be the seat of dilatation; and that this impulse is never communicated to the sternum except the aneurism be very large. He states also, that there is a hoarse and short bellows-sound above the clavicles, if the dilatation be confined to the ascending aorta, and that it is also hissing and superficial upon the sternum; and that, finally, the harshness of the "bruit" is always proportionate to the roughness of the osseous inequalities formed upon the inner surface of the aorta.

Dr. Hope describes the signs of a false consecutive aneurism of the ascending aorta and its arch to consist in a pulsation both above and below the clavicles, but that it is the least impulsive in the latter situation. If the ascending aorta be the seat of the disease, these pulsations are most distinct on the right side of the sternum; if the arch, or the beginning of the descending aorta, they are felt to the left side of that bone, and even on the shoulders and back. The sounds are not so loud as when the vessel is dilated. In large aneurisms the noise produced by the pulsations is dull and remote, and sometimes louder on the side of the neck opposed to the tumor than on that on which the tumor is situated. It is often loudest on the back; and when the disease affects the descending thoracic aorta, it is generally more evident posteriorly than anteriorly. If a strong rasping sound be heard also on the back, the disease may be considered as almost certainly present. The "frémissement cataire" is occasionally felt above the clavicles, but never below, except the ribs are perforated by the tumor. When the aneurism is large this sign often disappears. Dr. Hope has, with great discrimination, described the circumstances which render these signs fallacious, and the means by which these fallacies may be detected.

Thus, tumors in the anterior medias-

tinum may give the aneurismal impulse, but not the sound. Hydro-pericarditis may also occasion impulsion, but the shocks vary in force, and are not exactly synchronous with the beatings of the heart. The heaving movements of an aneurism are always felt in the same place; that from fluid in the pericardium constantly varies. Hypertrophy and dilatation of the heart may be confounded with aneurism; but in the latter disease there are evidently two points from which the impulsions proceed—the one from the aneurism, the other from the heart; in the former affection there is but one—the heart itself. The heart, also, when in a state of hypertrophy and dilatation, produces a loud noise upon its contraction, but an aneurism a dull sound, like that of concentric hypertrophy. Enlarged glands situated above the clavicles may also cause impulsion, and simulate aneurism, but it is rarely accompanied by sound.

Aneurisms of the abdominal aorta are usually distinguishable by the stethoscope. The impulse is then often enormous, always simple, and isochronous with the contractions of the ventricles. The noise accompanying these beatings is clear, sonorous, and often combined with the "*bruit de râpe*." Tumors lying upon the aorta frequently receive an impulse from the pulsations of that vessel, but then it is always infinitely less than in aneurisms. The aorta sometimes beats violently under the influence of nervous causes; but in these cases the pulsations are never permanent; and upon pressing the aorta with the stethoscope, they are found not to extend beyond the natural diameter of that vessel.

Treatment of aneurisms.—Corvisart attributed the occasional formation of aneurisms to certain tumors attached to the arteries, of the following characters:—Speaking of one of them, he states, "That this tumor was formed of a fibrous cyst, whose parietes were about two lines thick; that it inclosed a substance of a less consistence than suet, and of a deep red colour, similar to clots of blood which had long formed, and adhere to aneurismal sacs. The external coats of the aorta were destroyed at the point corresponding to the cavity of the cyst; and the thickness of the parietes of the vessel was, in that part only, infinitely less than at any other point. Although he believed, from the colour of the matter contained in the cyst, that it communicated with the cavity of the aorta, yet he could perceive no orifice of communication; he saw only a slight gray or livid stain, corresponding to the base of the cyst." He had observed two or three tumors bearing these appearances.

From these facts Corvisart inferred, that

if the patient had lived a sufficient time, these tumors would ultimately have so destroyed the coats of the artery, that the blood could have freely passed into the cavity of the cyst, which then would be transformed into an aneurismal sac, which would gradually become larger as the blood dilated its cavity.

Mr. Hodgson has, however, attributed the formation of these tumors to a very different cause. An aneurism of the extremities is occasionally spontaneously cured by coagula completely filling its sac, and obliterating also the canal of the artery communicating with it up to the collateral vessel nearest to the aneurism, after which these clots become converted into a fibrous tissue, which, with the vessel and the aneurismal sac containing them, gradually diminish in volume by the process of absorption. Mr. Hodgson believes, and his opinion is now generally received, that the tumors thus described by Corvisart are the remains of false consecutive aneurisms, spontaneously cured by a similar process.

Our indications of cure, then, should be to occasion the complete coagulation of the blood contained in the sac, so as to prevent any more of that fluid from passing into it. We should therefore diminish the quantity of the blood, and the force by which it is circulated. These effects can sometimes be produced by the method proposed by Albertini and Valsalva; a method I have described in speaking of the treatment of hypertrophy, and hypertrophy with dilatation of the heart, to which subjects I refer you. The acetate of lead has also been recommended. I have used it, but cannot say with much good effect. The coagulation of the blood in the aneurism may also be attempted by the application of ice upon the tumor. I think it often retards its increase; but it unfortunately happens, that, when the disease has arrived at the state to form an external swelling, little can be effected by any remedy.

If the morbid anatomy of this disease has been well understood, I need hardly state that the cure of aneurisms caused by simple dilatations of the arteries can never be effected, inasmuch as the current of the blood passing through them must tend to prevent the formation of coagula. It is true that they occasionally, although very rarely, do form; but it is scarcely possible that they can remain in such a state of repose as is necessary for their organization and permanent attachment to the parietes of the aorta, by which the natural caliber of that vessel can be restored. It is only in false aneurisms, where the sac is placed external to the artery, that such a cure can be hoped; for then the blood in the

sac is thrown out of the general circulation; it has time, therefore, to coagulate and become organized; and the whole may ultimately be considerably, if not completely, absorbed, without affecting the flow of blood through the artery itself.

DISEASES OF THE PULMONARY ARTERY AND VEINS, AND OF THE CORONARY VESSELS.

Pulmonary artery.—Diseases of this vessel are of rare occurrence; they consist of malconformations, of which I shall hereafter speak—of osseous incrustations, and of dilatation of the parietes of the vessel.

Ossific deposits are very seldom found in the parietes of the pulmonary artery; but dilatations of this vessel are not uncommon in persons subject to chronic diseases of the lungs. The artery has been seen at its origin of the breadth of three fingers. Ambrose Pare describes a case in which it was dilated to the size of the fist. The vessel in the latter case was also incrustated with ossific matter. No well recorded instance of false consecutive aneurism of the pulmonary artery is known.

Dr. Hope describes the signs of a case of dilatation of the pulmonary artery, which occurred to him, to have been as follow:—Pulsation, with fremissement caïre, between the cartilages of the second and third ribs on the left side, decreasing downwards, and not appreciable above the clavicles. This was accompanied by a loud, superficial, harsh, and sawing sound, which was heard above the clavicles, and upon the precordial region; the sound was loudest upon a prominence found between the second and third ribs. This state of the artery was combined with hypertrophy and dilatation of the heart.

Pulmonary veins.—Chaussier describes the case of a young woman in whom the left auricle was largely dilated, in consequence of obstruction of the mitral valve. The pulmonary veins were greatly enlarged; and one of those from the left lung was ruptured to three-quarters of an inch of its extent, at its emergence from the lung.

Affections of the coronary vessels.—The coronary arteries occasionally are observed ossified, and sometimes so completely, as to obliterate them at several points.

In hypertrophy and dilatation of the heart, these vessels are often dilated in the whole of their extent.

The coronary veins occasionally dilate; their distention is not unequal, like that of varicose veins of the limbs, so as to form a knotted appearance, but their bendings are considerably increased, so that their length is really augmented, as well as their diameters. The veins are commonly found in this state when the heart is hypertrophied and dilated.

OBSERVATIONS ON RENAL DROPSY;

Illustrated by Cases, and a Dissection.

To the Editor of the Medical Gazette.

SIR,

I BEG leave to transmit, for your perusal, a paper on the subject of "Renal Dropsy, illustrated by Cases and a Dissection," which I had the honour of reading before the Senior Physical Society, Guy's Hospital, on Saturday, February 7th. A request at the close of the meeting, that I would make it public through the medium of some widely circulated journal, and several subsequent similar requests from private friends, have induced me to forward it to you. Should you, therefore, sir, consider the subject matter sufficiently interesting and important, as attempting to illustrate a formidable form of disease only lately established, and still doubted by many, I have to request the insertion of it in some early numbers of your valuable journal, in such portions as may be most convenient. As the paper was not originally intended for publication, I have taken the opportunity of inserting in it some new matter, and of correcting and revising what had been previously written. I have also thought it right to subjoin an account of fifty of the patients whose urine was examined, as partly corroborative of any assertions that may have been brought forward. References to the works of the different authors quoted, are also inserted.

I remain, sir,

Your obedient servant,

JOHN ANDERSON,
Late Clinical Clerk, Guy's.

George-Street, Richmond,
March 14, 1835.

The subject of dropsy is one of considerable interest and importance. It is the consequence of disturbed balance between exhalation and absorption, and arises from so many and various causes, and is accompanied by, or dependent on, such extensive functional and organic derangement, as to render its presence an object of great anxiety to the physician, and its pathology, origin, and treatment, matter of considerable importance to which to direct his attention. In its different forms of acute and chro-

nic, idiopathic and secondary, it is of frequent occurrence, and is generally attended with danger; though this will, of course, vary with the extent, situation, and perhaps more particularly the cause of the effusion and its combination with organic disease. The acute and idiopathic forms are the most under our control, though, in the former, connecting circumstances will materially influence our judgment. Thus, then, the prognosis is for the most part unfavourable, and more especially as there exists, in many persons, a true hydropic diathesis, and this occurring generally in those whose constitution is weakened by disease, or debilitated and broken down by intemperate habits.

It is scarcely necessary to observe, that dropsy takes place in two very opposite states of the circulatory system and constitution generally, and in each state depends on various causes. We find it occurring as the result of debility simply, or of mechanical pressure, or of some thoracic or abdominal disease; and accompanied by relaxation of the whole system, and a want of power in the exhalant vessels. Very frequently, however, it occurs in a totally opposite state, and, instead of debility and relaxation, we have increased vascular action going on, and an active inflammatory condition of the system, attended, though not necessarily, by fever: this form has been called acute inflammatory or arterial dropsy. Thus, then, we arrive at two grand divisions of dropsy, according to the sthenic or asthenic state of the system in which it occurs: this will be found nearly analogous to Dr. Blackall's two divisions of dropsies according as the urine is or is not coagulable. The state of the urine in dropsy generally should always be regarded; in the latter form, though depositing nothing by heat, it presents certain appearances to which it is important and necessary to attend. In some cases it will be found clear, of a light colour, and copious in quantity; in others, diminished in quantity, but healthy in appearance; in others again (especially, I have observed, where there has been more or less disease of the heart), it is natural in quantity, but grows turbid on cooling, and deposits a copious light-coloured sediment, which is dissolved by heat. Lastly, the urine will be found scanty, and depositing a copious sediment more or less lateritious: this I

have generally observed when diseased liver has been the cause of the effusion.

The acute or inflammatory dropsy is frequently attended by the presence of albumen in the urine; a circumstance first noticed, and commented on nearly twenty years ago, by Dr. Blackall, and still more recently by our talented physician, Dr. Bright, who has made this a subject of deep investigation, and whose labours and conclusions have rendered it an object of the greatest interest and importance to the inquiring physician. This latter gentleman has collected together an immense number of cases, and has detailed their history, symptoms, and morbid appearances, with extreme minuteness, and to him belongs the merit of having first pointed out organic structural changes in the kidney, as referable to the existence of anasarca; and then again connecting this with the presence of albumen in the urine. No argument or theory is adduced but what is substantiated by what must be considered as facts in medicine—viz. reports of cases*; and no plan of treatment is followed, or proposed, but what pathology would justly indicate; and before these theories can be overturned, or these connexions and relations disproved, an equal mass of evidence must be brought into the scale, and pathology must be as intimately connected with an opposite train of reasoning, as in the cases just alluded to. I am quite certain, that if this subject were not treated so superficially by many, its importance would be more evident; and from experiments, I am sure that the continued appearance of albumen in the urine, unconnected with dropsical effusion, is by no means so constant an occurrence as is usually supposed, but that connected with anasarca it very frequently takes place, and that when present it should always be an object of great anxiety, as indicative of extreme mischief and danger. It is this form of dropsy (to which Dr. Bright has suggested the name of renal) that I have ventured to select for the present discussion, illustrating it as far as possible by cases that have recently occurred in this hospital, and more particularly by one that proved fatal, and which we had an opportunity of investigating after death.

* Vide Reports of Medical Cases, by Dr. Bright, vol. i.; also a critique on the third volume, in the Med. Gazette for May 19, 1832, p. 229, col. 1.

Dropsical effusion, connected with albuminous urine, is induced by several causes, which predispose the kidney to suffer.

1st. Searlatina.—In this case, the skin, from the previous eruption, is rendered very susceptible of cold, and its secreting function very much impaired; the kidneys sympathize, become functionally deranged, and serous effusion is the consequence. The urine will, in most cases, be found to be coagulable. Dr. Blackall relates about ten cases, illustrative of this, in five of which there was a bloody sediment in the urine. Dr. Hughes has found the urine albuminous in about twelve cases. Dr. Addison has frequently found it so, and further observes, that whenever this is the case, we may prognosticate anasarca*. This anasarca is truly of an inflammatory nature, generally coming on suddenly, and when early and properly treated does well. Antiphlogistic remedies are to be employed, and great reliance (according to Dr. Blackall) is to be placed on digitalis, the efficacy of which is fully shown in the treatment of the above-mentioned cases; these are related at full length in his valuable treatise†. Dr. Wells also has given much valuable information on the nature and cure of this form of dropsical effusion‡. Dr. Bright also observes, that “it is almost always accompanied by an obvious derangement of the kidneys, that the urine is frequently coagulable, and that there is more or less tendency to hæmaturia§.”

2dly. Abuse of mercury.—As to whether mercury has the power of producing a coagulum in the urine, and the propriety of its employment in renal cases,—on this I will observe hereafter, and shall merely now state that the anasarca arising from this cause is of a true inflammatory nature, and may come on either suddenly or gradually; the former being the most favourable. Antiphlogistic remedies are here requisite, and an immediate discontinuance of the mercury, supposing the patient to be undergoing a course of it. In furtherance of this I may notice the case of a man now

in Lazarus Ward, who had always enjoyed good health until attacked with syphilis some months ago, and took a considerable quantity of mercury; before this time he never observed any swelling, but, shortly afterwards, his legs became anasarcous, and his urine very decidedly coagulable. Dr. Blackall also relates nine cases illustrative of this form of inflammatory anasarca, treated principally by antiphlogistic means.

3dly. Several other remote causes are given by Dr. Blackall, as gout, the improper exhibition of bark and steel, topical injuries and inflammations (a rare cause), unsoundness of the digestive organs, which impairs the nourishment of the body and vitiates the blood; drinking too freely of cold liquors when heated (two cases illustrative of which are recorded by Dr. Blackall, which recovered under the use of bleeding and antiphlogistic remedies). The last causes to which I shall advert are those of most frequent occurrence; they were those, I may mention, that prevailed in the case to which I wish more particularly to call the attention of the Society;—I mean the exposure to cold and wet, and the free use of spirituous liquors, which some physicians have considered as capable of exciting a true dropsy; and certain it is that most of the renal cases which have occurred at this hospital lately are referable to these two causes, either separately or in combination: out of seventeen cases, sixteen were evidently thus produced. The sedative effects of cold and consequent deranged function of the skin, and the debility of constitution and irritation, induced by spirit-drinking, through the medium of the stomach, are well known. These causes predispose the kidney to suffer: this irritable organ sympathizing with the skin, a change in the renal secretion takes place, and, owing to checked perspiration, a vicarious discharge in the kidneys is produced: they become functionally deranged, and albumen appears in the urine; deranged function leads to disorganization; serum is effused first in the cellular membrane of the face, feet, and ankles; then gradually extending upwards to the thighs and abdomen; and the aching pain in the loins, the severe throbbing and lancinating pain in the head, and apoplectic tendency; the hard pulse, dry unperspirable skin, and albuminous, dingy,

§ Vide Gulstonian Lectures, 1833, delivered by Dr. Bright; published in Med. Gazette, June 22, 1833.

and sometimes bloody urine, fully characterize and establish a true and exquisite case of renal anasarca.

I shall now proceed to detail the case just alluded to; it will be found to bear upon the description and symptoms just enumerated, and its sudden and fatal termination will shew how formidable a disease we have to combat with, and how, as yet, ineffectual are our remedies.

Frederick Crown, ætatis 47, a stout well-formed man, of leucophlegmatic appearance, was admitted into Luke's ward, December 3, 1834, under the care of Dr. Bright. He stated that he had been ill six months, and had been subject for several years to rheumatism, to an attack of which he dated the present illness. For the last four months he had suffered from anasarca, which first appearing in the face and ankles, gradually extended itself over various parts of the body. He was a man of very dissolute and intemperate habits, drinking freely of spirits, and exposing himself to many and varied changes of temperature. At the time of his admission the most prominent symptoms and appearances were as follows:—Countenance pale and sallow; eyes of a dull pearly lustre, and eye-lids bloated and œdematous; lower extremities anasarcaous, and pitting on pressure; thighs œdematous, and hard on the inner side; cellular membrane of the scrotum and abdomen infiltrated and distended with serum; percussion gives no sense of fluctuation. Lancinating pain in the head, increased at night; oppression at the epigastrium, and pain in the region of the kidney, palpitation and dyspnoea following the least exertion. The action of the heart is labouring, and somewhat indistinct; rhythm tolerably healthy, and its beat diffused; pulse 104, with considerable jerk, regular; tongue dry, and skin unperspirable; bowels freely open; urine of a pale straw colour, acid, coagulable by heat and nitric acid, specific gravity 1.015; gouty and rheumatic pains (principally in the hands and wrists) very much complained of.

R Vin. Ant. ℥xx. ex Jul. Ammoniacæ Acetatis, ʒj. sextâ quâque horâ.

R Pil. Scillæ c. Hyd. gr. x. omni nocte.

December 4th.—Pains very much increased; pulse 100, with some jerk.

Mittatur sanguis e brachio ad ʒxij. Applicetur Cataplasma lini lumbis bis

in die. Omittantur Pilulæ. Pergat Mistura.

5th.—Blood drawn slightly buffed; pain in the loins relieved; that in the head increased; bowels rather confined.

C. C. nuchæ ad ʒx. R Ol. Ricini, ʒvj. statim.

6th.—Going on more favourably; symptomatic pains better; gout and rheumatism troublesome; urine rendered only opalescent by heat; very coagulable, however, by nitric acid.

Pergat.

11th.—Pains in head and loins much increased; dyspnoea very severe; skin dry; pulse quick and hard, with some jerk; urine about natural in quantity, acid, and very coagulable before boiling. Mr. Stocker saw him, and ordered the following:—

R Pil. Camb. Comp. c. Cal. aa. gr. iij. statim. C. C. lateri dextro ad ʒxii.

12th.—Pains rather relieved; skin dry; pulse incompressible; rheumatic pains more severe. Dr. Bright ordered the following:—

R Tr. Camp. Comp. ʒss. c. Vin. Colchici, ℥xx. et Liq. Ammon. Acet. ʒss. ex Mist. Camph. ʒj. ter die.

R Hyd. Submur. gr. j. sextâ quâque horâ. Admov. Emp. Cantharidis sterno.

15th.—Pain in loins increased; dyspnoea great; tongue dry; skin hot; pulse strong; urine very coagulable, but rather diminished in quantity; bowels rather confined; feels nauseated from the medicine.

R Mist. Magn. c. Mag. Sulph. ʒiss. pro re nata sum.

R Sp. Æth. Nit. ʒss. c. Liq. Ammon. Acet. ʒss. ex Mist. Camph. ʒj. ter die.

To this latter Mr. Stocker added on the following day—

Acet. Scillæ et Tr. Hyoseyami, aa. ʒss.

22d.—Has been a little improving up to the present time; but to-day the symptoms have recurred with their usual violence; great soreness of the loins complained of, and pain extending down the groin to the scrotum, with slight retraction of the testicle; also, a soreness and dryness in the throat, affecting deglutition, and causing a cough; these feelings probably owing to œdema of the glottis. Right hand puffy and œdematous; great thirst and heat of skin;

tongue dry; pulse quick and incompressible; bowels regular; urine of the same appearance, acid, and coagulable.

Pergat.

27th.—Œdema of upper extremities, and particularly of the right hand, very much increased; pain in the throat, and difficulty of deglutition, very severe.

Admov. Emp. Cantharidis gutturi.

R Pil. Scillæ Comp. gr. v. ter die.

R Liq. Ammon. Acet. ℥ss. ex Mist. Camph. ℥j. ter die.

30th.—Cough very troublesome; expectorates some viscid mucus stained with blood; throat very sore; œdema of right hand increased; urine in good quantity, and very coagulable.

Pergat.

Jan. 5th, 1835.—Pain in the head has continued very severe; breathing rather easier; skin dry; tongue coated; pulse quick; slight difficulty in passing his urine, which is of the same character and appearance.

R Mag. Sulph. ℥ss. c. Vin. Ipecac. ℥vj. ex Inf. Gent. Co. et Inf. Rosæ Co. aa. 5vj. sexta quaque hora. Omittantur alia medicamenta.

He continued during the next week rather to improve, though the throat was very sore, and the urine very coagulable. A few days afterwards (the day preceding his death) he was observed by Dr. Bright to be better in his general health; but towards evening his manner of speaking seemed rather singular and unusual; his breathing became more oppressed during the night, and he would not answer when spoken to. These symptoms and appearances continued to increase during the next morning, when, about half-past 11 A.M., he suddenly went off into a kind of apoplectic fit; his breathing became stertorous, eyes protruded, and pupils contracted; he foamed at the mouth, had convulsive startings, and the face was of a yellowish tinge.

He was ordered to be cupped behind the ears, a blister to be applied to the shaved scalp, and one grain of calomel to be taken every four hours.

He rallied, but had four more attacks of the same character, and a last one at 3 o'clock, when I was with him. The pupils were then dilated; the breathing was stertorous, and at long intervals; the face and hands were bedewed with

a cold, clammy perspiration; and in a quarter of an hour he died.

An inspection took place twenty-two hours after death. For the following minute and interesting account of the post-mortem appearances I am indebted to Mr. Sibson:—

There was a general state of anasarca present all over the body, penis, scrotum, upper and lower extremities. On cutting into the cavity of the abdomen, which was exceedingly tumid and tense, upwards of a gallon of clear slightly yellow fluid escaped. Liver appeared to be remarkably healthy; gall-bladder nearly filled with dark greenish bile. Spleen small; numerous white opaque spots on its surface; substance healthy; Pancreas rather small; healthy. The small intestines were rather blanched on their surface; their appearance gave rise to the idea of their being invested with a false membrane, from which, however, they were quite free. The stomach: towards the cardiac extremity, and along the greater and lesser curvature, the mucous membrane was soft, and easily separated from the middle coat. The mucous membrane of the pyloric extremity, for two or three inches from the orifice, was hard and granular; the pylorus itself was nearly half an inch in thickness, dense and white in its structure. The duodenum, for two or three inches at its commencement, had its mucous membrane hard and minutely granular. The rest of the small and the large intestines appeared perfectly natural. The left kidney was of little more than half the usual size, slightly lobulated on the surface, and of a much firmer texture than natural. The investing cellular membrane adhered pretty firmly to the proper tunic, below which were seen eight or nine cysts about the size of a pea, but varying a little in magnitude, and filled with clear fluid. One cyst of the same size was opaque. The proper tunic was readily separated from the surface of the kidney, which was covered with minute white granulations, of the size of small pins' heads; they were clearly contrasted with the light brown colour of the cortical texture. There were one or two white spots, about half the size of a silver penny, near the entrance of the vessels. On cutting into the kidney, its substance was found to be hard, and similarly granulated to the surface in its cortical part. One or two white spots

were seen on the tubular substance; and the cortical part was exceedingly narrow, the tubular structure appearing to be of rather more than its natural dimension. The infundibula and pelvis presented nothing remarkable. The vessels of the right kidney were injected; the veins with blue, the arteries with red size. The veins presented numerous stellæ on the surface. The arterial injection shewed itself in numerous small packets in the cortical substance; but the whole of the tubular, and greater portion of the cortical, part remained uninjected. The right kidney was similar in every respect to the left. The bladder was filled with urine.—Thorax: the cavity of the pericardium contained about half a pint of pretty clear, straw-coloured serum. The pericardium itself presented nothing remarkable. Heart: the cavity of the left ventricle was about four times its usual size; it was firmly contracted, and presented very great hypertrophy, the walls being about three-fourths of an inch in thickness. The mitral valve and semilunar valves of the aorta were quite healthy. The calibre of the aorta was nearly double its usual size. The right ventricle was considerably dilated, and its walls were thinner than natural. The right lung was free of pleuritic adhesions; it was crepitant throughout, and natural. The left lung was considerably congested and œdematous, especially at the posterior part; it was crepitant throughout. The pleura pulmonalis, on the left side, was universally adherent to the pleura costalis. The cavity of the pleura contained about a pint of straw-coloured fluid.—Head: There was very considerable sub-arachnoid effusion on the surface of both hemispheres. The base of the brain and the arachnoid presented small and slight opacities in numerous points. The pia mater was readily separated from the convolutions; and from their surface a thin pellicle of cineritious matter could be easily peeled off. The lateral ventricles were distended with about two ounces and a half of clear fluid. The carotids were at points opaque, and semi-cartilaginous.

On cutting into the knee-joints they were each found to contain about an ounce and a half of semi-opaque synovia, mixed with loose flakes of a white matter, having a gritty feel. The articular surfaces of the cartilages of the

femur, tibia, and patella, in both joints, were covered with a white gritty substance, and the synovial membrane had imbedded in it, at various points, masses of a calcareous concretion, the largest of which was about an inch in length, and half an inch in thickness. The cartilages were of nearly double their usual thickness, and much less firm in their texture than natural, and of a brownish colour. The elbow-joints had a similar secretion; but the surface of the shoulder-joints was quite smooth, as also the phalangeal articulation of the right great toe*.

A portion of the effused fluid from the different cavities was analysed by Dr. Barlow, who has been kind enough to favour me with an account of the process:—

“An aqueous extract was obtained from each of the fluids, and from this extract an alcoholic one was procured, absolute alcohol being used for the latter purpose: all the evaporations were conducted at a temperature not exceeding 200° F. Of each extract a syrup was made by the addition of a few drops of distilled water; and to each of these syrups were added a few drops of strong nitric acid. The syrup from the effused fluid of the brain, as also that of the abdomen, yielded within two hours a considerable crop of foliaceous pearly crystals, of an arborescent form. That from the pericardium, as also that from the pleura, yielded a very small crop of crystals, after a much longer time.”

Dr. Barlow has strong reasons for believing that these crystals were nitrate of urea.

The case just related, then, presents many particulars of practical interest and importance.

1st, The remote cause of his complaint—his imtemperate habits, and consequent exposure to changes of temperature; perhaps, also, his predisposition to gout. The manner in which these debilitating agents operate has been fully explained previously.

2dly, The most prominent attendant symptoms. Of these, perhaps the pains in the head and loins were the most universal. The affection of the head, certainly, was not particularly well marked in this case during its course; but it is generally of a very distressing

* Preparations of the injected kidney and diseased joints are carefully put up, and preserved in the museum of the hospital.

character, and is described as either a lancinating, darting, throbbing pain, occurring more commonly in the fore part of the head, or a feeling of constriction and tightness, as if an iron hoop were bound round very firmly; it comes on generally towards evening, and relaxes towards morning, going on in this way for some time, and then being absent for days together; it is the symptom usually most complained of, and certainly the one most distressing to the feelings of the patient. There are two patients now in the clinical wards who have just this character of pain; and I have seen it in them almost unbearable. Its acuteness is owing most probably to the inflammatory tendency of the body generally, and of the serous membranes in particular; perhaps also owing to the circulation of unhealthy blood. The pain in the loins was a well-marked symptom in this case; it was seated evidently in the kidney, and fully indicated the mischief going on there; whilst the post-mortem account corroborated it. He had cough, dyspnoea, and slight bronchial affection (frequent though not necessary attendants), for which the morbid state of the lungs and their adhesions fully accounted. He had palpitation; and the left ventricle of the heart was much hypertrophied. This morbid occurrence is of much interest and importance, and one to which I shall more particularly advert in the pathological remarks.

With regard to the dropsical effusions, there were both ascites and anasarca. The existence of fluid in the cavity of the abdomen gave no sense of fluctuation during life, from the thickened oedematous state of the abdominal parietes. This form of effusion, in connexion with albuminous urine, is not of frequent occurrence. From the observations of Drs. Wells, Christison, Gregory, and Bright*, anasarca, local or general, appears to be much more intimately connected with this morbid state of kidney and urine. In this case, the tendency to anasarca was very great, it being almost general.

Sometimes this affection is only very slight, and there are cases now in the hospital where it is confined to the ankles only (and these scarcely pitting on pressure), or to the face, giving it a

bloated, sallow, puffy appearance. This latter is a very characteristic sign, and will often detect the disease. With regard to the oedema of the face, this is sometimes very great, and particularly so early in the morning; the eyelids and cellular membrane, more especially in the direction and extent of the orbitales palpebrarum, are puffed, sometimes so as to completely obstruct vision. Imperfectness of vision also occurs from another mechanical cause, viz. effusion of serum between some of the membranes of the eye; but whether this is really the case, or whether the brain itself is in some way affected, is not, I believe, quite ascertained; perhaps both causes may operate,—though in favour of the latter I have observed, that when the tendency to head affection is greatest (independent of any oedema), and the paroxysms of pain before described are most violent, vision is decidedly most impaired; and also that the power of vision has improved simultaneously with the cessation of the paroxysms, though the oedema of the face and general anasarca may have remained the same; and this latter affection I have sometimes, though not always, seen less where the head affection was the greatest. Now, supposing these pains to depend partly on any inflammatory state of the membranes of the brain, may the greater effusion of serum in other and more distant parts modify, and to a certain extent lessen, this inflammatory action? And again, the cerebral paroxysms coming on worse at night, and the oedema of the face being greatest in the morning, may not this discharge of serum from the more superficial capillaries in some way relieve the congestion of the internal vessels?

Another prominent symptom in this case was the dry unperspirable skin, which is a frequent symptom in dropsy generally, perhaps more particularly so in the form now spoken of. It certainly must tend to keep up the irritation in the skin; and an attempt to restore the function of the skin must be considered an important point—its re-establishment a favourable sign. The pulse was generally quick and incompressible, indicating an inflammatory state of body, and fully justifying a strict antiphlogistic regimen. The gouty and rheumatic pains that were complained of were much more severe towards the termination of the case, and though always a

* See the *Cyclopædia of Practical Medicine*, article *Dropsy*, p. 641.

ground of complaint with him, were not an object of great attention, and could hardly be considered as having any thing to do with his dropsy, though now and then they do occur together, probably by the remote causes being so nearly allied. The urine was uniformly of a pale colour, and coagulable; and this leads me to make some remarks on the nature of albuminous urine in general. This kind of urine differs from all others in its property of coagulation to a greater or less extent by heat, by which we infer the presence of albumen, as no other proximate principle with which we are acquainted possesses this property. The coagulation varies in extent, probably in proportion to the severity of the disease; but this is by no means universally the case. Sometimes, on the application of a gentle heat, the urine becomes suddenly opalescent, and quickly curdles; at others, a thick scum forms at the top first, and remains there; and often a thick film passes suddenly through the heated liquid, and in a few seconds the whole becomes a tremulous milky mass. At an interval varying from a few seconds to two or three minutes, the whole of the albumen becomes precipitated, either in dense flakes or in curdled clots, and settles to the bottom of the tube. These phenomena sometimes do not take place until the urine arrives at the boiling point, and sometimes a little evaporation is necessary. When there is a less quantity of albumen present, the urine is rendered at first only opalescent by heat, and after a time brownish bran-like flocculi are precipitated; sometimes, however, not until the application of nitric acid, which immediately deposits them. Again, nitric acid will occasionally only increase the opalescence, and after some time a brownish coagulum becomes deposited. On what does this brown colour depend? Is it any re-action of nitric acid, or is it the colouring matter of the blood? for I have generally noticed a precipitate of this description to exist in urine more or less dingy, and not in that which is of a pale straw colour. It is always necessary to apply the test of nitric acid, as soon as the phosphates are precipitated by heat (according to Mr. Rees, from the decomposition of uræa and generation of ammonia), and present the same appearance as albumen, and the application of the acid will re-dis-

solve them; whereas, if it were albumen, the opalescence and precipitate would rather be increased. Again, nitric acid will sometimes give a precipitate that will be re-dissolved by heat; this probably arising from the presence of the lithates. It is therefore obvious, that to prove correctly the existence of albumen, neither the test of heat or nitric acid individually can be sufficient; but when applied conjointly, and the precipitate given by the one is not re-dissolved by the other, the evidence of albumen is pretty certain and correct. There are other tests*, but unimportant as regards the present subject, as I think, should the two former powerful agents fail, even though albumen be obtained by a more delicate test, the existence of much renal disease can scarcely be inferred. As far as I am at present aware, a lithate or phosphatic deposit, though occasionally happening, is by no means frequent, and has no connexion with the albuminous state of the urine. The colour of albuminous urine, and quantity passed, will be found to vary, being sometimes quite pale and straw-coloured, with no sediment, copious in quantity, and of a ropy, very slightly unctuous appearance; at others presenting all varieties of shade, from a simple dingy to a dark reddish brown, or completely bloody appearance, each shade of colour being with or without more or less bloody deposit; the most frequent kind, probably, is the pale. These different forms of coagulation and varieties of colour I have had repeated opportunities of observing in the several cases that have occurred during the present clinical session. It would be highly important to know if these different appearances can be associated with different stages or forms of diseased action; if from them we can infer the state of disease actually present in the kidney, and consequently the danger to be apprehended; and lastly, if they can be considered any guide to our practice, as pointing out an indication of cure, and regulating the activity of our treatment. If such were the case, probably much good might be effected in the way of remedies; but from what has been written on this subject, and from my own experience, I should fear that such were not so. I have certainly seen equally

* Bi-chloride of mercury and the acetic acid, with the ferro-prussiate of potass, are delicate tests of the presence of albumen.

bad and similar cases accompanied by totally opposite states of urine, both as regards its pale or dingy colour, its quantity, and the curdled, flaky, or flocculent nature, of the albuminous precipitate.

Resuming the remarks on coagulable urine in general: the specific gravity is said to be low. Dr. Bostock observes, that of 28 cases examined, the highest was 1.032, the lowest 1.006, the average 1.017. I have not myself seen it remarkably low: of 12 different cases, the highest was 1.020, the lowest 1.011, the average 1.018. It is said, that the lower the specific gravity, the more albumen there is; but this is not necessarily the case. Albuminous urine is almost always acid: out of 18 cases, 16 were acid; the other two were neutral. And when, in the course of renal disease, urine that has hitherto coagulated, and one particular day has not this property, will on that day generally be found to be alkaline or neutral. I have observed this to happen in three cases. This alkaline property, then, may be considered, perhaps, as a cause of the urine not coagulating; but whether is it that the re-agency of the tests is prevented, or that there really is no albumen present? Supposing the former to be the case, would the albumen be appreciable by test if the alkali were neutralized*? If so, nitric acid in excess would probably be the best test that could be employed; it would both neutralize the alkali and precipitate the albumen. Dr. Wells has considered a deficiency of salts in the urine a cause of its non-coagulation. Dropsical urine generally, and albuminous urine in particular, I have found by experiment to be less prone to decomposition than otherwise diseased or healthy urine; it also contains but little urea, and this Dr. Bostock considers may be a cause for the tardiness of putridity.

Blood drawn from patients labouring under this disease generally presents a true inflammatory character; it appears to be in some way or other vitiated; and the experiments of many distinguished chemists pretty nearly prove that it contains urea†; and moreover, that this latter substance always exists in the blood previous to its elimination from

thence by the kidneys and subsequent appearance in the urine*. From the serum of the blood drawn from a patient now in Lydia ward, Dr. Barlow obtained some crystals, which he has strong reasons for supposing to be nitrate of urea. I am aware it is a matter of great dispute as to whether it always exists; but as this subject has been repeatedly discussed in this theatre, and not yet settled, it would be as well if it were not resumed *this evening*, but rather allowed to give place to any remarks that may arise upon the pathology and the hitherto unsettled treatment of this formidable disease; not but that I allow the question is one of immense importance, and would, if settled, perhaps account for several singular phenomena that do now and then arise in the course of this complaint. It is impossible to doubt but that the circulation of unhealthy blood would greatly aggravate symptoms, and prove a source of much irritation to the system generally.

The presence of albumen in the urine is considered by some as of frequent occurrence, and very slight causes, it is supposed, will prove effectual in producing it; such as mere errors in diet, or excess of any kind. This may or may not be the case; and I am more inclined to believe that often the precipitate in such instances has not been fairly tested, and that it has not been albumen. With regard to the frequency of its occurrence, from the experiments of others, and from my own, I am inclined to think that albuminous urine, unconnected with dropsical effusion, but rarely occurs. These experiments I will relate more in detail. Dr. Barlow, Mr. Tweedie, and Mr. Rees, examined the urine of 296 patients, taken promiscuously, and found that 26 were coagulable by heat and nitric acid; of these 26, 11 had symptoms of anasarca, consequently 15 (very nearly 5 per cent.) had coagulable urine, and no dropsical effusion discoverable. My friend, Mr. Gorham (whose kind and zealous assistance I am happy to acknowledge), and myself tested the urine of 141 patients, taken promiscuously, by heat and nitric acid, and we found 18 to be positively albuminous†; of these, 17

* In one case where the alkaline state depended on the presence of ammonia, by continuing the heat for some time the albumen was precipitated in small flakes.

† Experiments of Drs. Christison, Gregory, Babington, &c.

* Experiments of Prévost and Dumas, Gmelin and Tiedemann.

† In all these cases, the precipitate given by one test was not re-dissolved by the other.

were labouring under different forms of dropsical effusion, one of whom was undergoing a mercurial course, the remaining one was in a state of confirmed phthisis, and the albuminous deposit were very trifling. Thus, then, out of 141 patients, one only had coagulable urine without every other concomitant symptom of renal disease*. I think these different experiments go far to prove that the presence of albumen in the urine, if not to be relied on as a test, can surely be considered as an indication and a guide to our practice.

PATHOLOGY.—On examination after death, in this disease, the kidney is very frequently found more in fault than any other organ†, and derangement, or disorganization, to a greater or less extent, is found to have taken place. Dr. Bright observes, “I have never yet examined the body of a patient dying with dropsy attended with coagulable urine, in whom some obvious derangement was not discovered in the kidneys‡.” Dr. Blackall gives an account of some dissections, in which the kidneys were found more or less in fault and altered in character. Dr. Darwall also notices certain morbid appearances and diseases in the kidney, attended by dropsical effusion§. When this disease has been but of short duration, the kidneys will be found congested or gorged with blood; but sometimes their colour and consistence are altered, being less firm than natural, and of a pale-yellow mottled appearance, both externally and internally;—again, they are found larger or softer than natural, and the texture of the cortical part becomes granulated with numerous white points, or specks of an opaque white matter, distributed throughout its substance, becoming more evident as the disease advances: this state of kidney with coagulable urine, may exist without any marked appearance of anasarca. Lastly, they are found rough and scabrous externally, of a lobulated contracted form, and of a semi-cartilaginous firmness: here generally the urine is highly coagulable. The state of kidney, in the case just read, appears to be referable to

the two latter forms. Besides these, the kidneys may be preternaturally soft, or firmer, with concrete-like deposits obstructing the uriniferous tubes, and the vessels of the tubular part assuming a waved direction: in these forms, the urine is only slightly or occasionally coagulable. The liver is generally found pretty healthy; it was so in this case: occasionally, though rarely, it is found congested, or of a spotted mottled appearance. The left ventricle of the heart has been occasionally found dilated and hypertrophied; and in the case related, this morbid appearance was beautifully illustrated. This organic disease of the heart, in conjunction with his apoplectic seizure, and the peculiar features of his complaint, is a point of great importance, as serving to establish a connexion and relation between these different affections. That there is an occasional coincidence between cerebral apoplexy and an albuminous state of the urine, with its consequences, is known; but whether it is of such frequent occurrence as to become an established point of decided importance, is still open (as far as I am aware) to future investigation. The connexion, however, between apoplexy and organic disease of the heart, is, I think, established on a pretty firm basis, by the facts stated in Dr. Hope's admirable paper*; where he observes, that of 42 patients who died of apoplexy, 30 had disease of the heart, and of the muscular structure of this organ especially. Richerand, Bertin, and Andral, have demonstrated this coincidence. Dr. Bright also notices and observes upon its occasional occurrence†. I have myself seen two cases of apoplexy where coagulable urine and hypertrophy of the left ventricle of the heart existed; and still more recently, a case in private practice, where serous effusion in the brain had taken place: the urine was not albuminous, but the left ventricle of the heart was hypertrophied; its walls being exceedingly thickened, firm, and dense in their structure. These facts would seem to trace out some connexion and dependence between these three points, and go partly to prove that in the case related this evening, these three morbid occurrences (which

* Similar experiments were made by Dr. Wells, with similar results.

† According to Dr. Bright, in the majority of five to one.

‡ Medical Reports, vol. i. p. 2.

§ Cyclopædia of Practical Medicine, article *Dropsy*, p. 641: the state of urine not mentioned.

* On the Connexion of Apoplexy and Palsy with Organic Disease of the Heart; published in the *Med. Gazette* for February 28, 1835.

† Gulstonian Lectures.

were all well marked) did bear some relation to each other. In forming these conclusions, the circulation of an unhealthy blood, consequent upon the disorganization of the kidney and the derangement of its secretion, must be taken into consideration. Marks of old or recent inflammations of the serous membranes are often found, more particularly the pleuræ. The adhesions in the chest sufficiently proved the previous existence of inflammation in the case before alluded to. The immediate cause of death was the serous effusion in the brain, which the post-mortem statement has sufficiently illustrated.

With regard to the treatment,—this must be directed with a view to restore the healthy function of the kidney, and to guard against any inflammatory affection, or apoplectic seizure, that may and does arise. That it is often unsuccessful, is but too true. We must, however, remember that the coagulable state of the urine may exist long before the anasarca shews itself: the patient's attention is not arrested until this latter affection occurs; and when at length our remedies are administered, the kidney is far advanced in disease. Does it not, therefore, behove every practitioner to examine carefully, in every suspicious case, the state of the urinary secretion? General and local depletion, and a strict antiphlogistic regimen, are the principal indications of cure; for (as Dr. Bright observes) there is reason to believe that a state of great congestion, perhaps an actual process of slow inflammation, exists in various internal organs, and particularly in the kidneys, where it probably lays the foundation for their future disorganization. Hydragogue cathartics act well—as jalap, elaterium, &c.; but we must be cautious not to purge too much, for there is a fear of abrasion of the mucous membrane of the intestines; perhaps also a danger of exciting or increasing inflammatory action in the kidney. Digitalis may be employed, with caution. Supertartrate of potash, from its gently purgative and diuretic property, is of great service; but all stimulating irritating diuretics are to be avoided, and we must act gently on the skin by saline diaphoretics. The loins should be surrounded with a large linseed poultice, which acts as a fomentation to the part, and will be found a very soothing application. Milk diet is the best. Tonics

are indicated by the debility occasionally present, and, in the more chronic forms, Dr. Bright is inclined to think they may be of benefit. Dr. Blackall also speaks of the use of tonic remedies. The occasional alkaline property of the urine in confirmed renal disease, in connexion with the absence of albumen, as before alluded to, would seem to indicate the employment of an alkaline remedy. Dr. Bright, with this view, tried the liq. potassæ in one case, but not with much apparent benefit. The uva ursi and bismuth also have been tried. In the case related, this plan of treatment, to a certain extent, was followed, but with how little success the result shews; indeed, when frequently occurring, or when long established, this disease appears incurable, and palliative, and not active, remedies must be employed; such a deep-rooted foundation does there appear laid for it in the broken down, debilitated habits, in which it occurs. Still we may hope that pathology and experience will yet point out a more efficient plan of treatment, enabling us to restore the healthy functions of the body, and to avert those formidable symptoms that now and then arise, and which, when present, baffle the art of the most skilful physician.

The propriety of giving mercury in these cases is very questionable; perhaps almost inadmissible. It appears probable, even almost certain, that mercury possesses the power of setting up that deranged action in the kidney, and, when already present, of increasing it; the result of which is albuminous urine, and the pytalism produced is most distressing to the patient. Dr. Wells has known it to produce albumen in the urine*. Dr. Blackall gives it as a positive cause for anasarca, and considers its exhibition as equivocal and hazardous†. Dr. Darwall is of the same opinion‡; and Dr. Bright observes, “the cases which have proved most successful in my own practice, have generally been those in which I have rigidly abstained from the use of mercury.” As far as my own experience goes, I have undoubtedly seen the urine become more coagulable under its

* Cyclopædia of Practical Medicine, article *Dropsy*, page 641.

† See some excellent observations and arguments on this subject, in Dr. Blackall's work, before quoted.

‡ Cyclopædia of Practical Medicine, article *Anasarca*, p. 76.

employment (in one case distinctly so), and cases also have occurred where I have tried the urine almost daily before the use of mercury, and, when the mouth has become sore, albumen has appeared; which albumen has gradually disappeared again with the discontinuance of the mercury and the decline of its salivating effects. These phenomena are by no means universal, but they do now and then occur in a very marked degree. Cases may also occur that are so complicated with bronchial and other affections, and where the disease in the kidney may be considered as secondary only, that the use of a small quantity of mercury is advisable and beneficial; but upon the whole, when the renal symptoms occur in a marked degree, and the urine is decidedly coagulable, arguing from facts, the employment of mercury can scarcely be sanctioned.

[To be concluded in our next.]

OBSERVATIONS
ON THE
CURATIVE PROPERTIES OF HY-
DRIODATE OF POTASS

IN PERIOSTITIS AND CHRONIC ARTICULAR
RHEUMATISM.

BY JOHN CLENDINNING, M.D.

Physician to the St. Marylebone Infirmary, and
to the Western Dispensary, Westminster, &c.

[Concluded from p. 837.]

My friend Dr. Holroyd has furnished me with the subjoined particulars of a case, in which, at my suggestion, he employed the hydriodate. It was a case of chronic articular rheumatism, treated by Dr. H. as a patient of the Marylebone Dispensary.

CASE IX.—J. D., ætat. 30, married, and never affected with venereal disease, admitted 25th September, 1834. He had been subject to rheumatism for fifteen years, and for the last eighteen months has been unable to work, or to walk without a stick. He had been in St. George's Hospital, and had there and elsewhere taken much medicine without advantage. The only part painful at his admission was the right knee, which for twelve months had caused him so much distress, that he had

latterly used opium at night, to the extent of fifteen grains at a dose, merely for ease from pain. On the 30th, no better, when the hydriodate, in doses of four grains thrice daily, was substituted for his former medicines. In forty-eight hours improvement was perceptible; slept for several hours the second night of the iodic treatment without opium. In ten days the pain of the knee was entirely removed, and he slept the whole night; he then continued for a few days, and left off gradually.

CASE X.—Rebecca Fuller, æt. 30, admitted in the St. Marylebone Infirmary, under my care, January 22d. She had been ill of chronic rheumatism for the last year, and when admitted, had painful swellings of the ankles, at the roots of the fingers, and in the palms of the hands; also a periostitis, extending over the olecranon and upon the body of the ulva of one arm. In the right arm, also, both external pressure and contraction of the muscles caused pain, which appeared to originate in the intermuscular fasciæ and tendinous attachments of the muscles. She was pale and flabby, with feeble pulse and cool skin. I ordered

Ammoniated Tinct. of Guaiacum, 5ss. in
℥iiss. of the Mist. Cinchon. Aromat.
of our hospital Pharmacopœia, thrice
daily.

Next day she had an attack of inflammation in the right iliac region, which was relieved by leeches and fomentations.

On the 24th a warm bath was tried, with seemingly bad effect, as she complained of increased rheumatic pains next visit.

On the 25th, a purgative, and Dover's powders at night.

27th.—No better. Ordered

15 drops Vin. Colchici in ℥iiss Mist.
Cinchon. Aromat. (Phar. nos.) ter
quotidie.

Feb. 3d.—No improvement.

The mixture as last ordered, with the Hydriodate of Potass, gr. iij. instead of Vin. Colchici, quater quotidie.

5th.—Better; complains of purging.

The Decoct. Sarsæ, Comp. to be combined with the Hydriodate, instead of the Cinchona mixture, and 5 drops of Laudanum to each dose.

14th.—The medicine has answered every purpose; the tenderness of the

olecranon, and swellings, and soreness of palms and ankles, have disappeared.

Omit the medicines.

19th.—Some slight return of pain, for which the iodic mixture was again employed; and she was quickly in a state to be removed to the convalescent ward. While using the hydriodate, her diet was full and generous—viz. roast meat, porter, &c.

CASE XI.—Ellen Putnam, ætat. 52, admitted into the St. Marylbone Infirmary, under my care, December 31, 1834. During the month of January, various remedies were employed—viz. colchicum, antimony, bark, opium in various combinations, but with little advantage. The symptoms principally complained of were tender swellings of the ankles, knees, and shins; on the right tibia there was a considerable node; she had severe osteocopi, and thence sleepless nights. She had been rheumatic for two years past, particularly about the greater articulations of the upper and lower extremities.

Jan. 30th, I substituted for her former medicines the hydriodate of potass, in mist. cinchon. aromat. (Pharm. Nos.), 5 grains thrice daily; and I ordered $\frac{1}{2}$ grain of mur. morphia every night.

On the 31st I doubled the dose of morphia and continued the mixture; and this plan was persevered in until the 7th February, when the node was quite gone, as well as all the painfulness, and most of the bulk of the swellings of the joints. I then suspended the medicines, but too soon, for on the 14th there was some return of articular pain and swelling, and I was obliged to prescribe again. I then directed the pil. veratriæ (Pharm. Nos.), which I had found useful in several instances not unlike the present, to be taken thrice daily.

On the 19th there was some slight amendment, and the veratria was continued and persevered in until the 2d March, when she still complained of pain of the right knee and ankle, which were swelled and tender. I then ordered for her the hydriodate of potass in mucilage, 5 grains every six hours.

On the 6th the swelling and tenderness of the knee and ankle were considerably diminished; she walked about the ward with much greater ease also.

March 9th.—To-day the iodic mixture continued, with morph. muriat. She

is still better, and will, I have no doubt, be very soon discharged convalescent.

March 12th.—Discharged to-day.

CASE XII.—Sarah Wood, ætat. 50, admitted into the casual ward, under my care, February 20, 1835. Seven years since, had what she called rheumatic gout, which obliged her to enter the Westminster Hospital, where she remained three months; left it still unwell, and has not since been free from gouty or rheumatic affections of the lower extremities. Her principal present ailment is painful swelling of the knees, incapacitating her wholly for labour during the last three months. Her general health excellent.

Feb. 21st.—I ordered the hydriodate of potass, 3 grains four times daily, in mucilage.

24th.—Improving rapidly; walks much better already.—Perstet.

27th.—Says she walks much better than at any time for seven years past; swelling of knees still considerable, with some tenderness on pressure; swelling of ankles quite gone.

March 6th.—Has persevered in the iodic medication since last report without inconvenience of any kind, and with great improvement in the use of the lower limbs; she “steps out” better (to use her own phrase), than at any time since the commencement of her treatment; has observed great improvement in her feelings in and power over her limbs, especially within the last three days. She is in the convalescent ward, and will, I expect, be discharged in a few days.

CASE XIII.—In October last I was visited in my bed-room, to which I happened to be confined, by a gentleman of 27 or 28. He was in perfect health, with the exception of a gouty swelling of the joint at the root of the great toe of the right foot, I think, which had incommoded him for more than half a year, and had proved obstinate and unyielding to every remedy he had employed. Having heard of Mr. M.'s case and the result, he applied to me. I had no previous experience of the effects of iodine in gout, but on mature deliberation considered myself warranted in trying the hydriodate in the case. I accordingly ordered him 20 drops of a solution (containing 1 drachm of the salt to the ounce of water) thrice a day, and warned him against taking the medi-

cine fasting. He revisited me a week after, and told me that he was then for the first time for six months able to wear his boot. In another week he called again, and announced that he was quite free from pain and swelling, and in perfect health.

I have at the present moment under observation, in the St. Maylebone Parochial Hospital, and at the Western Dispensary, three or four other cases of chronic articular rheumatism, which I am satisfied, from what I have already seen of them, will soon speak as unequivocally and strongly in favour of the iodine treatment as those above detailed.

OBSERVATIONS.—The employment of iodine as an antiphlogistic is of recent origin: so far as I know, Dr. Williams, of St. Thomas's, is the first that became acquainted with its curative power in certain forms of inflammation. I have not myself, in my limited reading, (Dr. Williams's paper excepted) met with any notice of iodine in this character. I do not consider as exceptions certain works on scrofula and syphilis, particularly the latter, of which I have at this moment one before me, by Dr. Richond, entitled, "*De la non-existence du virus venerien*," &c. Paris, 1826; a work with the use of which Dr. Williams has kindly favoured me. In none of the works I allude to, is what I would call the antiphlogistic property of iodine acknowledged or denied; to none of the authors does it seem to have been known. In Dr. Richond's work the remedy is spoken of, not as an antiphlogistic, but as a discutient; not under the head of periostitis, but as a means of effecting the dispersion of a phymotic swelling of the prepuce and of buboes, after their passage into the indolent state, often succeeding acute inflammation. Its use also was external, by friction, and not by the mouth. I have already mentioned that Dr. Williams seems to limit its utility to periostitis, but in extending its use to the chronic inflammations and irritations of the ligaments and tendons, which seem the essential elements in general of inveterate articular rheumatism, I have been guided by palpable analogies, anatomical and physiological. In one instance only I have tried it in chronic gout, and in that case (viz. Case XIII.) it seems to have produced effects as satisfactory as could reasonably be desired.

For the inflammations of the nutrient membranes, and possibly of the substance also of the hard parts, iodine, in the form of alkaline hydriodate, seems to possess many advantages over most remedies in common use, in the diseases in which such inflammations occur. One advantage is, that its use involves no restrictions of diet or regimen: so far as I have been able to judge, a full and even generous diet, and self-indulgent habits, offer no impediments to the action of the remedy. A liberal use of animal food, in particular, I think rather favours its action than impedes, where there is no pyrexia, owing to its enabling the stomach the better to bear the stimulating, and often at first irritating, qualities of the salt. 2. Its use occasions no susceptibility of cold, like warm-baths, or diaphoretics, or mercury. 3. It does not necessarily debilitate, like bleeding or other evacuations. 4. It harmonizes, chemically and medicinally, with almost every sort of substance it may be desirable to combine it with. It is compatible with bitters, astringents, opiates, antacids, aperients, and diffusible stimulants, as I myself experienced; and the experiments of Dr. Thomson and others prove its medicinal compatibility with chalybeates and mercurials. With regard, likewise, to the mode of using iodine, I may shortly notice the advantages of the internal use of the neutral salt. 1. It requires no handling, pressure, &c. of the tender part. 2. The whole dose is absorbed if but swallowed, and no labour or care is required to secure its due appropriation, in which it contrasts very advantageously with the endermic method. 3. It is infinitely more manageable in internal use than pure iodine; the internal use also is preferable to the external in most cases: first, it does not disturb the inflamed part; secondly, under the eye of proper attendants, its absorption is rapid and sure; thirdly, it is not troublesome, like friction.

The inconveniences are few and unimportant: the principal are heartburn, flatulence, nausea, and diarrhoea; and sometimes vomiting, colicky pains, and such like. But these symptoms are generally suffered only at the commencement of its use, and are easily prevented or subdued. By dilution—by taking it in a mucilaginous fluid, or in a bitter decoction, such as that of gentian—by taking it on a full stomach, or just after

meals, and at no other times—by beginning with a small dose of two or three grains, and increasing gradually—by the use of antacids and aromatics, when cardialgia is troublesome—by the prompt employment of chalk mixture and laudanum, to check intestinal pains and diarrhoea—I have generally been able, after the first few days, if not from the beginning, to use liberal doses of the salt, and quickly to bring the constitution and disease under the influence of iodine; and when other indications than those which iodine alone might be expected to fulfil have called for attention, I have found no difficulty in bringing it to co-operate with various remedies of different and even opposite characters, without its either offering or suffering impediment.

When first used, the hydriodate of potass sometimes causes pains and other inconveniences in the head, chest, and other parts remote from the stomach. Headache and vertigo are often amongst its first fruits; especially in nervous women, in whom it likewise excites the globus and other troublesome hysterical symptoms. In fact, from a consideration of the influence and sympathies alone of the stomach, we might *à priori* infer, that, as a powerful agent, it would be likely to give rise, in untried and susceptible subjects, to anomalous and unexpected symptoms. But such effects are of little importance, and easily mastered.

I have never observed any wasting of the mammae or testes, or of any other part of the body, in the patients I have subjected most fully to its influence; but have repeatedly remarked their improved looks and general appearance. Those of my patients who took most, as the second case in this paper (that of a young woman who took about 100 grains a-day for weeks together), suffered as little change of condition as those others that took but ten or twelve grains in twenty-four hours.

In a few instances it has produced acute ptyalism. The sixth case I have detailed in this paper (that of Mr. M.), was a striking instance of its occasional salivating power: that gentleman had not used it many days when his gums got sore and teeth loose, and severe ptyalism supervened, and continued for ten days or a fortnight. I have at this present moment under treatment, in hospital, a female patient, to whom I have exhibited the iodic salt, for peri-

ostitis of the occipital bone, and with considerable apparent advantage, but with effects on her gums, teeth, breath, &c. similar to those of mercury.

In this property, iodine seems to agree with digitalis and some other active substances, which, on rare occasions, have been known to produce like effects.

Its only sensible effects, which I should be disposed to call its regular effects, are increase of urine and of intestinal evacuations. The diuresis is not often enduring. After some days, or a week or two, the patients are not sensible of any thing unusual with respect to the quantity of evacuation. In the quality I have not myself observed any other change than a great increase, in several instances, in the proportion of lateritious deposit. In the urine of patients that drink but little, there may be expected, according to my observations, an unusual quantity of uric acid. With respect to the presence or absence of iodine in the urine, I have made no experiments as yet, and therefore cannot myself speak; but I am informed that there is little difficulty in detecting it, especially by means of oxymuriate of mercury.

With respect to the bowels, I have rarely found it fail to prove aperient in one degree or other. I have at this moment, in the Marylebone Infirmary, a female long afflicted with articular chronic rheumatism, whose stomach and bowels at first proved so intolerant, as to lead me to abandon it for veratrum, but who can now take five or six grains in chalk mixture, with five drops of laudanum, four times a day, without any inconvenient effect whatever. Her bowels are properly active, and yet she takes twenty drops of laudanum during the day, and gr. iss. of mur. morphie every night.

In the majority of cases, I have after the first few days found it to stimulate the bowels no farther than to cause free evacuation once, or more frequently twice, a day.

J. CLENDINNING.

Wimpole-Street, March 9, 1835.

PATHOLOGY OF PHLEGMASIA
DOLENS:

WITH A CASE.

To the Editor of the Medical Gazette.

SIR,

THE perusal of Mr. Anderson's case of phlegmasia dolens, as reported in your last number, brings to my mind one which occurred to me in the year 1828, and which so completely corroborated the then novel opinions regarding the nature of the disease, that I felt no hesitation in admitting their truth.

After the remarks of Dr. Robert Lee, and others, and immediately upon the report of Mr. Anderson's interesting case, it might appear superfluous to add more upon the subject; but as there are some points of novelty in the one I treated, I will submit it to your choice to publish or withhold it.

The subject of the disease was a thin delicate woman, about 40 years of age, weakened by frequent child-bearing. She had been confined only a few days, for (I believe) the twelfth time, when I first saw her; and she was then complaining of pain in the major saphena vein. This vein, just above the knee, was swelled, hard, and tender, and the integument over it slightly inflamed. Leeches, &c. were applied, without benefit. The inflammation gradually spread upwards along the vein, and it became interesting to ascertain, whilst approaching the femoral, whether upon its invading that vessel, swelling of the limb (hitherto absent) would ensue. It did so; and with all the characters of phlegmasia dolens. The inflammation moved along the iliacs, and could be distinctly traced, by the progress and extension of the pain, to the uterus, when the lochia ceased. Not so the inflammation, which then traversed the uterine branches of the internal iliac of the left side, and took possession of the main trunk, passed by it to the common iliac; and then swelling, &c. of the left limb ensued. Another course of the disorder was into the abdomen, where, from purging, feelings of great depression, &c. it was evident that the balance of the circulation was much deranged,—that nature was busy in restoring the equilibrium and preventing the ill effects of unrelieved congestion*. The circulation of the lower part of the spinal co-

lumn and cord seemed also to be impeded. The fever accompanying the affection (slight at the onset, aggravated when the lochia were suppressed), was throughout above the typhoid type. My patient recovered with much difficulty, and was for a long time extremely weak.

Most recent authors concur in attributing to the veins of the uterus the first agency in producing the phenomena of this disease; and it is not difficult to conceive that the great majority of cases will be found referable to their inflamed condition. The violence of the uterine contractions in labour, the pressure of the child, &c. must occasionally act as excitants of inflammation; and when the great extent of the venous development of that organ is considered, and that especially there is superadded an unhealthy state of the constitution, we cannot be surprised that phlebitis more frequently arises there than elsewhere. But in the above case we find the disease attacking the venous system in another quarter, open to the eye and touch, and subsequently involving the parts whence it most generally arises, yet productive of the same consequences. It may therefore, I think, be safely inferred, that this case affords additional proof of the justice of Dr. R. Lee's opinions regarding the nature of the disease; and, moreover, conduces to the conclusion, especially if we admit under the same head such instances as have occurred in the male, that although the disease in question is usually of uterine origin, it nevertheless is not invariably so.—I am, sir,

Your obedient servant,

WELLINGTON CLARK.

Sutton, Surrey, March 10, 1835.

P.S.—It may be as well to add that my patient was, under pregnancy, affected with cedema of the right leg.

MR. PHILLIPS'S METHOD OF TREATING ANEURISMAL TUMORS.

To the Editor of the Medical Gazette.

SIR,

I THINK it only proper to state the reasons why I am unable to give you more than a condensed summary of my memoir on a "new method of curing aneurismal tumors."

The committee appointed by the In-

* There was no peritoneal effusion.

stitute to examine the essays which were sent in to compete for the Monthyon prize (which, by the will of the Baron Monthyon, was directed to be "awarded to the person or persons who, in the opinion of the Academy of Sciences, shall have devised a means of perfecting medical or surgical science"), in declaring that I was entitled to the first place, had only completed a portion of their functions.

It has, I believe, always happened, that the committee have recommended that a portion of the 10,000 francs should be awarded to one or more persons whose memoirs are named as next in importance to that of the successful competitor.

In their report to the Academy, they say that "they have not yet determined the value of the prizes which shall be awarded to the successful memoir, nor to the other three who have been named, viz. M. Pinel, M. Serre, and M. Ricord."

The memoir being the property of the Academy, I do not think I ought to seek permission to publish it entire until the report is complete.—I am, sir,

Your obedient servant,

BENJAMIN PHILLIPS.

17, Wimpole-Street, March 16, 1835.

The essay commences by showing the necessity of inventing some operation for the cure of aneurismal tumors, by which the mortality attendant upon that of Hunter may be lessened, if not entirely avoided.

This necessity is based upon the following facts:—I have selected, indiscriminately, from the medical journals of the last ten years, 171 cases of aneurism affecting the larger arteries, which were submitted to the Hunterian operation; of these cases, 57, or exactly 1 in 3, were unsuccessful; and of these, with the exception of 2, all died, not of the disease, but in consequence of the operation.

In the cases which were ultimately successful, secondary hæmorrhage occurred 16 times.

I selected, quite as indiscriminately, from Lancisi, Scarpa, Pelletan, Boyer, and others, 29 cases in which the ligature was applied according to the ancient method, and of these only 7 were unsuccessful. So that if the only question involved were that of mortality, the evidence here offered would be in favour of the old operation.

Of the cases operated on after the method of Hunter, in 27 the ligature

was applied to the iliacs 20 times successfully; in 39 it was applied to the carotids 26 times with success; 37 times to the subclavian and axillary arteries, of which only 18 succeeded; 53 times to the femoral, of which 39 were successful; 15 times to the humeral, of which 11 succeeded.

In the cases which were treated after the old method, the ligature was applied to the femoral 22 times, of which 16 were successful; 7 to the humeral, of which 6 succeeded.

The wholesale result, then, of 171 cases of aneurism operated upon by the method of Hunter, within the last ten years, has given us a mortality, almost always consequent upon the operation, of 1 in 3.

If we look at an operation in appearance much more terrible, we shall find a much less mortality;—I mean lithotomy. I have resorted to an exactly similar mode of collecting 537 cases of persons who submitted to this operation, and I find, as the result, that 431 were cured, or more than four-fifths.

When we consider, too, that there are few successful cases which are not made public, whilst unsuccessful ones are often unrecorded, it does appear to me that I am borne out in the statement, that the Hunterian operation is not so successful as to justify us in resting satisfied with it.

The next question which is put is—what is the immediate cause of obliteration? the answer to which is, the existence of a certain quantity of inflammation in the parietes of the artery.

In the absence of the ligature, or of any other foreign body, if inflammation be developed in the parietes of an artery, the common, nay, almost invariably, consequence is a complete obliteration of the canal.

In support of this statement, among other observations, cases of *gangrena senilis* and *ergotism* are detailed.

Idiopathic inflammation of the internal tunie of arteries is very rare, and it is not easily excited even by the introduction into the tube of certain mechanical agents.

Inflammation of the external, or cellular tunie, may be excited at will by mechanical irritation; and when excited, produces almost invariably the following results: an exhalation of a fibrino-albuminous matter, and sometimes even of pus, between the arterial tunies, by which the calibre of the canal is consti-

derably lessened; a rosy colour of the internal tunica; a coagulation of the blood contained in the canal; and an exhalation, upon the internal surface, of an albumino fibrinous matter, which is presented under different forms.

After having very fully established the correctness of the preceding data, it occurred to the author that if he could devise any means by which he could excite inflammation of the external tunica, that the exhalation, coagulation, and obstruction, must follow.

To confirm that position a series of experiments were made, by introducing needles into the arterial tunics; and it was clearly demonstrated that the common effect of introducing these bodies through the arterial tunics was to excite the phenomena which have been already described.

This mode of exciting the necessary inflammation was abandoned, from the absence of any certainty that the arterial tunics were punctured.

The next series of experiments were performed to shew that the mechanical effects produced by a needle, within the canal of the artery which it had perforated, were not necessary to the success of the experiment.

In these experiments an incision was made upon an artery, and a small pellet of lint placed in direct contact with it. No injury was inflicted upon the artery by the operation, and the lips of the incision were immediately brought together.

On the second or third day the same series of phenomena as those which have been already described were produced.

As the desire of the author was to avoid all cutting, and yet to acquire a certainty that the arterial tunics were implicated, he at last resorted to the mode which has lately been stamped with the approbation of the Institute of France.

In the greater number of the cases of aneurism, the external, or cellular tunica of the artery, is a principal element in the composition of the sac; and whether that tunica be distended or not, its nature is unchanged, and its susceptibility to inflammation is the same; and where the aneurism is diffused, no long time elapses before its further progress is arrested by a cellular tunica of a new formation.

The cases, which will be detailed when the report is completed, fully justify the foregoing statements.

The operation as now performed, is to pass directly through the sac one, two, or more needles, each armed with a double thread of silk, which is permitted to remain there for a certain number of hours.

In all the observations which have been made, it has happened that within sixty hours a sufficient quantity of inflammation has been developed to produce the effects which have been detailed. If in any case those effects be not produced within sixty hours, the threads may be drawn backwards and forwards, so as to excite any quantity of inflammation which may be desired.

Commonly within forty hours the effects will be occasioned: heat will be developed, and a blush will be manifested along the course of the artery, as well as a dull pain extending for a short distance. When these effects are evident, the threads should be removed; and if the heat and pain be considerable, a few leeches should be applied.

As soon as coagulation is produced, the tumor follows the same course as after the Hunterian operation.

STOMACH AND COLON IN THE CHEST.

[Communicated by Sir J. McGRIGOR, Bart.]

Is the Museum of the Medical Department of the Army at Chatham, No. 63, Class vi., displays the whole of the stomach, and the greater part of the transverse arch of the colon, situated in the left cavity of the chest; which malposition is supposed to be owing to a wound of the diaphragm by a musket-bullet, received in 1811.

This very interesting specimen was taken from the body of Sergeant Dennis Barry, 88th regiment, aged 44 years, who died on the 4th January, 1833, in consequence of gangrene of the left lower extremity, produced, as it was supposed, by metastasis of a severe rheumatic affection of the larger joints. (For details of case, *vide* third volume of Original Documents, No. 16.)

The only information which can be obtained, calculated to explain the cause of the remarkable malposition of parts seen in the preparation, is as follows:—On the day preceding the battle of Fuentes d'Onor (which occurred in

1811), Sergeant Barry and his company being out skirmishing, one of the enemy, posted on the top of a steep hill, fired as he (the sergeant) was in the act of descending the same, and wounded him in the chest. The ball entered close to the nipple of the left breast, and passed out at the back, between the 8th and 9th ribs, as was evident by the scars seen at the post-mortem examination. It is stated in the document that the anterior opening of the wound soon healed, but the posterior one did not do so for a considerable period. When the latter closed, he became affected by such severe cough, with expectoration, that his medical attendant deemed it proper to lay the same open again. Being kept so, the symptoms were relieved, and portions of his shirt and jacket discharged. After this his health improved so rapidly as to enable him soon to rejoin his corps.

It appears, however, that the wound of his back afterwards repeatedly opened and healed—generally at intervals of twelve or fourteen months; but for the last five or six years it ceased to do so. It is stated that his appetite was very small and delicate; flatulency, &c. also much complained of; and if at any time the stomach happened to be overloaded, vomiting occurred. Bowels generally regular. The chief bad effects which this person himself attributed to his wound were—that since receiving it he never had been able to wear his knapsack with ease; and that his breathing became much affected whenever he walked at a quick pace, or ascended a hill.

REMARKS.—For the sake of those who may see the Catalogue of the Museum, but not this specimen, it will be necessary to describe the exact relations of the objects. The stomach and the greater part of the transverse arch of the colon (both rather small) are situated in the lower and anterior parts of the left cavity of the chest; the lung of this side, as might be expected, has become a good deal reduced in size, and occupies only the superior and posterior part of its proper cavity. The great arch of the stomach lies atlantalad. Right lung smaller than left, from the circumstance of the heart being so displaced by the stomach and colon, that instead of extending across the thorax from the second rib of the right side to the sixth of the left, as that viscus naturally does, it

now lies nearly parallel with the spine, having the apex almost on a line with the coronary ligament of the liver. The right lung therefore is smaller than the left, because the heart, of ordinary size, and situated in the anterior part of that cavity proper to the former, proved much less yielding during inspiration than the stomach and colon were in the other.

It is probable, from appearances, that the wound of the diaphragm extended about three inches in a transverse direction, near to the centre of the dorsal attachments of that muscle. But as the objects forming the hernia have contracted firm adhesions to the parts formerly injured, and as the peritonæum lining the diaphragm seems in many places quite continuous with that covering the intestines which pass through the preternatural aperture, there is on that account considerable difficulty in ascertaining this point with due precision. Nevertheless, an attentive consideration of the positions of the parts will easily enable the examiner to account for all the symptoms which Barry complained of since being wounded in the manner above described. As, also, he enjoyed perfect health before that period, and was even remarked by his officers for being an active soldier, it follows of necessity that the singular malposition of the parts seen in the preparation must have been the result of a wound of the diaphragm, and was not congenital, as some who have seen the preparation seem inclined to consider it. To these last the following explanation of the symptoms may be given:—Why did the breathing of the patient always become affected when he walked fast or ascended a hill? Because of the capacity of the chest being diminished by the presence of the stomach and colon in it. Why the dyspeptic symptoms? Because the great arch of the stomach was turned upwards, and the parts otherwise displaced. Why did vomiting always occur when the patient took more than a small quantity of food? Because the distention of the stomach impeded respiration; and the latter function influenced that of the former to such a degree, that the nervus vagus, or pneumo-gastric nerves connected with both, became affected, and vomiting was the invariable consequence.

Altogether this case and preparation are exceedingly important, as showing that wounds of the diaphragm do not

necessarily prove fatal. It must, however, be confessed, that several circumstances were much in this patient's favour:—1st, It appears from the document, that for nearly forty-eight hours previous to the receipt of the injury, he had been unable to procure food; and his constitution also being hardened (if I may use the expression), by the exercise consequent on an active campaign, it may be supposed that little predisposition to inflammatory action existed. 2dly, But by far the most favourable circumstance for his recovery was that the diaphragm had been separated from its dorsal attachments instead of receiving an injury nearer the centre. In the former situation are but few branches of the phrenic nerve; and if here the muscular fibres had been detached from their origins, no reason can be mentioned why they should not adhere to the parts in their vicinity. In the latter, however, the accident probably would have been fatal; for as the fibres of the diaphragm converge towards one centre, any wound made in them could not heal, from antagonist forces keeping it open; and also, as the muscle is here plentifully supplied by branches of the important phrenic nerve, the probability is that some of these might be injured by the wound, which, being disturbed by every respiratory effort, such continued nervous irritation must have been produced as could not fail to destroy the patient.

I have taken some pains in examining the authorities as to wounds of the diaphragm. In several works, mention is made of recoveries from such injuries, but the patients are described as living in a state of great suffering, owing to the functions of the parts which may have protruded into the cavity of the chest being impeded. As far as I am aware, there is not a case on record of a displacement, such as that detailed above, being attended with so little inconvenience to the patient.

F. McCRAE, M.D.
Staff-Assistant Surgeon.

THE MEDICAL CHARITIES AND PLACES OF INSTRUCTION.

To the Editor of the Medical Gazette.

SIR,

IN a late number of your journal, I read, with no small degree of satisfaction, a communication from Dr. Clen-

dinning, the spirit and tone of which merit general attention. The Doctor very frankly admits that the position in which he is now placed, as physician to the Marylebone Workhouse, affords him a wide field for medical investigation, and dwells forcibly upon the advantages that should result to medicine and society, from such institutions, if conducted in the manner he proposes, recording all important cases, and giving them as wide a circulation as the periodicals of the day may enable. This looks like the dawn of a brighter day in British practice.

If we look at the great medical charities of this metropolis, and ask ourselves what have they done, either for medicine or society, we are puzzled for an answer. In this country we scarcely possess any body of facts, purely the result of British investigation, which in the present state of medicine can be classed as authorities; whilst hardly a year passes on the continent without adding something to the general stock. It is idle to refer us to Baillie, Hunter, &c., and others of their day, who did much in their time to improve the science; their discoveries, though great then, have long since ceased to surprise us. It is true we have now and then garbled facts, adduced by men who, as being partly unknown, and unconnected with large hospitals, seldom meet with that attention which their industry deserves. Had these men been placed at our public hospitals, their position would have given authority to facts, which the most powerful talents, in private practice, can hardly raise to ephemeral reputation.

It is only in hospitals that medicine can expect to make any advances to the nature of a fixed science. The mass of facts which may be there collected by a careful and diligent observation, bear so strongly on the cultivation of medical science, that he who neglects to record them, and give them publicity, is culpable in the last degree. In all other countries, hospitals—the emporia of disease, are considered as the peculiar property of the science of medicine, whilst with us they come under the denomination of stock-jobbing concerns. I will not suppose that the founders of those charities intended to pay the medical officers by a monopoly of the knowledge to be there acquired, though I confess it savours a little of it, neither can I bring myself to believe that they

were designed to benefit those only received within their walls; such a supposition would be a libel on the memories of the dead. It would be acting more in the charitable spirit of those good men, and more in unison with the great-happiness-principle, to extend their advantages to the greatest possible number, by a faithful record of their several clinics. If the medical officers of those institutions cannot afford time for such minute inquiries, they perform but half their duties. It is not enough that they go through the usual routine of prescribing for A B C, noting one as pleurisy, another as enteritis, and a third as carditis; they have another and a paramount duty to perform—to make known the result of their experience upon numberless cases. This neglect has been productive of two evils of a very opposite nature, the one negative, the other positive. The negative arises from the indolence of physicians in not publishing the result of their experience. The positive, that a wide field is thus thrown open to young inexperienced physicians, who, becoming attached to dispensaries, generalize from solitary facts, and palm upon the young members of the profession their crude and illogical deductions, as the immutable laws of diseased and healthy animal action. This is an evil of great magnitude, a state even worse than positive ignorance. There are some, doubtless, who may find their account in this ignorance, and console the world with the doctrine of the poet, that since "Ignorance is bliss, 'tis folly to be wise;" but upon the grave questions of medical investigation, we should rather revert to the philosopher than the poet for consolation, "Iners remedium malorum est ignorantia." It is greatly to be lamented, that we should lose the great practical attainments of many of the hospital physicians, for whose acquirements I myself have the highest respect, but which cannot prevent me expressing my regret at their indifference to the welfare of the mass.

Our medical institutions are all conducted upon a system so totally at variance with the general interest of society, that the wonder is they have held together so long. What a contrast between our hospitals and those of France. France, liberal of every thing that concerns the welfare of human nature, addresses herself to the world, in the language of the poet, "Humani nihil a me

alienum puto." In her hospitals are to be found "men of all climes that never met before," seeking from her professors that information for which their European reputation had distinguished them; whilst with us, the reputation of our great medical officers is marketable only within its own parish: this, as I have already said, does not arise from ignorance, or a want of extensive erudition, but because they cultivate medicine as a trade, not as a science.

The limits of a letter will not allow me to go the length that the importance of this subject demands; but in addition to many other evils arising from want of legitimate induction in medicine, I need only briefly allude to the various and contradictory theories of many of our aspirants for medical fame. One makes the alimentary canal the seat of all disease, and forthwith proceeds to purge; another places it in a superabundance of blood, and immediately prescribes the lancet; if both these fail, then come the rubbing sect, and thus in

"The space of one revolving moon,
We have bleeder, purger, rubber, and buffoon."

Your obedient servant,

MEDICUS.

March 18, 1835.

MEDICO-LEGAL REPORT
ON A CASE OF
SUSPECTED INFANTICIDE;

With Observations,

By M. MARC.

Physician to the King of the French.

THE *Annales d'Hygiène* (No. xxv.), lately published, contains the several documents from which we gather the following facts. There are no less than five *rappports* on the case; but as the last two, drawn up by MM. Marc, Capuron, Hauregard, D'Heré, and Guichard, embody all the principal details, our abstract shall be chiefly taken from them.

The medical jurists just mentioned were summoned on the 8th of April last to examine, in presence of the Commissary of Police, the body of a female infant, newly born, and to make report touching the nature of its death. They found the length of the child to be 19 inches and a line; from the head to the navel measured 10 inches, and from the navel to the sole of the foot 9 inches and 1 line. The cord was divided by a

clean transverse incision two lines from its insertion at the umbilicus. The condition of the nails on the fingers and toes, the hair of the head and eyebrows, the eyelashes, and the weight of the body (which was 5 lbs. 5 oz.), showed that the infant had most probably attained its intra-uterine maturity.

On the neck was a circular impression of two red concentric rays, proceeding from before backward and horizontally to the nape, where the lines were disjointed, leaving spaces, of the natural colour of the skin, between them. The impression was more red on the right than on the left side. In front, it passed between the larynx and os hyoides; behind, it occupied the space between the occipital bone and the first cervical vertebra. About the middle of the left side of the neck there was a longitudinal ecchymosis, in the track of the impression, extending over the space of about $3\frac{1}{2}$ lines, and about 1 line in breadth, of a cherry-red colour. On the right side of the neck there were three similar ecchymoses, and behind there was something like a slight excoriation observable.

Dissection showed that an ecchymosis existed beneath the marks on the neck at intervals, and corresponding to their entire length.

No lesion was detected about the larynx or trachea; nor was there anything irregular in the appearance of the tongue or the mouth. But on the head there were remarkable lesions: externally, it was crushed from above downwards, with two livid spots on the forehead, the one extending along the left side, even to the occipital bone; the other on the right, not so extensive, but more livid, and to be traced no farther than the anterior portion of the parietal. A quantity of dark coagulated blood was found beneath these lividities. The scalp was deeply ecchymosed. On removing the periosteum, a fracture was seen involving the right parietal bone: it proceeded from a central point, dividing the bone into four angular pieces. The left parietal bone was also fractured.

On laying bare the brain, that organ was found shrunken, with sanguineous effusion in its convolutions. The vessels of the dura mater and the arachnoid were much gorged with black blood. The choroid plexuses and walls of the lateral ventricles were also injected. Behind the corpus callosum, towards

the fourth ventricle, there was a considerable effusion of blood. Fluid black blood was found deposited at the base of the brain.

The internal examination of the chest displayed the lungs, not quite filling the cavity,—the left not covering the pericardium; their tint was a rose pink. They floated in water perfectly when thrown in wholly or in part; and their crepitation was very distinct. They were, moreover, quite healthy; and there was no appearance whatever of any evolution of a putrid gas about them. The heart contained no blood.

The small intestines were filled with meconium, of a dark green colour; that in the large intestine was yellowish. The bladder was empty. All the abdominal viscera sound.

The conclusions of the report were—1, That the infant had been born at the full time, and was *viable*. 2, That it had breathed. 3, That it was difficult to conceive that its death was owing to strangulation by the cord, for the circular impression did not correspond to the ordinary volume of the navel-string, and the separate rays seemed incompatible with that hypothesis. Even supposing the cord to have gone twice round the neck, and that in a parallel direction, still it would not account for the appearances. 4, But supposing that the infant had been strangled with the cord, it is equally unaccountable how the respiratory process should have been established, unless previous to the compression; and then there should have been some signs of that sort of death detected about the air passages and the chest. 5, The severe lesions of the head are quite sufficient to account for death; but it is not so easy to imagine that injuries so serious could have been produced by the fall of the child at the moment of delivery. 6, The explanation of the accused is this—that the infant, on being expelled from her, fell on the floor of the apartment; and that when she took it up and grew faint and insensible, it had a second fall from her arms. The mother is a woman of short stature: the length of her lower limbs, measured from the fourchette, is but 2 feet 7 inches; from her bosom to the ground measures about 3 feet and 1 inch. The second fall is more likely than the first to have done the fatal mischief to the head.

At a subsequent visit the pelvis of the accused mother was examined. It was

found to be larger than ordinary in its external proportions: the internal shape and size were normal; but nothing unusual was observed about the sexual parts. The placenta having been sought in the dust-hole where it was thrown, it was found to have an umbilical cord attached to it thirty-two inches in length.

These facts somewhat modified the final report; and the examiners gave it as their opinion that the dimensions of the pelvis, on the one hand, and the length of the funis, on the other, were sufficient to account for the sudden delivery of the infant, and its severe fall on the floor.

It further appears from the informations sworn, that when the accused was delivered she was alone in her chamber; that the infant fell on the ground; upon which the mother picked it up, and ran to the door to get a pair of scissors from her sister, who was in the next room. Having got them, she shut the door, and was approaching her bed, when she fell insensible. Upon coming to herself she raised the child, which had fallen a second time; she cut the umbilical cord, but the infant was dead. In consequence of this investigation of the case the charge of infanticide was abandoned.

Observations by M. Marc.

This is one of the most obscure cases I have met with; for beside that some authors, Klein among the number, question the possibility of ecchymoses being produced by the cord, the double ecchymosed furrow in the present instance was not of a volume corresponding with that of the funis. However, the considerable length of the umbilical cord in this case (thirty-two inches) is sufficient to explain, up to a certain point, the possibility of *two* circumvolutions being so formed as to leave a very small interval between them, and to produce several of the appearances described.

But how are we to account for the total absence of all sign of suffocation? We can only suppose that the compression of the cord subsisted during fetal life, but ceased immediately after, or during, delivery; so that the infant was thus enabled to respire and to cry.

It is not easy to believe that the severe lesions of the head were effected by the first fall; more probably they were caused by the second, when the mother having fainted, and perhaps become convulsed, threw the infant with violence

from her arms. This also would explain how, by a *contre-coup*, fracture might be produced on the side of the cranium opposite that first injured. (See my article on *Infanticide*, in the *Dict. de Médecine*.) It may be objected that the infant remained attached by the cord; but that cord, be it remembered, was nearly three feet in length.

As to the division of the cord within two lines of its insertion into the navel, no inference can be drawn in favour of, or against, the necessity of a ligature in this case; for, as the mother stated, the section was made after the infant's death; and, accordingly, we did not perceive the least sign of any umbilical hæmorrhage.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Illustrations of the Botany and other Branches of the Natural History of the Himalayan Mountains, and of the Flora of Cashmere. By J. FORBES ROYLE. Parts III. IV. V. 4to.

Prodromus Floræ Peninsula Indica Orientalis: arranged according to the Natural System. By ROBERT WIGHT, M.D. and G. A. WALKER ARNOTT. Vol. I. 8vo. pp. 480.

Contributions to the Botany of India. By ROBERT WIGHT, M.D. 8vo. pp. 136.

Of the first work on our list, we noticed the two preceding parts in our 13th vol. p. 976, and now return to it, as it has reached the half of its intended extent. The others we are induced to class along with it, because they refer to the same part of the world, and because they are arranged according to the same principles. We are thus enabled to take a connected view of the Flora of a vast portion of our Indian possessions, and contrast the vegetation of the plains and lower mountains of the Neelgherries with that which clothes the sides, and even summits, of the mighty Himalayan range: nay, further, the *Prodromus* forms a link by which we can continue our examination of tropical plants to the islands of the Indian Archipelago,

and, by means of Blume's *Flora Javae*, extend our chain even to Australia; where we shall be aided by Brown's *Prodromus Floræ Novæ Hollandiæ*.

Thus has an important hiatus been most satisfactorily filled up; while the new genera and species, with which this and the other work of Dr. Wight have made us acquainted, are valuable as materials for calculating the degree in which certain tribes of plants predominate in the different localities. This interesting investigation, connected with the geography of plants, may be more easily pursued when the observations on the geographical distribution of the genera is supplied to the reader, which is promised in the second volume, and the absence of which is the only conspicuous defect in the present volume of the *Prodromus*.

In the parts of Mr. Royle's work now before us, forty-seven tribes of plants, of which members are to be found in India, chiefly on the Himalayan range, are treated of at greater or less length, according to their number or importance. Considerations are introduced connected with their structure, affinities, properties, and uses, both in ancient and modern times; and also with their geographical distribution, and the influence of climate. In these last respects, the tribe of the *Malvaceæ*, containing the cotton-plant, and the tribe of the *Terastromiaceæ*, containing the tea-plant, are the most ample.

Of the importance of these investigations we shall speak presently: their interest will be best known by quoting the words of the author.

"India would appear to be the *Mediterræanea*, or central country, botanically, which the natives fancy it to be geographically. Thus we have seen the southern parts of India, including the Peninsula, Bengal, and the forests of Silhet and Chittagong, supporting a tropical vegetation, which in many respects approximates to the floras of the other equinoctial parts of Asia, as well as of America; while a strip of tropical jungle runs up along the southern or plainward base of the Himalayas, nearly to the most northern limits of Hindostan. The Himalayas themselves we have seen supporting a different vegetation at different elevations:—Indian, at the base and within the valleys, European as we ascend, and almost polar when we reach the summits of lofty mountains,

which are only for a few months freed from their covering of snow. Inter-mixed with the Indian and European-like floras, we have many of the genera, and even species, which were thought peculiar to China, as fully detailed in the account of the tea-plants; and with these many also of the genera which were considered as existing only in North America."—*Royle*, p. 158.

Of his arguments in favour of the successful cultivation of cotton in India we shall say nothing, as their correctness has been demonstrated by the fact, that some cotton from Bombay has been sold at Liverpool for one shilling a pound, which was more than three-fourths of the American cotton was then selling for.

We are convinced that no one save he whose mind was deeply imbued with the principles of philosophic botany, could have presented the varied yet exact considerations connected with the proposed cultivation of the tea-plant in India, on the sides of the Himalaya; and the success, which we venture to predict will attend the experiment, will prove at once their soundness and the scientific character of the views of the author of this work. Indeed, we rise from an attentive examination of this work, in doubt whether the botanical knowledge which it displays and imparts, or the patriotic spirit which pervades it, calls for the higher admiration. We are, however, certain, that every botanist who desires to demonstrate what are the practical uses of his study, may appeal to it with satisfaction, to shew its bearings upon the affairs of life; while the merchant who is interested in the produce of the East should patronize it, as contributing largely to promote a just knowledge of the resources of that vast empire, the improvement of which would materially increase the commercial greatness of Britain and of India.

The present volume of the *Prodromus*, following the arrangement of Decandolle, contains eighty-three orders, and a detailed description of 1365 species of plants. The authors, in their preface, state the reasons which induced them to adopt the natural arrangement. These are of course quite satisfactory to every one interested in the progress of scientific botany, in opposition to that which consists only of a muster-roll of names. In consequence of adopting this

arrangement, it becomes a valuable key to the properties of the vegetable productions of the Indian Peninsula; and as the size renders it very portable, it should form a part of the library of outfit of every medical officer proceeding to India, as the best means of making himself acquainted with the peculiarities of the novel forms by which he will find himself surrounded, and from the careful investigation of which he may, perhaps, be rewarded with the discovery of the means of curing many of those diseases which we now scarcely possess the power of alleviating.

The contributions to the botany of India consist in an enumeration and description of plants found in the Herbaria of Dr. Wight, Wallich, and Royle, belonging to the three tribes of the Composite, Asclepiadææ, and Cyperaceæ. Of these, the first has been drawn up by the younger Decandelle, the second by Messrs. Wight and Arnott, and the third by Ch. G. Nees von Esenbeck. Their value may therefore be inferred from this fact, independent of their intrinsic interest.

Pathological Researches on Phthisis.

By E. CH. A. LOUIS, Physician to the Hospital of La Pitié, &c. *Translated from the French; with Introduction, Notes, Additions, and an Essay on Treatment.* By CHARLES COWAN, M.D., &c.

WE are glad to find this admirable work of M. Louis' introduced to English readers in so very satisfactory a form. The history of the original is curious. It is the production of a man who has made great sacrifices of time and money in the pursuit of truth, and who, if any medical inquirer of recent times may boast of the success of his endeavours in that respect, has certainly not sacrificed in vain. At the very time of life when most men have fully adopted the principles on which they propose to act for the remainder of their career, M. Louis surrendered those which he had acquired in the schools, and set himself down to the attainment of others which he deemed more worthy, if not alone worthy, of his best exertions. He had studied and practised medicine in Russia, and was now 33 years of age, when he visited Paris, and became strongly attracted by the doctrines of Broussais. He followed the clinical practice of that

celebrated physician for some time, and eagerly examined his writings; but the result was unfavourable. The impression produced upon his mind by M. Broussais' system and mode of proceeding was, that while that distinguished person so clearly convinced others of error, he was very far from demonstrating himself to be in the right. M. Louis found himself, in consequence, compelled to strike out some more likely track by which to reach the object he had in view. He resolved thenceforth to devote himself exclusively to the method of *observation*, and with a rare example of modesty combined with determination, entered La Charité as a clinical clerk under M. Chomel. For nearly seven years—the best years of life, perhaps, for active labour, whether bodily or mental (from 33 to 40)—he consecrated the whole of his time and talents to rigorous impartial observation. He relinquished all private practice, and allowed no considerations of personal emolument to interfere with the resolution he had adopted. It required immense perseverance and strength of mind to overcome the difficulties that beset him during this period; but he came off triumphant: his success was generally acknowledged; and he now ranks (he has been physician to La Pitié for the last five years) as one of the ablest—perhaps the most sagacious—of practitioners in his own, or any other country.

Let us, however, come more particularly to the work on Phthisis, of which we wish to give our readers some idea: we do not intend to give them a sample of its contents, but rather to tell them what it is made of, and how it has been constructed. For this purpose we shall allow M. Louis, through his interpreter, to relate his own story: we quote from the preface.

“Very shortly after we had exclusively devoted ourselves to observation, we ascertained that in the progress of phthisis, as in that of other chronic diseases, the greater number of the functions are remarkably disturbed; that the organs which discharge them are more or less profoundly affected, and that with regard to both these points the history of the disease was very incomplete, or almost wholly neglected; the hope of supplying this deficiency was the source of our present undertaking. Numerous facts early indicated to us,

that the history of phthisis could be elucidated by new observations, and this conviction was an additional motive for persevering in those investigations, of which the volume now presented to the reader is the result.

"In order to secure the greatest possible utility to our labours, we have observed phthisical patients with the same care we employed in collecting the history of those attacked by a disease (affection typhoïde) still little known; we have interrogated *all* the functions, and reverted as far as possible to their respective derangements, previous to our examination of the patient; and after death we have studied all the viscera with equal attention. This method was tedious, but simple and certain; it could not but lead to exact results, and this impression has rendered light the fatigue it necessarily included.

"Fully convinced of the importance of *negative* facts, and recollecting the embarrassment and regrets of Morgagni, when, on examining the observations of Valsalva, he found no mention of well-attested facts of this description, we have collected them with as much care as the most interesting of our affirmative ones; we have even noted down indiscriminately whatever the patients related respecting the alteration of their health at any period of their lives, provided always, that the circumstances of the recital gave evidence of its truth:—we left to future opportunities, and the post-mortem examination, the task of pointing out the facts to be retained or suppressed. It is easy to form a just idea of the importance of negative facts, if we reflect that organs, when their structure is extensively modified, frequently give rise to no appreciable symptoms, and that, if this absence of symptoms has not been expressly specified, we cannot form a proper estimate of the value of post-mortem appearances. Hence also the necessity of examining *all* the functions, whether apparently disturbed in their exercise or not:—another method may suffice for the verification of what observers have already remarked, but it can conduct us no farther.

"To remove all doubts as to the value of our notes, we have always mentioned the state of the patient's intellectual powers; quite decided, when we had to investigate facts anterior to the period of our own observation, only to

rely on those patients whose faculties, and more especially whose memory, possessed a certain degree of development.

"We have paid great attention to the mode of *questioning* invalids, for there are certain questions which almost inevitably dictate the answer. As, for instance, if we wished to discover whether the patient experienced pain, or any uneasy sensation on either side of the chest, we mentioned first the side where we supposed the pain did not exist; if he then indicated the other side as the seat of his sufferings, we regarded the fact as certain, and entered it as such. For the determination of dates, important to ascertain, we frequently resorted to the subject, asking the patient, not, if he had experienced such a symptom for such a time, but how long he had experienced it. It is evident, that to the first question a patient, annoyed or weary, might answer indifferently yes or no, while at the second he is compelled to reflect, and by a mere haphazard reply cannot so easily lead into error.

"After death, we have described with all the precision of which we are capable, the situation, the form, the colour, the consistence, and the thickness of organs; in a word, every alteration of tissue which they might present. To effect this, we have never examined the viscera, with the exception of the brain, in their natural connexions; for in this situation they are generally insufficiently illuminated, and in the case of organs which are membranous, thin, and compound in their structure, as the stomach and intestines, their thickness and consistence cannot be properly appreciated, and it is also difficult to examine the whole of their extent; at the same time many alterations, such as small superficial ulcerations, almost inevitably escape our notice. In these cases, to see clearly, we must not only remove the parts, but free them by repeated washings from the various substances which adhere to them, and, as was almost constantly our practice, immerse them for an hour or two in water."

After some examples of the application of this method, he proceeds:—

"The observations on which our researches are founded, were collected at the hospital of La Charité, commencing from the last three months of 1821. Since that period, we have noted down the history of all the patients admitted

into the wards of M. Chomel, containing forty-eight beds, equally distributed between men and women. The same plan has been pursued in the description of every case, and as the exactness necessary for such a task did not appear compatible with the practice of medicine, the latter was, for a time at least, relinquished. We have since regularly passed from three to four, and sometimes five hours a day at the hospital, devoting at least two hours to each post-mortem examination; and although habit has necessarily familiarised us with anatomical researches, we give up at the present moment as much time as we did two years ago, fully persuaded that to observe *well*, we must not observe *hastily*; that the only means to rectify inevitable errors, is continually to re-examine, and consequently always to observe an object, however familiar, as if presented to us for the first time.

“By comparing our latest observations with those formerly collected, we have been enabled to convince ourselves of the advantages that would result, at least when there is any intention of publishing, from having observed at an age when we can estimate things at their real value; when experience has already warned us against every species of illusion and theory, and where the first mental want is that of *truth*. Study was not less attractive to us formerly than it is at present, but a theory presented with art was not without its allurements: precision was less studied, and we devoted less time to the determination of facts. These mental tendencies, so contrary to sound observation, were at once depending on deficient experience and the spirit of the age; very few escaped their influence, and, if for no other reason, we ought to place less reliance on the labours of young observers, and especially avoid devolving the task of observation exclusively upon them. Independently of the disadvantages of age, it may be also said with truth, that we cannot observe for others with the same zeal, the same assiduity, the same precision, that we would employ for ourselves. The natural philosopher who wishes to advance the progress of science, does he let another make his experiments? The chemist, does he confide the operation of analysis to one just entering upon his career? And if, as indeed is the case,

there is complete analogy between the physician who observes, the natural philosopher who experiments, and the chemist who analyses, why should they adopt a different method in their inquiries? It is not enough to know that individual observations are necessary in medicine, unless we are at the same time convinced, that to render them valuable, much zeal, much time, and much practice, are required;—practice, we repeat, for to collect observations is a *trade*, and, like all other trades, must be learned, and cannot be divined.

“The reader will pardon us, perhaps, for having insisted so much on the care we have bestowed on the collection of our facts, and upon the distrust with which part of those daily published ought to be received, if he reflects, that *the edifice of medicine reposes entirely upon facts, and that truth cannot be elicited, but from those which have been well and completely observed*. Then, and then only, we shall be enabled to discover, in a series of observations, the data of a problem consisting of many quantities whose value is unknown; and since in mathematics, this value does not vary with the individuals who engage in the solution of the problem, we ought also in medicine to arrive at identical results, by the analysis of the same observations; always admitting, that where a mind of ordinary power arrives at few general deductions, one of superior capacity, from its power of examining the particular facts under more varied aspects, will discover a greater number; but it is inevitable that exact observations, studied under the same point of view, must conduct every one who attentively considers them, to identical conclusions. All is not then obscure or uncertain in medicine, when the observations which guide us are exact; but what results can be obtained from the consideration of facts which are doubtful, incomplete, or false?”

The plan of the work is simple. In the first part, which is devoted to the pathological anatomy, all the organic lesions are noticed, as observed in the fatal cases. The second part contains the history of the symptoms; and these are most full, comprehending, either affirmatively or negatively, notes upon the functions of every important organ. M. Louis' remarks on treatment are brief;

but every deficiency of that sort in the original is amply supplied by the additions of Dr. Cowan in his translation, who has, indeed, throughout shewn himself a very able and efficient expounder of the valuable performance which he undertook to illustrate.

MEDICAL GAZETTE.

Saturday, March 21, 1835.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE "SCHEME"

OF

DEALING IN MEDICAL DEGREES ABANDONED.

So!—the question of the London *University* having a charter, with the privilege of conferring degrees in medicine, has at last been definitively disposed of; and we need scarcely add, that it has been settled in the negative. After repeated applications to Parliament, after an annual siege of the Home Office, and after various petitions to the King—nay, after a pilgrimage from Guildhall to St. James's, of "wise men from the East,"—to this most lame and impotent conclusion have they come at last. So confident—so presumptuously confident, were they in the expectation of possessing the very unfair advantage which they sought to obtain over the other schools, that they actually announced in their prospectuses, not only that certain degrees would be conferred, but stated the time at which this would be done! It was not without cause, then, that we denounced this fanfaronade as an unworthy artifice to attract the notice of those at a distance) for it is on the supply of pupils from the country that they have all along depended); and it was not without sufficient reason that we set about

opposing their "scheme" by every fair means of ridicule and exposure, followed up by the more substantial step of having the true state of the question brought fully under the notice of the members of the government. It is not assuming too much to suppose, that the delay of what the parties had, at one time, all but in their grasp, and the present prospect of its speedy and final withdrawal, are in part at least attributable to the persevering and active opposition with which this nefarious attempt to raise a new medical school on the ruin of all the others, has been met in the pages of this journal. In this respect we have the satisfaction of reflecting, that we "have done the state some service."

When we drew attention, immediately after the assembling of Parliament, to Mr. Tooke's notice of a motion, having for its object to procure a charter for the London University, with the power of conferring degrees in medicine, we called upon those connected with the other schools to petition the House of Commons against the perpetration of such an injustice. Accordingly, petitions were got ready to be presented at the proper moment, and immediate communication was held with the Secretary for the Home Department. Numerous members of the opposition were also made acquainted with the facts; and we are quite satisfied, that Mr. Tooke's motion, if pressed, would have been negatived by a large majority. The declaration of Mr. Warburton against the motion, who, as Chairman of the Medical Committee, had heard the sentiments of the profession at large, would alone have been fatal to it; and the fact of his having stepped forward on this occasion shews in honourable contrast to the skulking silence of that member of our fraternity to whom accident has given a seat in Parliament, and who,

had he possessed one atom of candour or liberality, would not have left it for another, and a layman, to stand up in our defence; for we hold, that whether or not an association of speculating shareholders shall be allowed to deal in medical degrees, is a question involving the honour of the whole profession.

On its own merits, and on the *disinterested* advocacy of the *Lancet*, the London University must hereafter depend for its success; and we really do not think lightly of either. We know that it possesses several clever and accomplished teachers, but we also know that some of those who are now puffed so outrageously by our contemporary, were, a few years ago, held up to contempt in his candid and consistent pages. To the result of fair competition, even with the aid of what we may call its own proper journal, we object not: what we have set our faces against is the unfair attempt to ride over the other schools, by the mere weight of exclusive privilege; the effort to secure, by parliamentary interference, a monopoly, at the moment they professed to be opposed to every thing illiberal; the dishonest announcement of degrees in reversion, when they had not them to give, and well knew that it was extremely doubtful if they would ever succeed in obtaining such power.

However, it appears from what passed in the House of Commons on Tuesday, that the question is at length settled. Mr. Tooke said, "he was glad to be enabled to state, that understanding that there was reason to suppose that a medical board would be constituted in London, for the purpose of examining all candidates, and conferring degrees in the various branches of medicine and surgery, to which all the schools would be subject, he apprehended that the University of London would be recommended to agree to a restriction as to the power of con-

ferring degrees in medicine as well as divinity."

The arrangements alluded to we understand to be as follow:—Neither the London University nor King's College are to have the privilege of conferring degrees in theology, law, or medicine,—so that, in fact, they are to have nothing to do with the learned professions as regards the bestowing of licenses or honorary distinctions. The latter body already has, and the former is to have, a charter of incorporation, like many of the hospitals and other public institutions; besides which, they are both to be permitted to confer upon young gentlemen who have passed creditably through their preliminary general education, some mark or certificate of having done so by constituting them "*Associates* in arts." This is the appellation which we understand has been proposed, but we know not whether it has been definitively adopted; the only point being to select some appropriate title which shall not be confounded with the degree of Bachelor conferred by the English Universities. This is an arrangement which, while it bestows on the London University all the prerogative it has the slightest pretension to require, and on King's College all it ever asked, will have the advantage of holding out an encouragement to the preliminary studies, while it keeps the profession free from the immediate control of those engaged in teaching, and prevents medical diplomas from becoming the property of those who might convert academic honours into marketable commodities. The settlement of the question is earnestly to be desired, and we trust that the above, coupled with Mr. Warburton's expected bill, will accomplish the end in view.

The recent changes in the College of Physicians, sanctioned as they are by

the ministers, will no doubt anticipate some improvements which would otherwise have been contained in the expected measure, while they will probably be opposed to others; so that we do not expect that our friends in Pall-Mall will escape without some token of the honourable member's *regard*. Mr. Tooke, it will be observed, in the extract which we have given above, assumes that a board is to be appointed for the purpose of conferring medical degrees; and as it is quite clear that he has come to some understanding with ministers upon the subject of his motion, there can be little doubt about the authority on which this statement was made.

DEATH OF M. LOBSTEIN.

THIS venerable and distinguished member of our profession died on the 7th instant, of disease of the bladder. His chief published works are, *Researches on the Nourishment of the Fœtus*, an *Essay on the Great Sympathetic Nerve*, and a *System of Pathological Anatomy*. The school of Strasburg has thus lost two of its brightest ornaments within a very limited period.—Foderé, whose death we announced a few weeks ago, and now M. Lobstein.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

HENRY EARLE, ESQ. PRESIDENT, IN
THE CHAIR.

Tuesday, March 10, 1835.

A PHYSIOLOGICAL paper was this evening read to the society, by Robert Lee, M.D. F.R.S., which was entitled—

Observations on the Functions of the Fatal Kidney.

The author began by stating, that in the works of systematic writers on Physiology, little or no positive information is contained respecting the functions of the kidneys previous to birth. Haller, Blumenbach, Meckel, Bostock, and Mayo, he observed, had scarcely alluded to the subject,

and Magendie asserts that the condition of the fetal kidneys had not been ascertained, and that it is not known whether the kidneys form urine, or whether this fluid passes by the urethra into the cavity of the amnion. Abernethy was of opinion that the kidneys did not secrete urine till after birth, though some of the older writers believed the liquor amnii to be chiefly formed of the urine of the child.

The author then proceeded to state certain facts which he thought demonstrated that the kidneys of the human fœtus, like the liver, intestinal canal, and thymus gland, are in a state of activity, and perform each its respective function prior to birth.

Mr. Hay, of Osnaburgh Street, presented to Dr. Lee the kidneys of a still-born female child. Both ureters were impervious; and the pelvis of each kidney was greatly distended with a fluid which had the appearance of urine. The left kidney contained four ounces, the right nine ounces, of this fluid, which was analysed by Dr. Prout, and found to contain both uric acid and urea. A portion of the fluid, containing a deposition of lithic acid crystals, was exhibited to the society; and Dr. Prout concluded from the results of this examination, that the fluid from the kidneys of this fœtus with impervious ureters was of a urinary nature, and rendered it probable that as the liver in the fœtus secretes bile, so the kidneys secrete urine, long anterior to birth; and that, in a perfect state of the organs, the fluid is constantly escaping through the bladder. This fact, Dr. Prout remarked, had been often suspected, or rather taken for granted, but had never before to his knowledge been proved.

Dr. Lee then proceeded to state, that on the 12th of February last he had induced premature labour for deformed pelvis, in a patient who was six months pregnant, and had drawn off thirty-two ounces of pure liquor amnii with a slender silver catheter. Neither Drs. Prout nor Bostock could discover any trace of urea, or uric acid, in its composition. This observation renders it probable that a small quantity only of urine is formed by the fetal kidneys at this early period of gestation.

Dr. Lee had not succeeded in procuring specimens of pure liquor amnii at the end of pregnancy for analysis, though he had used every exertion for that purpose; but the presence of benzoic acid and urea, said by Berzelius to have been detected in the liquor amnii of the human subject by Frommherz and Gaugert, proved, he thought, that the urine of the fetus flows from the bladder, and mixes with this fluid in the latter months.

The author then quoted a remarkable case of a child with imperforate urethra, recorded by Mr. Howship, in which the bladder, ureters, and kidneys, were all distended with a fluid which had the characters of urine, and was believed by Mr. Howship to be urinary in its nature, though it was not chemically analysed.

Two beautiful drawings by Mr. Howship, taken twenty-five years ago from the parts soon after their removal from the body, were exhibited to the members of the society, and also a preparation of the parts themselves.

Dr. Lee's preparations were also handed round. The right kidney formed a sac, which was equal in size to the head of the child.

Sir B. Brodie informed Mr. Howship, that many years ago he had met with a male fœtus, in whom the external orifice of the urethra was impervious, and the bladder was moderately distended with urine, as were the infundibula and pelvis of each kidney. The urine was examined by Mr. Brande, who found it to have the other properties of urine, but to have no uric acid in its composition.

Dr. Lee next related a case from M. Billard's work, of a child who, four days after birth, had a round soft tumor in the lumbar region. On examination after death, this was found to be the right kidney, which consisted of a mass as large as a goose's egg, of semi-transparent lobules, irregularly agglomerated together, forming so many small cysts, full of a white inodorous fluid. The ureter was impervious. The bladder contained turbid urine, in which was found a great number of small particles of gravel as fine as sand. Another case of a still-born fœtus was quoted from the same author, in which the urethra was impervious, and the bladder contained an enormous quantity of a white inodorous fluid, which did not render trimsol paper green.

Dr. Lee concluded his paper, which seemed to excite much interest in the society, with a remark from M. Billard, that these observations might serve to prove that the excretions of the fœtus, at least those of the urinary organs, are passed in the natural state out of the body, and probably deposited in the liquor amnii; or, where there exists an obstacle to the passage of the urine, it flows back into its reservoirs, and distends them preternaturally, as we see in adults who are affected with stricture of the urethra, or paralysis of the bladder. This remark may hereafter find a place in the history of embryology.

Case of Disease of the Hip-joint resembling Fracture of the Cervix. By MR. CESAR HAWKINS.

AFTER some remarks upon the frequent discussions relative to union of the cervix femoris, Mr. Hawkins observed, that it was now generally agreed that union by bone, after fracture within the capsular ligament, was a very rare occurrence, and that many of the preparations formerly supposed to be examples of such union, were acknowledged to be specimens of a peculiar sinking of the head to a level with, or below, the trochanter, with shortening of the neck of the bone.

This change of structure has been well described by Sir Astley Cooper and other authors; but all the descriptions have been taken from dried preparations, or from the dissecting-room, and in none of them has the history been traced to an injury, with a knowledge of its subsequent progress. Examinations in the dissecting-room shewed that the appearances of the affected limb were very similar to those occasioned by fracture of the cervix; and Mr. Hawkins shewed some preparations which he had taken from a subject in the dissecting-room, in which he had observed these symptoms, and the sections of the bone looked very like the consequences of fracture; but as *both thighs* were in the same condition nearly, Mr. Hawkins expressed his opinion that they were deceptive only, and had arisen in reality from the disease in question. Like all preparations, however, obtained in this manner, without any history obtained during the patients' lives, there was a difference of opinion with regard to the cause of the sinking of the bone, and therefore the following history becomes very valuable.

An elderly woman, above 70 years of age, was placed under Mr. Hawkins's care, three days after having fallen down some steps upon the hip. She was unable to support her weight, or to move the limb, except to bend it a little with much pain. The toes were everted, but could be moved inwards with some pain; and the trochanter moved when turned in a smaller circle than the other thigh. The thigh was about three-quarters of an inch shorter than the sound one. There was also some bruise and tumefaction about the neck of the thigh-bone, with an indistinct sensation of crepitus. In short, Mr. Hawkins concluded that there was a fracture, by which the neck of the bone had been partly driven down between the two trochanters. The patient died of bronchitis thirty-eight days after the accident, having previously lost the pain and inflammation around the injured hip.

Some blood was found around the hip, and a drop or two within the capsule, but no fracture was found, nor any laceration of the bone. The upper part of the bone was sawn through longitudinally, and three preparations of these sections were exhibited. The interior of the bone was very vascular and dark, as if with extravasated blood, though none was really effused. In one section a white line was traced, having very much the appearance of an united fracture; but a quarter of an inch from this, another section shewed a different appearance, without any white line. The head and trochanter were approximated with depression of the neck to nearly a horizontal line. The other thigh-bone was exhibited to the society, the sections of which exhibited a softening and increase of vascularity, but without any alteration of figure; and other bones in the body were also softened, so as to be cut with a knife.

The case, therefore, was a curious coincidence of a blow just calculated to produce a fracture of the cervix, with disease (which Mr. Hawkins said must have existed *previous* to the injury); the symptoms of this disease being exactly like those of fracture, and the appearances on a *single* section being also such as a fracture might have occasioned, if complete union by bone had been possible in a weak person of her age in so short a time. Had the bone been examined in one part only, it might even now be supposed by some persons that the line across the cervix was that of a fracture; but as another section, a quarter of an inch only anterior to the other, exhibited no such appearance, this opinion was of course untenable.

Mr. Hawkins concluded by saying, that it could not be imagined that the disease had been *produced* by the blow, since the symptoms were in some respects better marked, from the presence of inflammation, at the time he first saw the patient, than they were at the time of her death, and since the same change of structure had commenced in the opposite thigh, and in other bones.

During the discussion which followed the reading of Mr. Hawkins's paper, some members observed that there might have been a *partial fracture*; but the preparation, Mr. Hawkins said, clearly proved that this was impossible, since, although the appearances of the section might be the same in fracture across a part of the bone, and in the disease in question, no partial fracture could in *this case* account for the depression of the head, and its approximation to the trochanter. In some cases a partial fracture across the *upper* or the *lower* part of the cervix might no doubt

allow the limb to be shortened by the remaining part of the bone bending downwards, as it did in partial fracture in young children; but the preparations shewed an apparent line of fracture only in the *posterior* section of the bone, and none in the *anterior*, so that the neck of the thigh-bone could not be shortened, had there been any fracture in this part of it.

CLINICAL LECTURE

ON

DISEASES OF THE KNEE-JOINT.

*Delivered at the Middlesex Hospital,
Dec. 6, 1834,*

By SIR CHARLES BELL.

WE shall continue the subject on which I addressed you last Saturday—diseases of the joints; and I must now more especially lead your attention to the knee-joint. I am sure that you have seen enough of the accidents and diseases to which the joint is liable, in the last half-hour, to mark its importance.

[The house-surgeon then read from the case-book the following list:—]

—————, injury of the knee by a fall.

Sarah Hinde, fractured patella.

Elizabeth Walpole, injury of the knee, previously affected with scrofula.

Susan Lyon, inflamed bursa.

Ann Brown, inflamed bursa, in a state of ulceration.

Mary Haller, hydrops articuli.

Susan Pontill, inflamed synovial membrane.

Susan Walsh, inflamed synovial membrane, with apparent enlargement of the bones.

Martha Meredith and William Quin, scrofulous disease, with great swelling of the knee-joint.

Susan Hunt and Sarah Oliver, acute pain of the knee, attended with hysterical symptoms.

John Stephens, knee contracted from rheumatism. Post-mortem.

Mary Davis, sympathetic pain in the knee, from inflamed hip.

Francis Phillips, scrofulous knee; true white swelling*.

* In addition to these, there have come into the hospital in the present week—a case of loose cartilage in the knee, and of a sprain, described to be from over-bending of the knee-joint, and supposed displacement of the cartilages.

Here then, gentlemen, is an argument eloquently delivered. By this simple enumeration you are told that you have no apology for ignorance of this subject; you have every opportunity of studying it. I shall limit my endeavours to the statement of some principles and of some circumstances; for the rest, you have but to look about you.

In the first place, why is it that the knee-joint is so frequently the seat of injury and disease? Because the bones are very large, and it is the largest and most superficial articulation of the body. The superficial position of the bones, and of the complex apparatus of the joint, make it not only liable to the influence of cold, to changes of temperature, but also to the influence of constitutional weakness. You will find, for example, that when there is disease of the bones, it is generally the superficial bones that exhibit the effects first, and to the highest degree; and when serofulous disease affects the ligamentous textures, the knee-joint is the most exposed to that influence.

The knee-joint being composed of bones which form each a large surface, and which have no socketing, there is no strength of the articulation from the mechanical adaptation of the one bone to the other, as in the hip-joint, for example; the surfaces are little more than placed in simple contact: hence it is necessary that the ligaments should be strong and numerous. I think you enumerate some sixteen ligaments as belonging to the knee-joint. Then, with regard to the synovial membrane, you know that it extends much further in the knee-joint than in any other, and necessarily so, not only because of the size of the joint, but from its being continued under the patella, and under the tendon of the quadriceps muscle. If the puncture of a joint be dangerous, the puncture of a joint the cavity of which is the largest, will be the most dangerous. Hence it is that the knee-joint is most exposed to injury, to constitutional influence, and that, when inflamed, the case is more formidable than when there is a similar affection of any other joint.

The very last case we looked at in the ward was an instance of a blow upon the knee-joint. Now that blow with a sharp stone upon the head of the femur, where it is covered by a reflection of the synovial membrane, is an injury to that membrane; and you may observe, as in that case, that the inflammation from such an accident rises very slowly—that is the character of the part; but at length the inflammation rises to an excess which you can scarcely describe in words too strong. This peculiarity is much more remarkable when the

capsule is punctured, than when it is hit and injured by a sharp corner without being punctured; the inflammation comes on very, very slowly, and you may be thrown off your guard, because many days may elapse before the utmost violence of the inflammation is exhibited. But at length you see the patient tossing with pain, rigid—not with convulsions or tetanus, but in the expression of intense suffering; his countenance flushed, his eye brilliant, and his pulse indicating the very excess of inflammatory action. Mark, then, that the inflammation of the knee-joint is attended with all this violence, but comes on so slowly that you are very apt to be deceived, and allow the patient to exercise a freedom of the limb which you have afterwards much reason to regret.

You will naturally inquire, what is to be done in these cases? When once you have seen a patient in this excess of fever and inflammation, you will observe the necessity of general bleeding, not merely to avoid the injury of the joint itself, but to prevent the violence of the action falling (of which, from the degree of excitement, there is danger), upon some other more important and vital organ. For these two reasons you bleed generally; and then comes the necessity for repeated local bleeding and fomentations. You find the patients treated by purging, and the saline draught with antimony; but frequently there is a necessity of giving calomel and opium to quiet pain, and sometimes colicium. By this time you will find not only the joint, but the limb, tumid all over; and when the violence of the pain and inflammation has a little subsided, you must cover it with slips of linen dipped in the *ceratum plumbi acetatis* and *diachylon*, so as to counteract in a slight degree the effusion which takes place in the cellular membrane. You mark with great care the coming on of abscess, and you open it early, otherwise the matter will burrow among the muscles. You will remember that it does not necessarily follow that these suppurations are connected with the knee joint; they are often consequent upon the violence of inflammatory action in the limb, and are quite different from the abscess which you see accompanying white swelling.

What is the termination? Generally, in ankylosis. The question will arise, in practice, what you are to do when the limb is getting fixed; whether you are to say that the ankylosis is a happy termination of the inflammation, with which you shall not interfere, or whether you are to attempt the restoration of the motion of the limb. Where you have a serofulous constitution to deal with, you had

better let the joint alone, and be satisfied with a stiff limb; but where there is youth and health, and no disposition to disease of the joints, no strumous tendency, you may begin to work upon it with embrocations, with friction, and with passive motion; that is to say, if you find the surfaces are not actually grown together by bone, you may by friction, warm oils, and motion (not under the effort of the patient, but by the hand of the rubber), gradually relieve the adhesion of the parts, and give freedom to the tendons in their sheaths. It is surprising how readily the whole apparatus of the joint is redeemable by being put to use. You will, however, be prepared for this, when you observe how a joint is formed when a bone is broken. If a broken bone, by motion, form a joint, how much more likely is a natural joint to become again moveable, though much disfigured and much destroyed in all its natural apparatus;—upon the great principle of Mr. Hunter, “put the part to its proper use, and the natural structure will be rebuilt.”

Last season there were some very interesting cases, which I may again shortly mention. There were two cases in which the knee-joint was opened; one of them was by an accidental wound, and in the other the operation was performed for extracting a loose cartilage: in both, the inflammation arose to the most severe degree. I will not hold up these cases to you in contrast again, but take the opportunity of pointing out to you a mode of avoiding the operation of extracting loose cartilages; and I am never more happy than when I can arrest your hand in using the scalpel, by the flourish of which so many surgeons at home and abroad obtain most undeserved reputation.

I alluded to one effect of these violent injuries of the joint—the formation of loose cartilages. You hardly ever find a patient with loose cartilage but you learn that at some previous time there has been an injury and a violent inflammation; so that it is a prevailing, and, I believe, correct opinion, that these loose cartilages result from an inflammatory process affecting the natural cartilages. However that may be, the symptoms are so distressing that we are tempted to cut into the joint and extract the loose body. But I mentioned to you, that the great advantage which we have in London, is the number of eminent and highly scientific and well-informed men, with whom we have occasionally an opportunity of consulting, and I take advantage of that circumstance now. In a conversation with that deservedly eminent surgeon, Mr. Copeland, he told me that he has on several occasions destroyed the loose

cartilage without the necessity of opening the joint; and the manner of doing it is to push up the loose body into the corner of the reflected capsule on the inside of the knee-joint, for example; and having got it there, to fix it. The manner is this: a ring is put on the prominence which marks the place of the cartilage; then a compress, adhesive strap, and finally a bandage. By this means the loose cartilage is fixed, and in time adheres; after which it is absorbed, or dissipated. I am quite sure, that if you remember the effects of a puncture of the knee-joint, whether accidental or done with all the care of the surgeon, and the destructive inflammation that sometimes arises from it, the violence of the suffering, and it may be the loss of the limb or of the life, you will be grateful for this exercise of ingenuity and of successful practice.

I will now advert to the case of

Hydrops Articul.

“Mary Haller, æt. 26, admitted November 18th. She observed a swelling of the knee a year ago, but had no pain in the swelling. She fomented the joint, gave it rest, and had it bound up; and in a week the swelling went down. Three months ago, the knee began to swell again; she bound it up, and the swelling disappeared. Three weeks ago it again began to swell. On her admission into the hospital the knee was puffy and swollen, chiefly above the patella. When the tendon of the quadriceps was pressed upon, the patella was raised up. There was no pain, except on going up stairs, and the knee was but little bent. The ankle was formerly similarly affected, but got well by bandaging. She was ordered a draught, with a grain of quinine and of sulph. of iron, with infusion of orange-peel; the knee to be surrounded with slips of lint, spread with ung. hydriod. potassæ, and rolled from the foot. In a few days the swelling almost entirely disappeared.”

Now this case brings us to reflect on the synovial secretion; and the first remark that I must make, I think may be of use to you hereafter; and I also think that the subject is too little adverted to in practical books—viz. that a slight inflammation of the synovial membrane will cause, we will not say the absorption of synovia, but a defect of the secretion of the synovia. The consequence of this deficient secretion is, that the joint, as it were, jars upon the hinge; the two surfaces of the cartilage come into such perfect contact that there is a jar, or crepitus, and very often, after certain injuries, the practitioner believes that he has got a fracture, attended with distinct crepitus, when it is only the motion of the two cartilaginous surfaces upon each

other, consequent upon there being no synovia in the joint, that produces the sound.

The next observation I would make is, that in dropsy of the joint, as it is called, the attack may have been inflammatory at first—that is to say, a copious secretion is thrown out in the second stage of inflammation; it may be therefore true that this effusion is a product of inflammation, and yet the case does not require the decided practice that inflammation of the synovial membrane demands.

From time to time I have put some of your hands upon the knee-joint, and bade you notice how little difficulty there is in ascertaining that the fluid is not only in the proper joint, but also under the tendons inserted into the patella. You will find, when there is any considerable accumulation of fluid in the knee-joint, that if you grasp the lower part of the thigh, and compress the great bursa there which communicates with the joint, you will then force up the capsule, raise the patella from the femur, and be able, by tapping upon the patella, to ascertain that it has so risen. This was particularly the case in this young woman.

Will you remember, too, that there is something in the natural structure of the joint that is very apt to deceive you? If a practitioner has forgotten the demonstrations that he had at lecture, he is very apt to conceive that there is a puffy swelling of the knee-joint, when there is nothing more than the natural fat of the joint projecting on each side of the ligaments of the patella. Remember that the interstices between the convexity of the femur and the head of the tibia are filled up with fatty appendages attached to the ligaments, and that these fatty appendages projecting on each side of the ligament of the patella, produce an appearance of puffiness. In order to fix this upon the mind, I will tell you a little circumstance. One of the heads of the profession, whose name is more frequent in your mouths than any other, and most deservedly so, had a very handsome sister-in-law. It happened that a young gentleman fell desperately in love with this young lady, and he took it into his head, that if he could get introduced to the brother-in-law, he might have an opportunity of seeing the young lady, who had taken his fancy in the ball-room. He went to him, being in perfect health, complaining of excessive pain in the knee-joint; and this gentleman, examining the joint, and tapping all around it, said, "Yes, there is puffiness on each side of the ligaments of the patella, and this puffiness being there, and the violent pain described, it is my duty to see that it is immediately attended to. I shall send

one of my young gentlemen home with you, and let sixteen leeches be immediately applied." A friend of the suffering gentleman had an opportunity of telling this to the young lady, and she was highly excited and delighted until it came to the *donoie-ment*—which was this, that when these leeches were applied, and the bleeding had become very profuse, he got very faint and sick, and never could think of the young lady again. So far he was wrong, and a fool at the end, as he was at the beginning. But you see it is possible, by the complaint of the patient, to be so far led from your just conception of the matter, as to take the natural fulness of the joint for puffiness or effusion.

How is the case of dropsy of the joint to be treated? In the first place, by fomentations with solution of the muriate of ammonia, with mercurial friction, with the ung. hydriod. potassæ, which in the case that has been read seems to have had a happy effect; blisters, alternately on one side and the other, and the blistered surface dressed with blue ointment. These, then, are the external means; but you must remember that the disease arises from a constitutional source: because I do assure you that I have found the complaint almost in every joint—in the shoulder, the wrist, both wrists, both ankles, and both knees. So that there can be no doubt that in these cases it was not a direct influence of injury to the joint that produced the swelling, but a very strong prevailing disposition in the system, which you must endeavour to counteract.

The first object, as I think I must have said before, is to correct the secretions and watch and order the bowels, since, without proper digestion and assimilation, there is neither health nor constitutional strength. There is a fashion at present of giving the blue pill, in doses of two grains, twice a-day. This, with a course of sarsaparilla, proves often the means of correcting the disordered state of constitution. What you see me most partial to in the strumous cases, is the liquor potassæ with bitters, or the carbonate of potash. It was with the idea of this young woman's state of constitution depending on chlorosis, that she had the sulphate of iron and sulphate of quinine in bitter infusion.

There is another practical point. I see it recommended that you should puncture the joint with a fine instrument. Now this appears to me quite out of the question; because the case does not require it. If you put down a bit of lint, dipped in spirituous solution of any kind, on the sides of the joint, filling up the irregularities, and then apply a roller skillfully, in twenty-four hours the fluid will be gone; and, as we say, we ex-

cite the absorbents. Whether we excite the absorbents or prevent the secretion, is practically of little consequence; but it is of consequence that we should be aware of what a puncture of the capsule may produce, and that puncturing it in such a case as this is not at all necessary. There is no difficulty in emptying the joints by the absorbents; the difficulty is to counteract the disposition to its return. When, therefore, the case is cured by puncture, there must be something more than the evacuation of the fluid; an action upon the surface of the synovial membrane must have been induced; and I may be excused for entertaining apprehensions of more violent inflammation arising.

White Swelling.

"Francis Phillips, æt. 15, was admitted May 29th, with a serofulous knee. Ten years ago he is said to have fallen down; the knee was swelled, and he was an outpatient here for two years. He went out upon crutches, and used them a year and a half: he then lived in the country. At the end of that time he left off crutches, and could run about; the knee, however, still continued swelled, but without pain. Two years ago he fell, and the knee bent under him; in consequence of which he was laid up for six weeks. A year and a half ago he had rubeola and scarlatina; since that time the knee has been occasionally subject to pain, and weaker than formerly. In the spring of this year it got worse, after a long walk; an abscess formed in the ham, and burst. Soon after this, his health became bad, and he was admitted into the hospital. The knee was then considerably enlarged, the surface round, uniform, and white, with blue veins upon the surface, and the limb somewhat bent. Abscesses formed on each side of the patella, which were opened; the openings closed, but have re-opened of themselves several times, after fresh attacks of cold and rigors. The opening in the ham has always continued more or less open from the time of his admission. He has been treated with light tonics, leeches, blisters, issues, &c. He gets a little better, and then a fresh cold throws him back again."

Now as to the name *white swelling*, it is objected to. If you please reject it; but at least understand the meaning of it. It is impossible that you could have gone round the hospital with me this morning without seeing that there are some diseased joints with, and others without, discolouration; and taking up the subject practically, one would at once say, we will arrange these joints in two classes, and call those not at all discoloured *white swelling*. When the joint is affected externally to the capsule

you have the usual character of inflammation. In these several instances, which you have seen of the housemaid's knee, where the outward bursa in front of the patella becomes the seat of inflammation, discolouration attends the swelling; but when there is the more formidable disease of the synovial membrane and cartilage, the serofulous disease which comes upon these internal parts in the first stage of the disease, there is a very peculiar swelling, one that you must especially notice, and it is without colour, that is to say, the joint is tumid, round, and pale, and as in the case "with a me blue veins upon it." You would at once distinguish this by the very term which has been long in use, that is, *white swelling*, the other affection being attended with discolouration.

You are aware that internal disease everywhere produces the same effect. Suppose a man has disease of the antrum highmorianum, there is a great swelling of the face but no inflammatory discolouration; suppose a man has disease of the frontal sinuses, there is a large swelling but it is colourless; it is a swelling sympathetic with the action within—it is not in itself the seat of disease. Now this is exactly what takes place in the serofulous disease commencing within the knee-joint; it is a *white swelling*.

What is the history of the case? The white swelling sometimes comes so distinctly and obviously from constitutional influence, that you find no blow, no sprain, nor wound of any kind, and that of course is unfavourable, as it implies that you will have more constitutional peculiarity to encounter in your cure. But on other occasions the disease takes its rise from local injury. I believe there is one case in the book which shows that a strain of the inner lateral ligament of the knee will degenerate into white swelling; and we know that a blow from a stone, which hurts the membrane by bruising it against the surface of the bone, will do the same. There can be no doubt, I conceive, taking the matter up practically, that a white swelling does sometimes begin in the cartilage; but in other cases it forms in the synovial membrane, or in the tendons and apparatus of the joint.

What is the progress of the complaint? Were I lazily inclined, I would say, read the cases in the book, or refer to what you have seen this morning; for in these fifteen cases you have all the features of the disease. However, let us run them over. There is deep-seated pain; this is always very alarming when the constitutional character, struma, prevails. Following this general pain there is swelling, and such as would lead us to believe that there

was an enlargement of the bone. I see it is put down in one of the cases, that the bones are enlarged. I am old enough to recollect when that was the very word used in determining the consulting surgeons as to the propriety of the operation of amputation. They would say, "The bone is enlarged; there is no hope here." Now the fact is, it is another disease altogether in which the bones are enlarged, and when this occurs, it may even give hope of ankylosis and cure. But it is a deception to believe that the bones are enlarged in white-swelling, and it is an appearance peculiar to the disease. The swelling takes place externally to the capsule; the effusion does not escape, on pressure, like œdema, the cells are distended with fluid, and sometimes they give such firmness and resistance, that you would actually believe the heads of the tibia and femur were enlarged one-third of their diameter, whereas when the limb is taken off and the integuments dissected, the bones are not a whit larger than natural.

The next thing that takes place is the contraction of the limb; and I should like to hear some of you explain this occurrence. It certainly marks as distinctly as the index of a clock the degree and progress of the inflammation. This contraction produces a good deal of apparent enlargement, from the new position of the bone: for the projection of the head of the femur adds greatly to the appearance of actual enlargement. This contraction will go on till the head of the tibia is altogether drawn behind the head of the femur; and I have made dissections where this bone was altogether pulled back and dislocated. I cannot at this moment state the reason why this should be, but I know it is most important that you should observe it. If I see a girl complaining of pain with her limb extended, I say the inflammation is external to the capsule; if I see another with her limb drawn up, I say the disease is more formidable and within the capsule. Always remember (and the review of this morning may tell you), that there is a contraction of the joint dependent upon hysterical affection. I have dwelt upon this from time to time, and I therefore now simply notice, that there is pain and contraction which all of a sudden gives way, like the other symptoms of hysteria. So there may be contraction from rheumatic inflammation in the muscles, and inflammation of the tendons and theca; but I am speaking here of contraction from diseases of the joint itself.

The next thing that marks a white-swelling, and indeed it is then no longer a white swelling, is the formation of a succession of abscesses. The violence of the

inflammation within produces an abscess in the cellular membrane without, and that abscess in time forms a communication with the joint; for I beg to state, that both here and in the hip-joint, in the early stage, there is no necessary communication between the joint and the abscess. These abscesses forming, and going through their regular processes and discharging, the appearances are more favourable; but then comes on a new accession of pain and fever, and new suppurations form and discharge, and become sinuses, so that a chain of abscesses goes round the whole joint, each successive abscess marked by a paroxysm of pain and inflammation, the regular return of which is one of the peculiarities of true white-swelling. You will observe in the case, that the friends state that he was thrown back by fresh colds. But that which they attribute to cold was the returning paroxysms of fever which attend the disease, and which sometimes attack the patient with surprising regularity. It is this fever which exhausts the patient, and comes to be an important consideration in the question of amputation.

But you naturally say, that the essential point is here omitted; what is doing in all these several cases. If I must mark certain things to be done under the head of cure, I would say, in the first place, the warm douche is advisable when disease of the joint is threatened, such as the frequent pouring of warm salt-water on the limb from a height; after which, let the joint be dried and rubbed well; an anodyne liniment may be used, and a flannel roller applied; a salt-water poultice is sometimes a good application. The next thing is a practice which you have seen to day, dabbing or spotting with blisters. In this disease leeches are to be applied but sparingly; but when you apply a blister, the excitement will extend further inward than you intend, unless you have preceded or accompanied it with leeches. But what I conceive to be much better is this dabbing it with a small blister, applied in succession to different parts of the surface, a fresh blister being put on every third day, so that the whole surface is kept in a state of excitement, without there being at any one time much violent inflammation produced. Moxa may then be applied, or kali purum, making two very small sloughs to-day and two to-morrow, thus keeping the whole surface by this mode in a state of activity. When the violence of the symptoms is subdued, you have seen the method of dressing; surrounding the joint with slips of lint, spread with the extract of conium, or the emplastrum thuris and mercurial oint

ment, or the ung. hydriodatis potassæ. Small slips should be put over and over and across every part of the joint, then a bit of oiled silk, plenty of cotton wadding, and over that a roller. When we have got over the violence of the disease, I believe this is a most excellent practice; that is, keeping the limb perfectly still, and attending, at the same time, to the constitutional peculiarities of the patient. As to the general constitutional symptoms, they may be combatted by sponging with warm salt-water or the use of the warm salt-bath. As I said, I much prefer the liq. potassæ, the bark infusion, bark with mineral acids or steel; in a young patient, the vinum ferri, soda, rhubarb, and precipitate of iron, and, lastly, iodine. This practice, generally speaking, is what you will find pursued in the wards at the present moment.

The last point upon which I shall address you, is on the question of amputation in this most formidable disease of the knee-joint. I do think there is too great a disposition to lop off limbs. It is certainly no great credit to the profession that we have recourse to this so frequently and so readily; however, there are cases in which we must do it. When the disease is irritating the general constitution, so that there is continual hectic fever, night-sweats, and wasting or diarrhœa—when, in short, the local irritation becomes so powerful upon the general constitution, that you are in danger of losing your patient, it becomes then a duty to amputate. Even when this is not the case, amputation may be proper, as when the joint is destroyed, the tibia twisted and drawn back from the head of the femur, the thigh and leg wasted: in short, when the whole condition of the limb is such, that if you could say, "To-morrow the disease will terminate," yet that limb would be an incumbrance. Since it would be much more in the way than a wooden leg, why attempt to preserve it at a certain hazard to life? If, then, this be the case, and at the same time the young person is hindered from all education, all hope of providing for himself, and he is teased and wearied with this continual complaint, although life be not in immediate danger, I conceive that we are bound to recommend the operation. But so long as there is any hope of the limb becoming stiff, and the bones uniting by ankylosis, I do not conceive that we are authorized to give such advice.

The meaning of all this discourse is to entreat you, for your own sakes, to keep a sharp eye on all these cases of disease of the joints. You have no apology for not attending to them; and you must consider

it as an expression of my friendly anxiety concerning you, that I take this opportunity of recommending you to do so.

ST. GEORGE'S HOSPITAL.

Hæmorrhage from Necrosis of the Femur—Ligature of the Femoral Artery—Slight Gangrene of the Toes.

ELEANOR DALY, about 60 years of age, was admitted January 14th, under the care of Mr. Hawkins. She has had some disease of the thigh for many years, and some abscesses have at present been open about a year, from which small quantities of blood have several times come away. Four days before her admission, however, violent hæmorrhage took place, requiring the use of the tourniquet to control it; this returned to a great extent yesterday, and on her way to the hospital to-day in a cart, notwithstanding the precaution of using the tourniquet, some more blood, though not much, had been lost. By all this she was almost entirely exhausted, and required the constant use of brandy and wine to keep her from sinking.

She was seen by Mr. Hawkins and the other surgeons soon after her admission, when in the state of exhaustion, and they agreed that it would be quite improper to do any thing for her at that time, as the least further loss of blood must necessarily have been fatal. It was a question what should be done for her, if she recovered sufficiently to admit of any operation. There were two or three openings in the thigh from which the bleeding took place, one in the ham, and two others in the inside and front of the thigh, so that it was impossible to tell whether the hæmorrhage took place from small vessels in the inside of an ulcerating and sloughing cavity, or whether the main artery had been opened; and if the latter, it was still very doubtful whether it might be from the femoral artery in the front of the thigh, or from the popliteal artery; and as the opening an extensive cavity in this uncertainty must have been attended with further effusion of blood, it was finally agreed that the femoral artery should be tied,—several cases of the success of this line of practice being related.

About four hours after her admission Mr. Hawkins came again to the hospital, and found her sufficiently sensible and re-

vived to allow him to tie the femoral artery above the abscess.

Jan. 15th.—The stomach has been so irritable that no food has been able to be taken, so that she has required the continuance of stimulants. She appears a little revived, the pulse being just perceptible at the wrist, though very feeble and variable. The foot and leg of proper temperature. She has had no sleep, though she lies tolerably quietly.

16th.—Very restless and delirious last night and to-day. Pulse a little firmer. Sickness and nausea continue, so that a little beef-tea is all the food she has taken since her admission. Slight appearance of mortification about the toes and sole of the foot, with vesication. The openings of the abscess have ulcerated considerably, with profuse thin discharge.

R Aect. Morphiae, gr. $\frac{1}{4}$; Ext. Conii, gr. iij. M. fiat Pil. 3tiis vel. 4tis horis sumenda.

17th.—Blackness very little extended on the toes to-day, but the warmth both yesterday and to-day is only preserved by hot bottles constantly applied. She lies nearly insensible, and can hardly swallow, small quantities of liquids being frequently put into her mouth, which she can only be made to swallow by stopping the nostrils for some time. Beef-tea enemata are also used. She was quieted by three pills yesterday and one again to-day, when she threatened to be restless.

18th.—No extension of the blackness; and what is dying appears to be only part of the cutis, which is becoming dry. She was quiet last night with one pill, and can swallow voluntarily, and answer questions; the warmth of the foot is also greater.

19th, 5th day.—Blackness a little increased, without swelling. The abscess of the thigh has become very extensively opened by ulceration and sloughing, and is very painful; the opening reaches from the calf to the middle of the thigh, exposing the flexor and gastrocnemii muscles and the popliteal nerve. She seems, however, much better as to her general state, and takes more nourishment.

Applr. Sp. Camph. Pedi.

20th, 6th day.—She is better, taking a little meat and some porter, and requiring less egg and brandy, &c., by which she has hitherto been kept alive; restlessness and pain very great, requiring the morphia pill occasionally; wound made in tying the artery nearly united by the first intention; bowels not open since her admission.

R Extr. Coloc. C. gr. viij. statim.
Enema commune vespere.

21st.—Repr. Pil. Coloc. C. Bowels open in the evening.

23d, 9th day.—Has improved a good deal in appearance, though still very exsanguine. Yesterday the foot was a little cedematous, to-day less so; no extension of the blackness, which seems to be superficial only. The abscess extending up the thigh, an incision became necessary at the upper part, so that the back of the limb is now open nearly from the calf to the trochanter. The orifices in front, between the sartorius and vastus muscles, have also enlarged. The discharge is very profuse, and she suffers dreadfully, chiefly from the exposure of the popliteal nerves.

25th.—More irritable, requiring the pills more frequently; countenance more haggard and anxious.

26th (twelfth day).—Hæmorrhage suddenly returned this morning to the amount of several ounces, by which she was much exhausted. The front opening being filled with coagulum, was enlarged, and the coagulum found to come from behind, where the bone was felt dead to some extent at the bottom of the large abscess. Pressure was made in the course of the vessel with bandages, and amputation proposed, if she revived sufficiently to justify the operation, but her friends refused their consent to it.

From this time she continued very restless, and suffered much from the sloughing of the abscesses in the thigh; the discharge from which, however, was not great. The dark parts on the toes and sole of the foot recovered themselves a good deal, so that the portions of the skin which were destroyed by the want of circulation were very small, and confined to the skin at the under part of the toes. She gradually sunk till the 31st, when she died.

On examination after death, the cavity at the back of the thigh was found to be very great, dissecting the muscles and popliteal tibial and fibular nerves; the latter being entirely insulated to some extent from the other parts, and surrounded by weak granulations. The popliteal artery and nerve were covered, on the surface next to the nerve, by similar granulations, and on this side of the artery was seen an oblong ulcer leading into the vessel, involving half the circumference of the tube, and about half an inch long; from which, no doubt, the hæmorrhage had occurred. On tracing the vein, it was found not to be above a third of its usual size, from the division into the tibial branches upwards

to the profunda; a very small part of it, where joined by the saphena, alone remaining of its proper size. The part of the artery on which the ligature had been applied, was closed on both sides by a coagulum, and the ligature was very nearly loose. A considerable part of the back of the femur, where it expands into the condyles, was exposed and dead, and an opening led into the centre of the shaft. The mortification was found to be very slight and superficial; a great part of what had been dark having recovered its proper colour and circulation before her death. Viscera healthy.

WESTMINSTER HOSPITAL.

Dropsy from Diseased Kidneys.

JAMES WILLIS, æt. 19, was admitted into King William's ward, under Dr. Roe, January 14th, 1835, with anasarca swelling of the whole body; the œdema extending from the ankles to the thighs and scrotum. The abdomen was lax, but fluctuated; the wrist, arms, as well as the face and palpebræ, partook of the general anasarca; the skin was pale, even to exsanguinity, and the extremities had a peculiar marbled or mottled appearance; countenance strikingly phlegmatic; pulse 80, small, and compressible; tongue dry, inclined to brown; bowels regular, without the use of opening medicine; urine scanty, not more than a pint in the twenty-four hours, and of a white milky appearance, but often varying in colour and quality, abundantly coagulating by heat; respiration 30; dyspnœa on very slight exertion; slight evidence of the râle crepitant humide; heart's action perfectly normal; appetite unimpaired, but craves constantly for drink. The patient's illness is of not more than five weeks' standing; he was previously in very good health, and was generally accounted a healthy lad. The patient cannot refer his symptoms to any particular cause, as they came on gradually, first by œdema of the feet and ankles, attended by diminution and altered quality of his urine. Is a shoemaker by trade, and possesses a character for remarkably temperate habits. Has been an out-patient of this hospital for the last three weeks, and has been twice bled to the extent of 5vj. each venæsection, with apparent relief to the dropsical symptoms. He was ordered at the same time to take the compound pill of calomel, digitalis, and squill. The symptoms have, however, now become so aggravated, that Dr. Roe con-

sidered him a fit object to be admitted as an in-patient. He was ordered

Fish diet, and Pil. Hyd. e. Pulvere Scillæ et Digitalis. Capiat unam quartis horis et ad libitum Potassæ Supertart. bibendum.

Jan. 17th.—Ptyalism has been induced by the pills; urine had not increased in quantity till last night,—about three pints were passed in the twelve hours: it is of an orange-brown colour; coagulates copiously by heat. ʒiij. of the urine contained 18·25 grains of dry albuminous matter. Tongue clean; pulse small.

Omittantur Pilulæ et utatur gargarism. Aluminis, p. n.

19th.—Nearly a pint and a half of saliva is secreted from the mouth in the twenty-four hours; urine about four pints in the same period; œdema of the legs somewhat less; face still continues puffed; urine much clearer and lighter coloured; sleeps well, and can lie equally on either side; maintains without difficulty the recumbent position.

Capt. Potassæ Carb. in statu effervescentiæ c. Acido Acetico dil. et Tinct. Scillæ, ʒss. pro dosi quarta quaque hora. Omittatur Potus Potassæ Supertart.

22d.—His urine has increased to near six pints in the twenty-four hours; anasarca much diminished; hæmorrhage from the mucous surface of the mouth; craving; thirst; appetite continues good; bowels regular.

24th.—Urine still continues to increase; anasarca generally subsiding.

Cont. Mist. Efferves. Superbibet Decoct. Spartii Scopar.

26th.—Is much improved in general health; limbs the natural size; urine clearer; appetite good. Feet and ankles swell towards night.

27th.—Has not felt so well the last twelve hours. Urine has become scanty, and deposits much animal matter on cooling. Fluid is rapidly mounting from the ankles upwards; tongue dry and brown, but not coated; pulse 80, small. Some degree of dyspnœa is induced in the recumbent position.

Decoctum Uvæ ursi, Oj. quotidie bibendum.

31st.—Anasarca continues to increase; orthopnœa. Succussion affords obscure evidence of fluid in the thorax. The uvæ ursi has caused so much pain in the sto-

mach, that it was discontinued. Complaints this morning, for the first time, of dull heavy pain in the loins.

Repetatur Haustus Effervescens.

Feb. 14th.—Anasæra partially subsiding; orthopnoea has diminished, and he can lie down in bed; sleeps well; bowels continue regular; appetite unimpaired. His diet has more than once been changed from fish to rice pudding, &c. An examination was this day completed of the relative quantity of dry solid albuminous matter contained in three ounces of urine passed while an out-patient, and that voided on the 27th January. The former contained 18.25 grains, the latter 19.50 grains of animal matter. The hospital does not afford the means of ascertaining the specific gravity of fluids. The patient continued in much the same state to the

11th, when the anasæra again returned; the face became much puffed, and palpebræ quite closed; respiration hurried and difficult; urgent dyspnoea; percussion affords evidence of fluid in the chest; stethoscopic symptoms; râle crepitans humide; indistinct murmur at the inferior regions of the thorax; urine not more than one pint daily, depositing much animal matter on cooling.

Pil. Hyd. Sub. e. Scilla sine Digitale.

14th.—Œdema of the face increased; vision obliterated; respiratory murmur indistinct at the lower regions of the thorax; râle crepitans humide very evident in the mammary region of both sides.

10 P.M.—Breathing has become still more urgent; respiration husky and stertorous; frequent sense of suffocation; tongue dry; a blackish stain on the dorsum; pulse scarcely perceptible, from the œdema of the wrists; the cuticle of the legs and thighs is perfectly glaring, from over distention; urine about three pints. Can only exist in the upright position in a chair. A vein was opened, but only an ounce could be obtained.

Appl. Empl. Lyttæ cruribus.

15th.—The blisters have risen well, and many pints of fluid have drained away; respiration more free from anxiety; face not so much puffed; can return to his bed; suffers much from cough, returning in severe paroxysms.

Spiritus Æth. Nitrici, ʒj. p. r. n.

Heart's action laboured, about 118 beats per minute.

16th.—Passed a very restless night; respiration continues stertorous and husky; countenance sunken. The effort of speak-

ing is too much for his respiratory powers. He continued in this state till 12 o'clock at noon, when he died.

Sectio cadaveris, 21 hours after death.—The whole surface of the body was anasærous, and the cellular tissue of the surface perfectly infiltrated. About four pints of a dark, clear, brown fluid, were found in the cavity of the thorax. The lungs were partially œdematous, and gorged in places with blood. One or two detached tubercles were observed. The pleura had contracted no adhesions. The abdomen contained about six pints of fluid. The liver was much enlarged, and when cut into, presented a granular majuscated appearance. The kidneys were externally pale, much enlarged, somewhat more lobulated than natural, and not at all differing from each other in morbid appearance. On a section being made, the structure of the organ was well shewn; the cortical part was pale and much indurated. The tubuli presented their accustomed fasciculated projections, but around them an interstitial deposit of a white granular cartilaginous substance had taken place, appearing to be lost in, or continuous with the cortical portion, and dipping down and surrounding the calyces, so as to give the morbid structure a convoluted appearance. There was more than a usual quantity of fat about the infundibula and pelvis of this organ. The bladder and ureters were healthy. No morbid appearances could be detected elsewhere.

This, I think, must be considered a case of dropsy arising from that abnormal condition of the kidney pointed out by Dr. Bright. It must be observed, in the foregoing report, that the patient has but once (although frequently inquired for) complained of that pain referred to the loins, and accompanied by a corsting sensation passing across the abdomen, which Dr. Bright has considered as pathognomonic of that degeneration of the renal organs, to which he called the attention of the profession. Notwithstanding the absence of a symptom so prominent in most of the recorded cases of this disease, the post-mortem appearances of the kidneys can leave no doubt as to the nature of the affection. An additional testimony is also afforded of the unfavorable nature of our prognosis, and the utter hopelessness of remedies in this universally fatal disease.

ADVANTAGE
OF THE
EARLY EMPLOYMENT OF THE
CATHETER,
IN CASES OF RETENTION OF URINE.

To the Editor of the Medical Gazette.

SIR,

READING in one of your late publications of camphor and ammonia as a cure for retention of urine, I beg leave to offer to the consideration of your surgical readers a different practice to that which is generally employed in these cases. I mean, that in all cases of retention of urine, except in those in which some mechanical obstruction is known to exist (as permanent stricture), it is far better to use the catheter immediately, than to try a number of different supposed remedies. These very frequently fail, as I have formerly experienced; and by the time they occupy, not only suffer the bladder to be more distended, but add very greatly to the agony of the patient, and increase the local and constitutional irritation. In fact, they place him in a much more unfavourable condition for the introduction of the catheter than he was some hours before.

There is another very great advantage derived from the early use of the catheter; it is seldom necessary to repeat it above once or twice; whereas, when the complaint is suffered to continue for forty eight hours, or longer, it requires many weeks, or months, for the bladder to recover its healthy action.

In the course of a rather extensive practice, I have for some years followed this plan, and almost universally with success. I have now a gentleman for whom it is necessary to introduce the catheter daily, and has been for more than a year, in which case the catheter was not introduced till the very last extremity, in consequence of a former surgeon having declared, from certain circumstances, that it was impossible to introduce it.

If the catheter cannot be introduced without producing hæmorrhage and great pain, bleeding and other means must necessarily be instituted before the attempt is persevered in. I always use a large catheter.—I am, sir,

Your obedient servant,

W. HILL.

LECTURES

ON THE

DISEASES OF THE CHEST,

In the course of which the Practice of

PERCUSSION AND AUSCULTATION

IS FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE XXVI.

NERVOUS DISORDERS OF THE HEART AND ARTERIES.

By nervous affections of the heart and arteries, we mean the affections of those organs which do not depend upon organic changes of their structure. The symptoms of these disorders are not of permanent duration, and they appear at indeterminate periods. We shall describe them in the following order:—

1. Angina pectoris, or neuralgia of the heart.
2. Nervous palpitations.
3. Spasm of the heart, with bruit de soufflet and fremitus cataire.
4. Nervous affections of the arteries.

ANGINA PECTORIS.

This disease usually commences with a sensation of pain, oppression, weight, or constriction, at the cardiac region. In severe cases, the patient feels as if the heart were violently squeezed; and he then supports himself by firmly embracing any fixed object; at the same time he retains his breath, for the purpose of relieving himself from this sensation. As the fit continues, the dyspnœa is often extreme; sanguineous congestions are formed towards the head and face; occasionally syncope or convulsions supervene, and the patient manifests the most unceasing jactitation

and apprehension of imminent suffocation. I have seen instances of sudden death occurring in the midst of the most agonizing distress. The access, after lasting for an uncertain time, usually ceases, to recur at an indeterminate interval. Certain circumstances often invariably bring it on in the same individual at any period. Thus, if he endeavours to walk a little quicker than usual, or ascends an inclined plane, the sense of obstruction, or weight, or squeezing, and the dyspnœa, immediately come on, and he is obliged to rest a few moments, and these feelings then generally suddenly disappear. Emotions of the mind will also occasionally reproduce the same symptoms.

Previous to and during the access, a painful numbness is felt in the inside of the left arm; it is rarely experienced in both arms, or on the whole of the left side of the body; and more rarely still in the right arm only, or in the four extremities. This sensation is usually felt along the inside of the left arm, from the axilla to the elbow; sometimes it continues in the course of the ulnar nerve to the little finger, and to the ulnar side of the ring finger. These pains often follow, also, the course of the left anterior thoracic nerves, and are therefore felt upon the left anterior parietes of the chest; they vary not only in situation but also in character; occasionally there is a sensation of mere numbness without pain; sometimes the pain and numbness are combined. The increase of the sensibility of the skin and mammæ is often so great that the slightest pressure is excessively painful. I have met with patients whose torments have been so great, that they described their flesh to feel as if torn by the talons of an animal. These signs finally disappear for a time, leaving only a slight numbness or uneasiness of the parietes of the chest and of the inside of the left arm.

I have often observed, that these neuralgic sensations attacking the parietes of

the chest occurred alone, especially in a slight degree, without any feeling of obstruction, weight, or squeezing in the region of the heart; the anterior thoracic nerves being then only the seat of the neuralgia. Sometimes the cardiac symptoms are present, unaccompanied by any pain on the surface of the chest or in the arm. When the junction of both sets of symptoms obtains, then the *angina pectoris* may be said to be completely formed.

Angina pectoris, in a moderate degree, is by no means an uncommon affection; but the disease, in its most violent form, is very rare. In ten years, I have seen but two instances of death occurring during the violence of the paroxysm.

When the anterior parietes of the chest and the arm are affected, there can be no doubt that the disease depends upon some peculiar condition of the nerves supplying these parts,—a condition similar to that which occurs in the facial nerve in *tic douloureux*, and to which the term *neuralgia* has been applied,—an expression simply denoting the fact of pain or aching of the nerves, without implying any notion of their specific lesion. But when the heart is also affected, various opinions have been entertained as to the cause of the symptoms.

Heberden and Parry, Bertin and Kreysig, believed the disease to depend upon ossification of the coronary arteries. The Germans and Italians are of opinion that it is consequent upon some organic disease of the heart; but the only means by which such questions can be decided—the scalpel—has distinctly shewn, that although *angina pectoris* may coincide with every organic change of the structure of the heart, yet that it exists often also independently of any apparent lesion of that organ. The cause of the disease must therefore be referred to some inexplicable state of innervation. It is probable that when the cardiac symptoms exist alone, that the disease depends upon a lesion of the eighth pair of nerves, and of the filaments sent to the heart by the great sympathetic. When the anterior parietes of the chest and the inside of the arm are only affected, the anterior thoracic, the internal cutaneous, and the ulnar nerves, are the seat of the disorder; and finally, in those cases when the heart, lungs, surface of the chest, and inner side of the arm, are thus affected, then these combined disorders are the result of a simultaneous neuralgic state of all the nerves supplying these parts.

Treatment of angina pectoris.—*Angina* often affects individuals in whom the digestive functions are in a state of derangement. It is necessary, in such cases, to pay great attention to the stomach and

bowels, obviating accumulations by gentle emetics and purgatives, correcting acrid secretions by antacids—as the soda, and chalk, and magnesia—and giving tone by the employment of tonics, as iron, quinine, &c., combined with carminatives.

When the attack has arrived, the patient should be placed in a state of repose,—at least as much as his irritability permits; for sometimes his extreme distress forces him to quick movements or violent strainings, which no effort of volition can control. Bleeding, at this moment, has been recommended, if the patient be plethoric; but it is a remedy of suspicious value in most cases. Opium, the diffusible stimuli,—as æther, camphor, &c.—the fetid gases,—as *assaftetida*, are often highly advantageous during the access.

During all periods of this disease, I have long been in the habit of employing the belladonna to the surface of the chest, and generally with excellent effect, especially if the *angina* be not complicated with organic lesions of the heart; although even then it affords temporary relief. I prescribe a plaister, of the size of the hand, formed of one part of extract of belladonna, mixed with four parts of soap plaister, and place it upon the region of the heart. I once had an opportunity of seeing the full effects of this medicament in a most unexpected manner.

I was requested, about three years since, to see a gentleman who had just arrived in London from Dublin: I found him labouring under a severe form of *angina pectoris*,—so severe, that he could bear no movement whatever, except upon the water, without its producing a violent access; he had therefore lodged himself in a street close to the Thames, for the purpose of readily obtaining the only exercise he could enjoy. Upon a most careful examination of his heart, I could find no organic disease, nor could an eminent physician, Dr. Billing, who is a practised auscultator. The usual belladonna plaister was applied to the chest of the patient about the middle of the day; towards evening alarming symptoms arose: he became slightly amaurotic, his head was confused and giddy, and he articulated his words with great difficulty. The plaister was immediately taken off, and the surface of the skin beneath it was found covered by ulcerations of various sizes, produced by the action of the tartar emetic ointment; a circumstance which of course we had been totally unacquainted with. He recovered the integrity of his functions in a few hours, but the symptoms of *angina* had totally disappeared. The patient returned home in the mail coach, the movement of which, for a long time before, he could not have borne, and from that time

he has remained perfectly free from his disease.

Laennec had great confidence in the magnet in angina pectoris. He applied a plate of steel, of a line in thickness, and strongly magnetized, upon the left precordial region, and a similar one exactly opposite, on the back, so that their poles were opposed to each other, and the magnetic current traversed the parts affected. He frequently applied a blister under the anterior plate. I have tried this plan, and have thought with good effect.

Blisters, tepid shower-baths, and change of air, are often of utility also in this affection.

Nervous palpitations of the Heart.

Purely nervous palpitations of the heart are often more distressing than those which arise from organic causes, for, instead of diminishing by repose, they are often aggravated by it. They usually commence at the beginning of the night, and the patient, for many hours, obtains no sleep. A moderate exercise often diminishes these palpitations, or at least distracts the attention from them.

Palpitations consist in the beatings of the heart being sensible to the patient; the impulsion, noise, and frequency of the pulsations of the organ are then increased; a sensation of internal agitation, particularly in the head and abdomen, is consequent upon this state. The urine is generally clear and limpid during the access. The duration of these palpitations varies; when they arise from a sudden emotion, they may pass off immediately: in young, plethoric, nervous persons, they may last for years, with but little intermission.

It has been supposed that purely nervous palpitations must ultimately induce hypertrophy, or hypertrophy with dilatation of the heart: this fact, although probable, has not yet been proved.

Nervous palpitations differ from those produced by hypertrophy, or hypertrophy and dilatation of the heart, inasmuch as in the former the application of the stethoscope shews that the organ is not really of considerable size, the noise of the pulsations is not heard to a great extent upon the surface of the chest, and, above all, the shocks communicated by them have but little impulsion, for they never sensibly move the head of the observer. Sanguine congestions rarely form, except in old persons.

These palpitations are very frequently found in hypochondriacs and hysterical women. Their treatment merges into that recommended for these diseases. Warm or cold baths, according to the season, may be used. Digitalis, combined with antispasmodics and tonics, I have often seen produce advantageous effects.

The hydrocyanic acid has been also employed with some success. Bleeding is rarely beneficial, but is often hurtful in nervous persons, except they be plethoric. A change of air, combined with constant pleasing occupations, are perhaps the most useful means of combatting this disease.

Spasm of the heart, accompanied by bruit de soufflet and fremissement cataire.—The bruit de soufflet of the heart, although frequently connected with organic lesions of the organ, may exist independently of them. It then depends upon some peculiar state of innervation. This sound is found particularly in hypochondriacs of sanguine and nervous constitutions. Frequently it is present in some artery at the same time. Often the bruit alternates from the artery to the heart, and from the heart to the artery. It is sometimes continued, occasionally intermittent; in the latter case it is produced by the slightest mental emotion: even coughing, or breathing deeply, may be sufficient to cause it. The symptoms are usually serious in proportion to the intensity of the sound, to its duration, and to its extent in the heart and arteries. When the bruit is marked, and continued in the heart only, there is always more or less dyspnoea and general weakness: these symptoms are aggravated if the fremissement cataire be present also. There is usually but little nervous agitation, especially if the patient be in a state of repose; but in walking quickly, dyspnoea is soon produced, and, in severe cases, the head becomes affected by exercise as well as the lungs.

Nervous affections of the arteries.—These disorders may be considered in three points of view:—1st, arterial neuralgia; 2dly, augmentation of arterial impulse; 3dly, spasm of arteries, with bruit de soufflet and fremissement cataire.

1. *Neuralgia of the arteries.*—Pains, more or less violent, continued or intermittent, sometimes follow the course of the arteries, and appear to be seated in the nervous network furnished by the ganglionic system surrounding these vessels. These pains are commonly found in hypochondriacs and hysterical women. The treatment recommended for angina may be employed here. A blister applied over the affected artery is very often efficacious.

2. *Augmentation of arterial impulsion.*—It occasionally happens that the pulsations of one of the carotids, temporal or radial arteries, are stronger than those of the other. In many persons in health there is a perceptible difference, the right pulse being stronger than the left. Sometimes the radial arteries will pulsate alternately, with a different force.

The abdominal artery is often the seat of this augmented impulsion: the vessel

then always appears increased in its fullness also.

When the impulsion exists only in a small or middle-sized artery, it scarcely affects the general health, except it occurs in consequence of inflammation of the parts which that artery supplies: thus, when the hand or fingers become inflamed, the digital, radial, or cubital, or even the brachial artery, beat more strongly than those of the opposite or healthy side. Anormal pulsations of the carotids often accompany nervous affections, but are not always present in persons menaced with apoplexy.

Nervous palpitations are sometimes combined with increased impulsion of the arteries of the whole body: the beatings of these vessels are then universally felt, and very small arterial branches often become perfectly visible under these circumstances.

These palpitations, when they affect the aorta, or any portion of it, always produce sensations which are more or less painful. When the ascending aorta is thus disordered, it causes a certain degree of dyspnoea, anxiety, and disposition to syncope; its beatings are heard above the middle part of the sternum, stronger and more noisy than at the heart itself. If the descending aorta be the seat of the palpitations, the symptoms are nearly the same: the pulsations can then also be heard with greater distinctness on the back, and particularly on the left side, near the vertebrae, than in the precordial region.

Nervous palpitations are more commonly found in the abdominal aorta than in the rest of the course of that vessel. Gaseous accumulations, forming tumors, often arise over the artery, and, as the pulsations are communicated through them, they frequently simulate aneurisms; but these swellings and pulsations rarely remain above a few days, and upon examination with the stethoscope the impulse is never strong, bounding, and extensive, like that of aneurism. The pulsations also are confined to the natural caliber of the artery.

Spasm of the arteries, combined with bruit de soufflet.—When the bruit de soufflet exists in a moderate-sized artery, and is found in only a small part of its course, and particularly if it be intermittent, it is usually accompanied by slight nervous agitation and an acceleration of the pulse. This state is especially found in young hypochondriacs of sanguine or sanguine-lymphatic temperaments, under the slightest exercise or mental emotion. The bruit is usually distinguishable in the subclavian arteries—more rarely in the carotids—more frequently on the right side than on the left. It commonly occurs in persons attacked by disease of the heart, or nervous palpitations.

When the bellows-sound is situated in the aorta, and particularly in its abdominal portion, there is great anxiety, and a tendency to lypothymia, from the slightest causes: the pulse is then always quickened.

When the two carotids are affected, especially if the *fremissement cataire* be felt also, the same symptoms obtain, although in a less degree. When the sound exists at once in the heart, the aorta, the carotids, subclavians, brachial and femoral arteries, the anxiety of the patient becomes extreme, the respiration is oppressed, the pulse is frequent, and sometimes he experiences the sensation of great internal heat, although the skin, &c. indicates no sign of fever. This state is attended with considerable danger, and death may even be the consequence.

If the *bruit de soufflet* be very intense in a number of arteries at once, the *fremissement cataire* is usually perceptible in some of them; the latter phenomenon is not, however, always found to be in proportion to the intensity of the bellows-sound, nor to its extent, for it sometimes occurs in one of the carotids when the bruit is very feeble.

In many cases where the *bruit de soufflet* is tolerably evident in the arteries, the pulse of the radial arteries produces a trembling or trilling vibration, similar to that which a tight metallic string, slightly struck, would give to the end of the finger. This is probably but a minor degree of the *fremissement cataire*, yet it is often found where the *bruit de soufflet* is present in some arteries, and the *fremissement cataire* in none. It is sometimes also present when there is neither the bellows-sound nor *fremissement cataire*; but then the former sound can often be produced by making the patient walk gently, or inspire or cough forcibly.

This trembling, or trilling vibration, can often be produced by a certain degree of pressure upon the artery with the finger; it is then sometimes felt for a moment, and then lost. If the pressure be increased, it instantly re-appears, but it is extremely difficult to seize and continue the precise degree of compression necessary to render the sensation, under these circumstances, permanent, or to produce it at will.

The bellows-sound may exist in the highest degree with or without the *fremissement cataire*, either in the heart or arteries, without any increase of their impulsion. When these circumstances are united, the above-described symptoms become infinitely more marked.

Treatment of neuralgia of the arteries.—When the arterial impulsion is greatly increased, bleeding is indicated; and it is often by that means alone, frequently repeated, that any relief can be obtained;

but abstraction of blood should be very cautiously effected if the *bruit de soufflet* exist without impulsion. Tepid warm and shower baths, of that degree of temperature that the patient may feel ultimately a slight sensation of cold, are commonly very useful. Laennec asserts that he has occasionally found success by the use of the magnet, when the *bruit* existed only in the heart and aorta. If the *bruit de soufflet* is found without increased impulsion in pale and cachectic subjects, then iron, the fetid gums, and tonics, often produce good effects. A moderate diet, and abstinence from all kinds of stimulus, should be recommended.

Displacements of the Heart.

The heart is retained in its natural position by the diaphragm, the mediastinum, and the habitual plenitude of the chest; but the following circumstances may force it to deviate in various directions:—

The organ may be thrown to the right side by effusion of fluid or air, or by large tumors placed in the left pleuritic cavity.

It may deviate from its position farther to the left side, by the above causes operating from the right pleuritic cavity.

It may be forced *upwards* by aneurisms of the abdominal aorta, by tumors, and by ascites.

It may be forced *downwards* by the compression of an aneurism of the ascending aorta, or its arch, or by any other voluminous tumor situated above it. The heart, also, has been seen in this situation without any obvious cause; this is the *prolapsus cordis* of the older authors.

Malconformation of the Heart and great Blood-vessels.

A circumstance essentially necessary to the healthy state of the circulation is, that the blood should have free access to the lung during a portion of its course round the system. If, by any derangement or alteration of the heart or its vessels, that fluid is prevented from entering into the pulmonary organs, death is the immediate result. The case of malconformation I shall first speak of, is that in which there is no communication whatever between the heart and lungs. It is what is called a single heart, and its parts are arranged in the following manner:—

The two *venæ cavæ* enter into the auricle in the usual way; the auricle communicates with a ventricle, from which the aorta arises; there is but one auricle and one ventricle, an aorta, but no pulmonary artery or veins. The blood, therefore, in this case, can never be renovated by the contact of the atmospheric air; it is therefore venous in the systems of the arteries

and veins, and the subject can live but a very short time after birth.

It is necessary also, for the healthiest state of the circulation, that the arterial and venous bloods should be kept separate and distinct from each other; thus it is that they flow in different sets of vessels, the arteries and veins; thus it is they are prevented from intermingling in the heart itself, by the septa of the auricles and ventricles. If by any alteration of the structure of the vessels, or of the heart, these two fluids can intermix, then disorder will be the result. If the mixture occur from a lesion of the arteries and veins, the affection is generally local, and but of little consequence; if it occur in the heart, it always occasions, sooner or later, a fatal result.

A vein and artery are sometimes seen to communicate, so that the blood flows directly from one into the other. This constitutes a varicose aneurism; but the disease is confined to the lesser parts only; the quantity of blood intermingling is insufficient to disturb the general circulation. Occasionally the smaller arteries and veins open and communicate with each other, as in certain *nævi*; but the consequences here again are only local, the system remains undisturbed.

But when the admixture of arterial and venous blood takes place in the central organ of the circulation, then the most serious results occur, in consequence of the quantity of these different fluids which become mixed, and by which union each of them is deteriorated, and unfitted for the specific functions which it has to perform. All the malconformations I have to describe have for their consequence the mixture of the arterial and venous bloods in greater or less proportion, as well as the difficulty of transmission to the pulmonary organs.

Malconformation of the heart may be divided into two classes—1. *single hearts*; 2. *imperfect double hearts*.

1. *Single hearts*.—The following is the usual structure of a single heart:—The two *venæ cavæ* and the four pulmonary veins enter into an auricle; the auricle opens into a ventricle, from which arises an aorta; the aorta soon gives off two pulmonary arteries, which proceed to the lungs, and then the vessel continues in its usual course.

In this case there is a perfect mixture of the arterial and venous bloods. The black blood passes into the auricles from the two *cavæ*, and mixes with the red blood flowing from the four pulmonary veins into the same auricle; the united fluids are propelled into the single ventricle; the aorta then receives them, and transmits these fluids all over the arterial system, and to the lungs also, by the two pulmonary arteries arising from it.

Two or three modifications of this form of single heart have been observed, but they are but slight. Thus, in the above case, two pulmonary arteries arise from the aorta; sometimes, however, there is only one, which afterwards divides into two branches; and occasionally the aorta and pulmonary artery originate in the single ventricle by a common trunk.

2. *Imperfect double hearts.*—These imperfections consist in the incompleteness of the septum of the auricles, or of the ventricles. In either case the arterial and venous blood must intermix.

Species 1: Imperfect septum of auricles.—The foramen ovale is often found a little open; but from the equal pressure of the fluids in the two auricles, and from the slightness and obliquity of the opening, rarely any intermingling takes place. I shall state the following case of a patenscent foramen ovale, which I believe to be unique; at least, I know of no such case on record.

I was requested to see a young man of about 18 years of age. I found him labouring under the most severe dyspnoea; his face, body, and limbs, were œdematous, cold, and of a dark slaty purple tint; the beatings of the heart were strongly impulsive, and extended over the greater part of the parietes of the chest; the lungs were infiltrated with serum; the “rhoncus crepitans” was distinct; his expectoration was pituitous, and often tinged with blood. Upon inquiring into his history, I was told that up to the age of twelve years he enjoyed the most perfect health; that at that period, on using violent exertion at cricket, his breathing suddenly became very difficult, and he coughed up a large quantity of blood. He had gradually become worse up to the time I saw him; he had suffered therefore during a period of about six years from the original attack. He lived but a very short time longer. On a post-mortem examination, the heart was found large and hypertrophied; the edges of the foramen ovale were smooth, and so widely opened that the thumb could easily pass through, as you perceive in this preparation [shewing it.]

The violent exercise which this lad had made at the age of twelve years, must have caused the rupture of the partition between the auricles, and admitted the passage of the blood from one to the other: the disease could not have been congenital, for the individual was in perfect health for so many years after his birth.

The next case of imperfect auricular septum is more complex, at least in the explanation of the alteration of the current of the circulation through the heart. It consists in the foramen ovale not only being open, but the ductus arteriosus also.

Under these circumstances the blood must have passed in the following way. A large proportion, let us say half of the blood, was transmitted into the right ventricle, and from thence into the pulmonary artery into the lungs: a diminished quantity was therefore sent into the latter organs, and we shall see how a compensation was afforded. The other half of the auricular blood traversed the foramen ovale into the left auricle, by which the quantity of blood was there preternaturally increased; the mixed bloods then passed into the left ventricle and into the aorta; and as the ductus arteriosus was open, the superfluous proportion of mingled aortic blood was sent through it into the pulmonary artery, by which the deficiency was made up of that transmitted into the latter vessel by the right ventricle. A consequence of this state of things is as follows:—if there be a due relation between the diameter of the open foramen ovale and the caliber of the ductus arteriosus, so that a sufficient supply of blood be conveyed to the lungs, life may be sustained for a considerable period.

I present you a preparation of a singular malformation in which the foramen ovale is open, the pulmonary artery impervious at its origin only, and the ductus arteriosus widely patenscent: the right ventricle is so completely in a state of concentric hypertrophy, that its cavity would scarcely contain a small pea.

In this case the whole of the venous blood must have passed from the right auricle into the left, and the mixed fluids from thence into the aorta. The circulation then divided into two currents; the one through the ductus arteriosus into the open part of the pulmonary artery, the other continued its course along the aorta. You will notice that the blood which had been transmitted through the ductus arteriosus in this case flows in a different direction to that which occurs in the foetal circulation; for in this malformation the current must have been from the aorta into the ductus arteriosus. In the foetus, its course is from the pulmonary artery into the aorta.

Species 2: Imperfect septum of ventricles.—A malformation of this species has been observed in which a trunk common to both the aorta and pulmonary arteries arose from both ventricles, in consequence of the septum being incomplete at its upper part. The aorta formed a sudden curve, and descended to supply the body and lower extremities only. A second aorta proceeded from its ordinary situation, ascended and formed its curve, giving off the innominate, the left subclavian, and carotid arteries; then becoming impervious, and terminating in the

form of a ligament in the parietes of the thoracic portion of the descending aorta previously described. In this case the septum of the ventricles being imperfect, the arterial and venous bloods must have passed into both the aorta and pulmonary artery.

The septum of the ventricles is sometimes imperfect in its centre, so that a round and smooth orifice of communication has existed between the two cavities.

The preparation I hold in my hand beautifully shews a singular transposition of the vessels and cavities of the heart. The two cavæ, you perceive, enter into the right auricle as usual; the foramen ovale and the ductus arteriosus are widely open; the aorta arises from the *right* ventricle, whose parietes are as thick as those of the left generally are; the pulmonary artery arises from the *left* ventricle, the walls of which cavity are thin, and similar to the ordinary state of the right ventricle: so that in this case the blood contained in the right auricle must have divided into two currents, one of which passed into the right ventricle, and from thence into the aorta; the second into the left auricle, ventricle, and pulmonary artery. When arrived at the latter vessel, that fluid again divided into two parts; one proceeded to the lungs, the other through the ductus arteriosus into the aorta; by which a compensation was effected for the diminished quantity of blood sent into the latter vessel by the right ventricle.

The symptoms of these malconformations consist in violent palpitations, irregular pulse, dyspnoea occurring in paroxysms, panting, coughing, screaming. Serous effusions and hæmorrhages frequently take place. The cerebral functions become disturbed; torpor, coma, convulsions, or paralysis, may supervene. The digestive functions become also disturbed, and the little patients finally arrive at a state of extreme marasmus. To these symptoms are frequently superadded an appearance of blueness or lividity over the body, and a general coldness over its whole surface.

The theory of this unusual coldness and livid colour of the body, is as follows.—When two substances enter into chemical combination, the specific heat of the resulting compound is different from that of the constituents. The respiratory and circulatory movements bring together two fluids, air and venous blood, each containing a certain quantity of specific heat. By the chemical action of these fluids upon each other, two compounds result, carbonic acid and arterial blood; the first having less specific heat than air, the second more than venous blood,—the sum of their spe-

cific heats being less than that of the air and of the venous blood. A portion of this heat becomes sensible, and is expended partly on the air, partly in the lungs themselves, and partly in raising the sensible heat of the arterial beyond the venous blood. When the arterial is converted into venous blood in the capillaries, a portion of its specific heat is also evolved, becomes sensible, and gives rise to what is called animal heat.

The lungs may be considered as a stove placed nearly in the centre of the body; the air and the venous blood are the fuel which supplies it. If either of these fail, the body necessarily becomes cold. The air is almost always present in due quantity; for malconformations rarely affect the trachea, or the bronchial tubes. The venous blood occasionally either does not arrive at all at the lungs, or it is not carried there in sufficient quantity, in consequence of some of the malconformations I have just described; that fuel then fails, and the body becomes cold; so that the coldness of the body becomes a measure of the diminution of the quantity of the venous blood sent into the pulmonary organs.

The greater part of the blood, and, indeed, occasionally the whole, becomes finally venous, in consequence of its insufficient exposure to the air. The rosy hue of health is then lost, and the skin is tinted blue, dark purple, or livid, from the transmission of the colour of the venous blood through the cutaneous capillaries.

OBSERVATIONS ON RENAL DROPSY;

Illustrated by Cases, and a Dissection.

BY JOHN ANDERSON, Esq.
Late Clinical Clerk, Guy's.

[Concluded from p. 866.]

ANASARCA (even inflammatory) may and does occur without albuminous urine; and it is by no means necessary to the existence of renal disease that anasarca should be present; coagulable urine does, though rarely, occur without it, as instanced in the experiments of Dr. Barlow, &c. before alluded to. In apoplexy this may happen; and in one of the cases before mentioned, I think I am correct in saying there was no dropsical effusion. In dyspepsia the urine is said to be albuminous; this coincidence

The following is a TABLE, in part illustrative of the Experiments before detailed, shewing the state of the Urine in various Diseases, principally with regard to its coagulability by heat and acid, taken from 50 Patients promiscuously. The Urine of the remaining 91 was examined in a nearly similar manner.—With regard to the specific gravities, those will be found high where the Urine had a copious sediment, from this latter not having been allowed to settle,—the most correct way, as I was then informed, of taking the specific gravity of urine of that nature.

Name.	Age.	Colour of the Urine.	Colour and Nature of Sediment, if any.	Coagulable by Heat.	Coagulable by Nitric Acid.	Acid or Alkaline Properties.	Sp. Gr. Water being 1000.	Disease the Patient laboured under at the time.
Timothy Calligan	40	natural colour.	no sediment.	no coagulation.	no coagulation.	slightly acid.	1.016	Fever, convalescent.
James Pantou	24	natural colour.	no sediment, cloudy.	scanty flaky precipitate.	quite re-dissolved.		1.017	Fever.
Samuel White	40	dark coloured.	copious dark sediment	no coagulation.	no coagulation.	acid.		Fever, 2 hours before death.

I have not yet noticed; but the sympathy between the stomach and kidney, and deranged state of the former, render it possible and probable. In diabetes again, the presence of albumen is now and then manifest, and is said to be a favourable occurrence. The last stage of phthisis is occasionally accompanied by albuminous urine: three cases of this kind have occurred to me*. It must, however, be remembered, that any of these morbid states may be accompanied by certain degrees of dropsical effusion; and on a careful review of the different diseases just enumerated, a certain occasional degree of similarity in their terminations will be discovered; whether this can have the most distant relation to, or be in any way the consequence of, the morbid state of the urine, is still open for investigation.

In drawing towards a conclusion, it is but right to state that there are a few cases on record which would seem to shake our confidence in the importance of the coagulable state of the urine, and create a doubt as to whether the inferences just drawn are accurate—the treatment advanced correct—the principles laid down established on a sufficiently firm basis: added to this, the oppositions and objections of many eminent physicians; the opinion of many that the presence of albumen in the urine is so frequent, and so easily produced, as to afford no diagnostic mark whatever; and a generally prevalent idea, that in every case where the urine is coagulable, the kidney must be in a state of disorganization. To observe upon, and attempt to answer, these different theories and opinions, and more particularly to shew the entire fallacy of the latter, would lead to arguments equally long as unnecessary at present; they may probably form the subject of a future communication.

From what has been written, as partly the result of my own observations (however inadequate to the importance of the subject), and from the opinions of several eminent men whose works I have re-

ferred to, we may, I think, reasonably and unerringly infer, that there does appear to be some great and intimate connexion between these three points—coagulable urine, diseased kidney, and dropsical effusion. The importance of the former will be found principally in serving as a guide to our treatment, and being, as it were, a presumptive evidence of deranged kidney, before that derangement could, without some such evidence, be appreciable by us: not that we are to be entirely guided by the quantity, colour, or firmness of the coagulum,—this will be found fallacious; but, when this phenomenon is present, we may be assured the kidney is more or less involved; there is tendency to inflammation, to serous effusion, and active antiphlogistic remedies are peremptorily called for. The healing and reparative powers of the body will also be found much impaired and weakened in energy.

I fear I have already encroached too long on the time of the society; but the extent, interest, and immense importance of the subject, must be my apology; and, in conclusion, would beg to offer the following points for discussion:—

1st, The frequency of albuminous urine unconnected with dropsical effusion, but in conjunction with serous or sanguineous effusion, independent of general anasarca; and whether the different quantities of albumen present are to be considered as so many stages of diseased action.

2d, The connexion (if any?) between anasarca with coagulable urine, apoplexy, and organic disease of the heart, whether of the muscular or valvular structures, but principally with regard to hypertrophy of the left ventricle.

3d, The connexion and relation between anasarca, diseased kidney, and the presence of albumen in the urine.

4th, The pathology, as directing the plan of treatment; and

5th, The treatment most admissible and successful.

* In one of these cases the urine assumed a form not often met with where albumen is present; it was excessively turbid when made, became clear at a temperature of about 150° F., and remained so for a few seconds. By continuing the heat, a copious precipitate of albumen, of the curdled form, took place. The anasarca was the most extensive I almost ever witnessed.

ON FEMORAL ANEURISM,

AND THE PATHOLOGY OF SECONDARY ANEURISMAL HÆMORRHAGE:

With Remarks.

By JOHN MURRAY, M.D.

Deputy Inspector-General of Hospitals.

Cape of Good Hope, Nov. 1, 1833.

IN the month of August, 1833, Monsieur Marchand, a Frenchman, resident in this colony, 39 years of age, five feet seven inches in height, of a healthy constitution, and very corpulent, came to Cape Town, from the country, for the treatment of a large pulsating tumor in the left thigh, which had been upwards of twelve months in forming. It originated in consequence of a severe blow received from the butt-end of a fowling-piece, between the upper and middle third of the thigh, in the situation of the femoral artery, where the sartorius muscle crosses it, and which gave him violent pain at the time. It was not, however, till upwards of two months after the accident that he became aware of the formation of any tumor, or of any unusual degree of pulsation in the part; and he was able to go about his ordinary business till within the last two months, when it began to be painful, to hinder his using the limb, and to prevent his sleeping at night. The tumor was very small when first observed, and increased gradually, attended with very strong pulsation.

On the 23d August, 1833, he presented himself to surgeon Bailey, who called surgeon Abercrombie and myself into consultation; and then the tumor was more extensive than could be covered by both my hands, of a flattened shape, and above three inches in elevation at the highest part. It reached from within an inch and a half of the crural arch, nearly to where the femoral artery passes through the tendon of the triceps; and its extent in the transverse direction was equally great. It was generally very solid and resisting; but in the central and most prominent part, where the skin was becoming thin, inflamed, and tender, it was more compressible than towards the circumference. The history and symptoms left no doubt of its being a circumscribed aneurism of the femoral artery, formed below the usual origin of the profunda, the progress of which

had been restrained by the strong fascia of the thigh.

The only treatment that had been tried in the country was that of compression, by the application of lead and various sorts of plaisters over it, with a strap buckled tightly round the limb; which he was no longer able to endure, as the skin at the centre of the tumor was becoming inflamed and sore, the leg stiff and painful, and the veins congested; but his general health was very good.

It became a question which plan should now be adopted for the most effectual interruption of the circulation through the diseased part of the artery, in order to bring about the obliteration of its cavity and the absorption of the tumor. Mr. Bailey proposed tying the external iliac. I suggested, as there was sufficient room, that it would be more according to surgical principles and to the general recommendation of authors, to apply the ligature below the crural arch; which was agreed to.

A reference was then made to some works on anatomy, respecting the distance from the arch at which the profunda is usually given off from the common femoral; and we were not a little surprised at the difference in the accounts given by different authors on this point. Sir Charles Bell states it to be "four inches, more or less, *according to the size of the subject.*" Eyle says "about two inches, and sometimes, though rarely, three inches;" Bransby Cooper, "one inch and a half." Litzars specifies no distance as being general; and Barclay says, in regard to it, that "he will not attempt to define what nature herself has not chosen to define." It seems therefore that no specific distance is to be depended upon.

As the situation of the tumor did not admit of getting the ligature placed with confidence below the origin of the profunda, it was agreed to tie the femoral artery about an inch under the arch, which we supposed would be above the origin of the profunda, and at the same time not too near to the lower branches of the external iliac.

The operation was performed on the 2d September, at 3 o'clock p.m.; when it was found that there was just barely scope for it, as the artery lay in such a deep hollow between the man's fat abdomen and the tumor.

An incision was commenced about an

inch and a half above the middle of Poupart's ligament, and continued downwards, in the line of the artery, to about two inches below it; being carried, in the first instance, through the skin and cellular substance. The superficial fascia below the arch was next divided, and in doing this an arterial branch was cut, which jetted furiously for a few seconds, but on being pinched by the forceps it soon ceased to bleed. Two or three large lymphatic glands were then separated to either side, out of the way, and the internal saphena vein, which was seen bending inwards to the femoral, was kept on the pubic side, and avoided. The fascia lata was then carefully slit open, when the femoral artery was discovered by its pulsations (which could not be felt before this fascia was divided), embedded in cellular and fatty substance. One or two nervous twigs crossing from the anterior crural were obliged to be cut, which seemed to give him sharp pain. The sheath of the vessel was now opened, and the artery separated and tied by a single round ligature, at about an inch below Poupart's ligament. It did not appear to us that the artery had yet given off the profunda, as the pulsation of only one vessel was to be felt.

The pulsation in the tumor ceased immediately, and a considerable degree of insensibility of the limb ensued; but we were rather surprised to find that only little diminution of temperature took place in it, which led us at the time to conjecture that the ligature had probably been applied below the origin of the profunda.

The usual treatment was pursued, and, in regard to the wound and aneurism, nothing worthy of notice occurred for nearly a fortnight. He suffered, however, dreadfully, for some days after the operation, from flatus in the intestines, which he was unable to expel: indeed he complained of nothing but of the agony which this occasioned him, and was constantly calling out that he was sure he would burst if not relieved. Purgatives, carminatives, absorbents, assafoetida, and anodynes, were exhibited without effect; and at last I thought of Dr. O'Beirne's plan of introducing the tube of the stomach-pump up beyond the upper annulus of the rectum; and were it only for the information which the Doctor has given us, of this effectual remedy for the tympanitic state so fre-

quently attendant upon operations about the abdomen, constituting a symptom both distressing and dangerous, I should consider his work on Defecation as one of great value to suffering humanity. Upon the entrance of the tube into the colon, an immense volume of air rushed out through it, with instantaneous and perfect relief; and he was not troubled with any return of this complaint. He was harassed, however, soon afterwards, with the effect of the purgative medicines which he had previously taken, and which began to act severely after the removal of the confined flatus; but a good dose of fresh olive oil (an excellent medicine for soothing and checking the purging of irritated bowels) soon remedied their teasing action.

Although every thing seemed going on very well for fourteen days, yet we were by no means without great anxiety about the result of the operation, having found the profunda given off *at less than an inch* from Poupart's ligament, in every one of six different subjects we had examined in the interim—*i. e.* higher than where we had applied the ligature; and therefore we were afraid of hæmorrhage from the upper part of the artery when it separated: and a reference to the results of other cases, where the femoral artery had been tied in the groin, did not tend to allay our apprehensions.

In two out of the six subjects which we examined, the profunda was given off *at less than a quarter of an inch* from Poupart's ligament, and, in these, the ligature of the femoral artery could not perhaps have been applied above the profunda with safety, on account of the proximity of the epigastric and circumflex ilii branches, which were large.

In the patient mentioned by Mr. Allan Burns, upon whom Sir Astley Cooper tied the femoral artery underneath Poupart's ligament, hæmorrhage occurred on the fourteenth day after the operation, from the vessel having been tied close to the origin of the epigastric. No plug was found in the canal of the femoral, and the adhesion at its extremity appeared to have been lacerated, after the separation of the ligature, by the impulse of the circulation.

With reference to the aneurismal tumor, it was observed at the end of a fortnight, that the inflammation and tenderness of the integuments had nearly subsided—that there was no return of

pulsation in it—that it had become much softer and more compressible—but that when the bandage was taken off, it resumed fully its original size.

In the event of hæmorrhage occurring, Madame Marchand had directions to apply pressure at the groin, and to send immediately to the hospital for assistance; and such instruments and dressings as might be wanted were kept at hand in the room.

On the morning of the fifteenth day after the operation (16th September), which we had always deemed a critical one, the wound was dressed at 10 A.M. and looked healthy; the ligature remained, and no attempt was made to take it away. Our patient was recommended still to keep very quiet in bed, and he was in high spirits, as his cure seemed going on so prosperously. In less than ten minutes, however, after our visit, a violent hæmorrhage came on, which had nearly proved fatal before Mr. Bailey's assistant (Mr. Bickersteth) got to him. He had already lost between three and four pounds of blood, the effect of which, from the sudden manner in which it had come away, was such that he seemed dying: his countenance was ghastly; his pulse imperceptible; his skin covered with a cold clammy sweat; his stomach was forcibly ejecting its contents, and he was gasping spasmodically for breath.

Mr. Bickersteth found the blood, *which was of a florid red arterial colour*, still eddying up from the wound by the side of the dressings, and made pressure upon the external iliac artery; after which it stopped. Mr. Abercrombie and I arrived soon after, and from the critical state of the patient, seeing that no further operation for tying the femoral in the groin was practicable, and conceiving the bleeding to be from the upper orifice, we agreed upon the immediate necessity of tying the external iliac; consequently, after waiting a short time for Mr. Bailey, who was not to be found, and for the patient to rally from his state of collapse, I performed the operation without moving him from where he lay, after the method of Sir Astley Cooper; and it was found to be a much more simple and easy one than the preceding: indeed, with a knowledge of the anatomy of the parts, no operation can be more simple in the manipulations—nothing more easy than the division of the integuments, and of

the successive layers of the abdominal muscles—the separation and pushing aside of the peritoneum from its loose connexion with the iliac fascia—the finding and detaching of the artery, and the passing of the ligature round it.

Previously to and during the operation, a sort of precautionary pressure had been kept up on the crural artery, by the handle of the door-key placed over a linen pad; but this had been gradually relaxed to almost none at all, and was taken off altogether before I tightened the ligature. Therefore, on finding the external iliac beating very strongly, so close to the divided femoral, and considering also that his strength was much recovered, and that the pulse at the wrist was good, we were rather surprised that the hæmorrhage had ceased of itself before I tied this vessel.

He bore the cutting part of the operation remarkably well, and not above a tea-spoonful of blood was lost from it; but the tying of the artery seemed to give him a very great shock. His breathing became instantly oppressed; he complained of a pain about the heart, and said he had an agonizing sensation in the leg, at the same time that it became quite cold, and felt to him as if perfectly dead. Two stitches were put into the external wound (which was long and deep), to bring its edges and the integuments together, and these were supported by straps of adhesive plaister. We were now enabled to examine the wound in the groin to the bottom; the coagula were removed, and no bleeding ensuing, it was dressed with dry lint, compress, and bandage. The limb was rubbed and rolled in warm flannels, with bottles of hot water placed round it; and, to allay the general irritation, he had at first twelve drops of black drop in camphor mixture, and ten more in two hours afterwards, which succeeded. In the course of a few hours he seemed to have nearly quite recovered from the bad effects of the sudden loss of blood, as well as from the shock of the operation; and he passed a fair night.

The natural warmth of the limb did not become perfectly restored till after two or three days; and it was curious to observe the effect which the obstruction to the supply of blood after this operation had upon its nervous functions:—At first, while it remained quite cold, it was found that he was unable to move a toe or a muscle, and that the skin and

flesh were insensible to the touch, and even to pinching, although he was groaning from the pain he felt in it, particularly about the knee. It seemed the same sort of sensation which persons feel after amputation; but here the trunks of the nerves were uninjured. When the natural heat was becoming restored, he said he felt a pricking and creeping sensation throughout the limb, which was far from being agreeable, yet not altogether painful; he described it as like to that which a person feels after his leg has been benumbed, or what is commonly called *asleep*.

The following day he began to complain of much pain in the side, above the site of the last operation, which was evidently from inflammation of the external integuments, and not of the peritoneum. The scrotum was also painful and swollen, proceeding probably from irritation of the spermatic cord during the operation. This ended in rather an extensive circumscribed suppuration of the cellular membrane of these parts, some portions of which sloughed, and came away from underneath the skin on the 11th day; after which period the parts granulated kindly. Symptomatic inflammatory fever attended this cellular inflammation, and ran high; but his constitution rallied most favourably after the 11th day.

The aneurismal tumor, which seemed at first to diminish a little after this operation, was observed towards the end of a fortnight to become again rather distended, and more compressible, as if the contents of the sac were becoming more fluid; but there was no return of pulsation nor of pain in it, and the limb had long re-acquired its natural heat and sensibility. No fear was entertained of a recurrence of hæmorrhage from the wound in the groin, as it was granulating and healing most favourably; and we had much confidence that none would happen from the external iliac artery, when the ligature upon it should become detached;—in short, we were not anticipating any further untoward occurrence to prevent a speedy cure, when, in the evening of the 29th September, about 7 p.m. (at the end of the again critical 15th day), I was suddenly summoned from dinner, with the announcement that our patient was *bleeding to death*!

Reflecting upon this alarming intelligence on my way to him, I came to the

conclusion in my own mind, that if the bleeding was from the external iliac artery, it would most probably have proved fatal before any assistance could have been rendered him; but as I had for some time been entertaining doubts in regard to the source of the former bleeding (*i. e.* whether it had proceeded from the cardiac or distal end of the divided femoral), from the way in which it stopped, and from the appearance of the tumor latterly, I thought, if I found him still alive, that the bleeding might probably proceed from the distal end of the artery, by a retrograde current from the anastomotic branches of the profunda.

On my arrival I was delighted to hear him speaking, although he was quite exsanguine and almost exhausted. He had again lost about three pounds of blood. Mr. Bailey, who had reached him a little before me, was keeping up a strong pressure with his hands in the iliac region, above the site of the last ligature, by which he said the hæmorrhage had been suppressed. He conceived the bleeding to be from the external iliac, but had not been able to make any examination, having only taken the place of Madame Marchand, who had been making pressure where he was now doing, from the time the bleeding was discovered.

The bloody cloths and dressings were speedily cleared away; and on the parts being exposed, it was soon evident that the hæmorrhage had come from the wound in the groin; and when I removed the coagulum that was in it, the blood began to flow afresh, *not per saltum arterialem*, although it was of a red arterial colour, but in a *continued uniform stream*; and I was delighted to find that it stopped by pressing my finger upon the aneurismal side of the artery; on which I ventured to pronounce our patient safe; and, confident that I commanded the hæmorrhage, Mr. Bailey now removed his hands, to his own and the man's great relief both of body and mind. A graduated compress was placed over the pervious end of the vessel, and bound tightly down by a bandage, which completely prevented the further escape of any blood. The wet cloths about him were changed, a dry flannel bandage was put upon the limb, and all parties were again tolerably at their ease.

Being less able to bear the second

hemorrhage than the former, he remained for many hours in a state of great prostration, with excessive pain and oppression at the præcordia, and a most unquenchable thirst; for which he was prescribed with advantage some draughts, composed of liq. ammon. acetat. ℥ss.; spt. æther. nitr. ℥ss.; gutt. nigr. iv.; mist. camphor. ℥j.; syrup. simpl. 3j. M.

A renewal of the suppurative inflammation of the cellular tissue, above the upper wound, ensued (probably from the pressure that had been kept upon it), which persisted for nine or ten days, accompanied with a great degree of serious constitutional disturbance, which was not without danger. The aneurismal sac continued distended, soft, and undulatory, for about a week, from which circumstance it appeared to be fed by fluid blood; but it had no pulsation, and no whizzing sound.

On the 9th October, however (not having seen it for several days previously), I observed a very sensible diminution in its size on removing the bandage; but it did not feel as if any solid coagulum had formed in it. The compress, originally placed on the lower orifice of the artery, was retained for a fortnight in the same place, the wound being daily dressed by introducing lint at its edge. The ligature upon the external iliac did not come away till the 17th October. At the present date the wound in the groin is almost perfectly cicatrized, and that in the abdomen will soon be closed also. He now walks about upon crutches; but the limb feels very weak, and he has great pain and stiffness about the knee.

For the last fortnight the limb has been tightly bandaged, from the toes upwards, and an additional degree of compression kept upon the aneurism by the application of a gum plaister under this bandage, with a compress and a strap buckled over it. Still, however, upon examination, the tumor has not made a satisfactory progress towards becoming absorbed, as it retains two-thirds of its original size. It is soft and fluctuant when he lies upon his back with the leg and thigh semi-flexed; but when he stands upright, or bends the thigh much up, it feels quite tense and hard. Upon strong compression by the hand or a bandage, its volume becomes very sensibly diminished; and, on the contrary, when this pressure is removed,

or when he stands up, it becomes visibly augmented. But as he complains of great pain in the site of the wound in the groin when this strong compression is made, we are careful of employing it, for fear of rupturing the adhesion at the orifice of the artery, whence the hemorrhages proceeded.

Whether any further means will require to be resorted to for effecting a perfect cure I cannot yet well judge; but I rather think it probable that the aneurism will not disappear spontaneously, considering that it is now two months since the direct current of blood was interrupted in the main tube of the artery; and that it is pretty certain that the disease must, to a certain degree, be maintained by the collateral circulation. Whether any blood actually continues to circulate through the diseased part of the femoral artery we cannot ascertain, as no pulsation or undulatory vibration is to be felt in, or immediately below, the tumor. In the popliteal portion of it, however, a pulsation is perceptible, which seems equal to that in the other ham.

REMARKS.—Reflecting upon this case, I have thought it of sufficient interest for publication, as the candid details of untoward occurrences after operations are often of more advantage to pathology and practice, than those of uninterrupted progress to favourable results.

I have no doubt now that the first hemorrhage was from the distal end of the femoral artery, and that it might have been stopped in the same manner as the second was, without any necessity at all for tying the external iliac, had we been equally prepared to expect what we discovered afterwards, and had we examined properly into the state of the parts before proceeding to that operation.

I still think that the first operation was certainly done in conformity to the recommendation of some of our best surgical authorities; but, conjointly with many recorded cases of the ill success attending it, the result has taught me not to recommend tying the artery in the groin in similar cases; for, to say little of the greater difficulty of the operation compared with that of the ligature of the external iliac, it appears to me that it must always be attended with great risk of secondary hemorrhage, whether the artery be tied

above or below the origin of the profunda. In this instance I conceive that it was tied above, and that both hæmorrhages took place from the distal end of the artery, by a retrograde current from the anastomosing branches; but should it be tied below, and, as might happen, near to the origin of the profunda, there must then be great risk of hæmorrhage from the cardiac end, which is still more dangerous, as coming with a full arterial impulse direct from the heart. In regard to the plausible reason advanced for preferring the first operation—viz. the prospect of a more efficient collateral circulation for the nourishment of the limb, on account of the preservation of the lower branches of the external iliac, I consider this to be of very little weight; for the almost innumerable anastomoses that exist between the vessels of the internal iliac and those of the thigh, constitute such a circle of communication, that, in a healthy subject, no one need hesitate to tie the external iliac, without fear of destroying the life of the limb; and Harrison says, “the success which has followed this operation has so far exceeded that of tying the femoral artery for the cure of popliteal or femoral aneurism, that some surgeons have suggested the propriety of performing the iliac operation in the first instance, for the cure of those diseases.”

I should have mentioned, that Brador's method of tying the artery, *ultra tumorem*, was agitated at first, as it seemed possible to apply a ligature upon the vessel before passing through the tendon of the triceps; but as the sac was already thin, inflamed, and about to ulcerate, from over-distension, it was rejected, being thought likely to hasten its rupture, by increasing the impetus of the circulation against its parietes; for that an increased local impetus actually does take place, for a time at least, at the part immediately above the ligature after an artery is tied, every operative surgeon who has taken hold of, or felt, a recently tied vessel, must, I think, be convinced: hence I deem the practice unadvised, to operate on this plan in cases of aneurism where the integuments have become thin, and disposed to ulcerate or slough; and certainly, in many of the recorded instances where this mode of operating was adopted, the rupture of the sac was rather accelerated by the operation. In cases, however, where the integuments are sound, and

the walls of the sac strong, and able to resist the temporary increased efforts of the circulating powers to propel the blood in its natural channel, there seems much reason to expect that it will succeed; for, after a certain time, when the blood has found a new route to the lower part of the limb, this increased local energy gradually diminishes, till at length the divided or tied extremity of the artery becomes quiescent, the blood in it stagnates and coagulates, and is carried off by the absorbents; and the end and sides of the artery contract, adhere, and become obliterated.

Sir Charles Bell states, “if it were by any accident to happen that there was a necessity of amputating below the knee, in a case of aneurism in the ham, he has no hesitation in saying that the tumor would diminish, and the aneurism suffer a kind of spontaneous cure.” But this, I think, must depend upon the state of the sac and integuments, as I have just mentioned; although, in respect to the sympathetic call upon the energies of the collateral circulation, the removal of the limb would make some favourable difference; and I would further observe, that the success of Brador's method must also depend very much upon whether or not the artery be tied at a part between which and the aneurism no branches of importance originate, to lead the current of the circulation through the diseased portion of its tube.

I have the notes of a case which occurred in the Hôpital of La Charité in Paris, under Messrs. Boyer and Roux, when I was there in 1816, to which I would refer, as bearing upon this point. A man was admitted with two aneurisms in the course of the left femoral artery, the one situated in the groin, the other in the ham; and the foot and leg had become gangrenous. On the 28th February amputation was performed above the knee, and on the 2nd March Monsieur Boyer gave a clinical lecture upon the case, wherein he stated that he was called to see the man six weeks previously, when, finding the aneurismal tumor in the ham very large, and the other in the groin also about the size of a hen's egg, the idea presented itself to him that the most proper plan of cure would be to tie the external iliac artery; but the house being ill adapted for the performance of an operation, and the patient unwilling to go to the hos-

pital, he merely recommended compression. A month afterwards he was again called to him, when he found that the pulsation of the popliteal tumor had ceased, and that the foot and leg were beginning to mortify. The man was now persuaded to go to the hospital, and amputation has been performed. He pointed out that a chance of union by the first intention was given to the stump, by the application of agglutinative plaisters (which plan was just beginning to be introduced at this hospital by Roux, after his journey to London), and that nothing was attempted as yet for the cure of the inguinal tumor, as he thought any operation to interrupt the circulation through it might interfere with the cure of the stump; and there was no urgency for it. Besides, two operations would have been more than his constitution could bear at one time; and he thought it would be right to give the aneurism a chance of being cured by compression along with ice. After the stump heals, if this does not succeed, it was in their power either to tie the crural artery below Poupart's ligament, or the external iliac.

March 23d.—No union of the stump has taken place; its edges are still kept drawn together very tightly by adhesive straps (a great deal too much so, as they evidently excite much pain and irritation), and the use of pressure to the aneurism in the groin has been commenced by a sort of tourniquet over a pad.

30th.—Stump not doing well; it looks irritable, and the surrounding integuments are hard and inflamed. The trial of making its lips adhere by straps is still continued, and over these poultices are applied. The pressure upon the aneurismal tumor causes great uneasiness, and does not seem to be of any benefit.

April 5th.—Stump much swollen; the straps are applied so tightly and so close as to confine the discharge.

May 8th.—The stump is healed; pressure has been continued, along with a bladder of ice over the aneurism; but, on minute examination, these applications are found to have done no good, for the tumor is as large as ever. A more general pressure is now commenced by a tight bandage over the whole stump, with graduated compresses placed immediately over the aneurism; but Roux has no hopes of success from this plan, and thinks that the external

iliac will have to be tied eventually; but they seem very shy of this operation here.

I left Paris very soon after this, and do not know the ultimate result; but the above is enough to shew that amputation performed at some distance below an aneurism will not effect a cure if important branches arise between it and the ligature on the artery.

In regard to secondary hæmorrhage, Mr. Guthrie deserves the highest credit for the clear and impressive manner in which he has drawn the attention of the profession to the frequency and danger of its occurrence from the *distal* end of a divided artery. He states it as a very curious fact, that in recent wounds, when bleeding occurs after being arrested for a period of four hours, it takes place, in all probability, from the distal end of the vessel; and that this arises, according to his observations, from a difference in the process of closure adopted by nature in one end of the artery to that in the other; having found that when an artery is divided, the retraction and contraction of the distal end is neither so perfect nor so permanent as that in the cardiac extremity; and that in the former the internal coagulum is either altogether wanting, or comparatively very defective; and he mentions, that when the blood comes from the distal end of the artery, it may be distinguished by its being, at least for many days, of a *dark venous colour*, and by its *welling* out in a continuous stream, without any arterial impulse.

In aneurism, when an artery is tied by a single ligature, no retraction of its ends takes place, but a process of adhesion is instituted, to prevent hæmorrhage when that portion of its cellular coat embraced by the ligature dies; and if this adhesion be not sufficiently strong at either end to resist the impulse of the circulating powers when the ligature becomes detached, secondary hæmorrhage must ensue. Sometimes this will take place from one end of the artery, and sometimes from the other, according to circumstances; but it generally happens that when it does occur, surgeons almost invariably consider it to proceed from the cardiac orifice, and resort to means adapted to arrest it upon this supposition; by which, however, it is but too well known they are not always successful.

To account in some degree for the

frequency of its occurrence from the distal end of divided arteries, it must be mentioned, that it has been found that the adhesive process is not so rapid nor so effective in this as in the cardiac ends, which, I think, may be owing, in a great measure, to the interruption of the supply of blood and nervous energy through its nutrient vessels or *vasa vasorum*, caused by the ligature; as the quantity and quality of the coagulable lymph effused from its edges and inner surface, and the activity of the organising powers by which the union is effected, must be in direct proportion to the degree of vitality and energy of its vessels; and hence there seems a strong reason why, in all cases of secondary hæmorrhage after operations for aneurism, we should expect it to proceed *even more frequently* from the distal than from the cardiac end of the vessel.

On taking into consideration that the frequent occurrence of secondary hæmorrhage, in the present mode of curing aneurism, arises entirely from a division of the artery being made by our way of applying the ligature, I think that in some situations a preference is due, and will some day be more frequently given by our surgeons, to the French method of obliterating the canal of the vessel "*par aplatissement*," by which its continuity is preserved, and the risk of this most dangerous accident thereby prevented.

In the foregoing detail of our case, I have spoken of the hæmorrhages as having proceeded from blood brought into the distal end of the femoral artery, chiefly through the profunda, by a retrograde current from its capillary inosculation with branches of the iliac arteries; but I am aware that this explanation is not sufficiently correct as to the nature of the collateral circulation which is ultimately established in a limb, after the ligature of its main arterial trunk.

At the commencement of the collateral circulation, or rather before the vessels through which it is eventually carried on are properly developed and perfected, it would appear, that although a supply of blood by the ordinary or natural anastomosis is very speedily conveyed into the distal part of the limb, yet that the properties of this blood become altered in its passage through the capillary inosculation, and that a change is effected in it analogous to that which it

undergoes in its passage from the arteries into the veins, which must render it unfit for the proper nutrition and other vital functions of the limb; and that hence there arises a necessity or sympathetic stimulation for the immediate establishment of a more direct and efficient circulation, which, in fact, does take place in a short period.

Barron Larrey, in his *Clinique Chirurgicale*, mentions several cases of very astonishing changes which appear to take place in the course of the circulation after wounds of large arteries; and Guthrie's description of the process by which the collateral circulation is effected is so highly interesting, that I cannot help transcribing it. "If," says he, "a limb be injected and dissected most carefully four or five days after a ligature has been placed high up on the principal trunk of an artery, the capillary vessels will be seen to be well injected, but few or none will be found large enough to admit of the inosculation being traced throughout. If another limb be so injected and dissected forty days after the ligature has been applied, a difference will be distinctly observed between the two preparations; in the latter, the capillaries will not appear to be so fully injected, but several larger and more tortuous vessels will be found in situations where they were not expected to exist; and the anastomoses of these, one with another, and generally by arches, may be traced to their communication with the principal trunk, both above and below the obliterated parts. Let an incision now be made in the nearest pervious portion of the lower part of the artery, and red arterial blood will issue from it. The communication has become direct by direct vessels, and the capillaries have returned to their accustomed duties."

I may observe, *en passant*, that Mr. G.'s words imply that red arterial blood would issue from the injected limb, which is *poetical*.

At what time within forty days this direct communication becomes established, or whether it is always complete at that period, the histories of cases and of dissections do not lead us precisely to determine: it seems, however, worthy of being noticed in Marchand's case, that hæmorrhage occurred exactly on the fifteenth day after each operation, and that each time the blood was of arterial character; from which it may

perhaps be inferred, that in fifteen days special vessels become developed between the parts of the artery above and below the ligature; but I doubt whether this communication be even now so perfect in our case as the above quotation would lead us to imagine, else the direct vessels must enter below the diseased part of the artery; for otherwise there would surely be a return of pulsation or undulation in the aneurism, synchronous with the contractions of the heart, which does not exist here, although this has occurred in some instances after Hunter's operation. Had hæmorrhage only taken place after the first operation—from its coming on in such a sudden and profuse manner—from its being attended with such excessive exhaustion of the vital powers—and from the blood being of arterial character,—it would have passed off as having proceeded from the cardiac end of the artery, and only been considered as another proof of the frequency of the cellular coat of the artery becoming divided by the action of the ligature about the fifteenth day; but as from the time the first hæmorrhage took place there was no ligature upon the vessel, and no particular pressure kept upon the wound, it would seem to prove that the collateral circulation *then* became more fully formed, or established in a perfect manner; particularly, too, as all the natural functions of the limb seemed also to have become perfectly restored by this time.

In reading over other cases of secondary hæmorrhage after ligature of the femoral artery, I am now very much inclined to think that in many of them it proceeded from the distal end of the vessel, although this was not recognised at the time, from the operators probably not being aware of the great proneness to its occurrence, or of the possibility of its being from the end, but forthwith proceeding either to tie the artery higher up, or to amputate the limb, without any examination of the wound.

Perhaps even to this mistake are we indebted for one of the most brilliant improvements in surgery—the ligature of the external iliac artery! which, it will be remembered, was first performed by the late Mr. Abernethy, in a case not dissimilar to the one here detailed; for I am inclined to think, when secondary hæmorrhage occurs from the cardiac end of such a large artery as the crural, that,

in 99 cases out of 100, it will prove fatal before proper assistance can be rendered to the patient, if a surgeon be not immediately at hand. But *then death is not always inevitable* without tying the external iliac; for I have known the crural artery to be obliterated by pressure on the groin, and the limb saved too, although no one would recommend the practice.

I confess that in the first instance no suspicion of the real source of the bleeding occurred to me in this case till after I had applied the ligature round the external iliac; and had it not been for the recurrence of the accident, I should have continued in the belief of its having proceeded from the upper orifice of the artery, and that I had done a mighty good deed for our patient by the second operation, which it now appears he might have been spared.

If nature does not effect a cure in Marchand, it may be required to tie the artery on the distal side of the tumor, which can now be done under the advantages I have stated as necessary for a fair prospect of success. There is, however, a choice of other plans to be taken into consideration—as the application of *maras*, recommended by Larrey; and of *acupuncture*, suggested by Velpeau, &c. For some time, however, we purpose trusting his recovery to the farther efforts of nature*.

JNO. MURRAY, M.D.

Deputy Inspector of Hospitals.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à aléger.”—D'ALEMBERT.

Observations on the Causes and Treatment of Ulcerous Diseases of the Leg.

By J. C. SPENDER, Member of the Royal College of Surgeons in London.

MR. SPENDER says, in his preface, that about a thousand cases of “diseases of the leg” have fallen under his care during the last five years, and adds, that he must have been very careless not to derive some practical information from

* Dr. Murray has informed us, that the patient mentioned in the foregoing paper got perfectly well, and that the aneurismal tumor became absorbed in the course of two or three months, without any further treatment.

such a field of observation. One of the first inferences from those opportunities which we are presented with, is, that we are incorrect in ascribing the frequency and obstinacy of ulcers of the leg to the dependent position of the limb, or to its distance from the heart. The frequency of the disease in question our author attributes, first, to the exposure of the lower limbs to injuries, and, secondly, to a palpable unhealthiness of the structures of the part, particularly a varicose state of the limbs. It is quite clear,

however, as he himself admits, that the dependent posture of the limb, and distance from the centre of circulation, may be said to cause the varicose state directly, and therefore indirectly the ulcer; in short, the attempt to get over this point savours too much of special pleading and sophistry. However this may be, great importance is attached, and not without justice, to a varicose state of the limb; and the fact is farther rendered apparent, from the calculation that out of 100 cases he found—

79 Varicose, consisting of 41 simple,	27 very irritable, 11 very indolent.
21 Non-varicose 15 ditto,	4 ditto, 2 ditto.
Of the whole number	68 females 32 males.
Of the 79 Varicose	59 ditto 20 ditto.
Of the 21 Non-varicose	9 ditto 12 ditto.

Now all this, though very true, happens not to be very new; in answer to which Mr. Spender argues thus:—

“An examination of the works of the most celebrated writers on Ulcers will soon convince us that the varicose state of the veins has not been considered so frequent and essential a cause of these diseases as I have attempted to prove. A very brief review will be sufficient to show that this affection of the veins, though recognized by some authors, has not by any been brought so prominently forward as I think its importance demands; much less proposed as affording the leading character for arranging ulcerous complaints of the leg. This inquiry will also serve the purpose of introducing us to the consideration of the classification of ulcers; which is one of the objects embraced by the present chapter.

“Although it is well known that Wiseman speaks of a varicose ulcer, and used in its treatment the laced stocking, his opinions of the nature of this kind of sore are not, I think, so generally understood. He does not view the varicose state as a cause of the ulcer, strictly speaking; or certainly not to any great extent; for when this diseased condition of the veins was found in combination with a sore, he arranged it, to use his own words, amongst ‘the accidental differences which are taken from those things not intrinsic to the nature and constitution of an ulcer.’ But even had this distinguished man considered the varicose affection in the juster light of an essential cause and element of the ulcer, yet, by the arrangement of sores which he afterwards

adopts, it is obvious that he did not think it operated to the extent which I believe it does in the formation or continuance of the disease.

“The paragraph already quoted for another purpose from Mr. B. Bell is the only instance in which he refers to the existence of the varicose disease, in his whole book; and there he viewed it merely as a symptom or effect of the ulcer. What he has stated in that place is very plain and unequivocal; but if any farther evidence were required to prove that he did not consider this affection of the veins as productive of any kind of sore, it would be afforded by observing the manner in which he praises the use of pressure in the serophulous ulcer. ‘In no species of sore,’ says he, is it so evidently indicated, and of so much utility.’ That in this kind of ulcer, when situated in parts which will admit of it, compression is of great benefit, by levelling the edges, every one must allow; but then its advantage must be much greater in those cases of sore arising from varicose veins and adventitious deposits. In confirmation of the correctness of the view here taken of Mr. Bell’s opinion, it may be farther added, that in his arrangement of sores the name of varicose finds no place, although he has eleven divisions of ulcerous diseases.

“Mr. Baynton, it is true, speaks of varicose veins ‘attending’ two or three of the cases he has recited; and likewise asks, in another place, whether ‘one of the difficulties in curing ulcers may not arise from a deficiency of the absorbent powers of the veins in that variety of the disease attended with a vari-

case state of those vessels; but he nowhere assigns the varicose affection as a cause of ulcers; neither was it with a view to sustain the action of the veins that he introduced the adhesive plaisters. The thought which directed him to try the strapping in states of old ulceration, was the good he had observed from having as small a cicatrix as possible after the healing of the sore; and justly considering that this desirable object would be greatly effected by approximating the edges as nearly as he could, he had recourse to strips of adhesive plaster to obtain this end. The obstacle to be overcome in permanently curing a bad sore, he thought consisted in a disordered state of the lymphatics, and that the general pressure on the limb acted beneficially on the ulcer by assisting their function. After advancing arguments for this opinion, he states, 'I therefore conclude that the principal difficulty which occurred in the curing of ulcers, has been occasioned by deficiency of power in the absorbent vessels.' In another place, we shall have a better opportunity of inquiring into the manner in which compression acts; where I think it will be evident, that although it is of great service, by exciting the lymphatics, especially when unnatural deposits exist, yet that its chief advantage arises from supporting the veins, and thus indirectly accelerating the capillary circulation. All that is required to prove here is, that Mr. Baynton did not view the varicose veins as a leading cause of ulcers; nor was it with the primary intention of aiding and strengthening this class of vessels that he introduced his very useful method of treatment.

"Dr. Underwood and Mr. Whately have not once alluded to the existence of varicose veins in the leg as being a cause of ulcers, although they are both very able and strenuous advocates of pressure. The first of these writers has not, that I can find, even mentioned this condition of the veins in any place of his treatise; and the second has only once incidentally adverted to it, in a part of a note, as being a state benefited by the use of the bandage, in common with some other advantages obtained by its employment. 'I have been very particular,' says Mr. Whately, 'to discover the true cause of an acknowledged fact; namely, that wounds on the lower extre-

mities are healed with much more difficulty than those which are made in other parts of the body.' He judiciously observes, 'If the cause of this fact be ascertained, we may then hope to arrive at a certain method of cure.' He then continues—'That wounds and ulcers of the leg are of more difficult cure than those in any other part of the body, is a circumstance which is attributed either to their dependent situation, or to the greater languor of the circulation in them as extreme parts. The more general opinion, I believe, is, that it is owing to the former cause; but Dr. Underwood attributes it to the latter—'I think, however, that we shall find, on the strictest examination, that it is almost entirely owing to their dependent situation.' Although I believe these explanations of the fact not sufficiently precise to be satisfactory, yet both of these writers carried out their principles into practice much more consistently than many others entertaining their opinions. Mr. Whately employed compression to a great extent, as the agent most suited to counteract the real or supposed ill effects of a dependent position; and Dr. Underwood used the remedy to the same degree, as being able to admit of exercise with a view to rouse and assist the vitality of the parts. Neither of these authors has, however, acknowledged, or at least not mentioned, the frequent presence of the varicose state which I have attempted to establish; the admission of which is, I think, not only necessary to account for the greater liability to sores, and difficulty of healing them, in some legs than others, but at the same time affords a more defined cause of the disease, against which our remedies can be applied with better precision and success, than merely directing them to the natural condition and properties of the limb."

He next proceeds to comment on what Sir E. Home has said on the same subject, and, we think, makes good his position, that the varicose affection has never been made the *basis* of an arrangement of ulcers, which has usually been derived from their superficial aspect. The evil which Mr. Spender protests against, as having resulted from this, is the "limitation given to the employment of pressure," and the use of "washings, fomentations, and poultices;" to all which our author has a mortal

antipathy. His arrangement is abundantly simple, depending upon this—whether the ulcer has or has not “the varicose affection and its consequences;” at the same time he observes, that the success of his treatment remains unquestionable, whether his theoretical views be admitted or not.

When the difficulties are such as the unassisted efforts of the system are capable of overcoming (as is usually the case in ulceration on the surface), the principle of treatment laid down consists in *imitating a natural process*; when the obstacles are such as the unaided powers of the body are unable to vanquish (as is usually the case in the deeper-seated ulcers), the principle of treatment consists in *introducing a healthy action*.

The natural process witnessed in the healing of wounds, when left undisturbed, is the formation of a scab; and thus our author strenuously endeavours to imitate.

“Of all the kinds of outward application which I have tried, an ointment containing a very large quantity of prepared chalk forms the best artificial crust. The earthy matter must be in a much greater proportion than enters into any ointment in the Pharmacopœia, consisting of about three pounds of chalk to two pounds of lard. Even four pounds of chalk will be readily taken up by two pounds of lard; and if about three ounces of olive oil be added, the ointment will not be too stiff, but will easily admit of being spread on the linen. The best method of preparing this application is not by rubbing the chalk down with the lard; but, having previously reduced the chalk to a very fine powder, heat the lard to a tolerable temperature, and, whilst it continues hot, gradually add the levigated chalk in the same vessel in which the lard was warmed. By this means it forms more of a solution than a mere addition; and the two ingredients thus become more intimately blended together. This should be stirred until it is nearly cold, and then placed by for use. I have found that preparing the ointment in this manner is preferable to the more usual mode of making such substances, by simple admixture or trituration, as it produces a mass more homogeneous, containing less of the earthy particles in a distinct or separate form. I have for several years past been in the habit

of using very extensively an application thus prepared, and have watched very closely its effects.

* * * *

“It is scarcely necessary to remark, that these observations apply with undiminished force to all wounds and ulcerations, on whatever place of the body they may be situated. The employment of the chalk ointment is not restricted to sores on the leg, but may be advantageously extended to those which occur on other parts of the surface. It is particularly serviceable in all cases where we are anxious to bring about as speedily as possible the healing process. I have had recourse to it, with very great advantage, in the treatment of burns and scalds, where an extensive surface is exposed, and requires either the natural crust, or some artificial protection resembling it. Another instance in which I have found it of very essential benefit is, when a blister has been applied to a very young child, and the vesicated part shews no disposition to heal. Every one must have observed this to have taken place; and probably there are very few medical men who have not once, at least, been mortified and grieved, to find that the sore, instead of healing, has, by its irritation, absolutely destroyed the child. In all such ulcerations, the chalk ointment is particularly useful. It allays the excitability of the sore, forms a crust over the exposed surface, and thus protecting it, hastens onward the natural process of cure.”

The fulfilment of the second indication—that of introducing a healthy action—is still more simple, and may be comprised in the single word—pressure; so that the chalk ointment, and “powerful and well-adjusted compression,” make up the sum of the treatment. We shall, in conclusion, allow Mr. Spender to describe his mode of proceeding in his own words:—

“The first thing is, to cover the surface and sides of the sore for some distance beyond its edges with the chalk ointment, spread about the thickness of a wafer on thin linen. I think the linen is preferable to lint, as it seems to allow the disengagement of the chalk more readily. No compresses of any sort are placed on this, as I am convinced the frequent use of paddings of linen, calico, and the like, placed between the dress-

ing and the roller, are prejudicial, by unnecessarily loading and heating the part, and by confining, or preventing, the escape of the matter. They are injurious, also, by interfering with the regular operation of compression; because, if the bandage is applied tightly all round the limb, which ought to be done, the ulcer is pressed beyond its proper share. It is like driving in one of the parts of the superficies of a cylinder; it is depressing the ulcer more than the other portions of the limb just to the extent of the thickness of the padding; and thus, if the compression be sufficiently powerful, it is not only unequal, but bears too much on the ulcerated part. The pledgets made of tow are, I think, also objectionable on much the same principle. These are generally thicker in the middle than at their margins, resembling in figure a sort of double convex. The consequence is, that the centre presses more powerfully than the sides, and the face of the ulcer is driven in more than its edges; when, generally speaking, it is the margins of the ulcer which demand the greatest pressure. Thus, then, without the addition of all compresses and paddings, and in preference to all pledgets made of tow, a single piece of linen, containing a spreading of the chalk ointment, is placed over the centre and sides of the sore. By using this simple unencumbered dressing, in addition to the advantage of obtaining more quickly the chalky crust, all the evils just adverted to are completely avoided. The ulcerated part is not heated nor overloaded; the matter can more freely escape; the face and margins of the ulcer admit of a more equal pressure; first, amongst themselves, and, secondly, in relation to the general outline of the limb. If the edges of the sore are too high, they are brought down; and if the granulations are too prominent, they are depressed by the application of compression upon this flat and even dressing.

“The advantage derived from the bandage does not, as I have already attempted to prove, arise from the local levelling of the sore only, but from the general support and assistance which are given to the structures of the limb. Thick compresses of linen, plates of lead, and the like, placed over the ulcer, or on a varicose vein, may, therefore, do harm, by acting as an obstacle to the

circulation of the inferior parts of the limb. Any thing approaching to the nature of a wedge becomes improper; and instead of adopting these local expedients, we should be very careful that every portion of the limb, from the toes to the knee, be equally and evenly compressed. For this reason, an objection might not unfrequently be advanced against the adhesive plaister. The portion of the limb included within the strappings is compressed so much more tightly than the parts below and above it, that I have sometimes seen both edges of the plaisters girding round the skin as completely as if the integuments had been cut, and considerable inflammation and partial ulceration have been the consequences.

“The face of the sore, and the surrounding integuments for some little distance, as well as any other portions of the skin which happen to be excoriated, being covered with a thin linen dressing of the chalk ointment, the next stage of proceeding consists in the application of the bandage. This is useful, in the non-varicose class, to retain the dressings, in order to form the incrustation, as well as to counteract any ill effects of the dependent position of the limb during the period of granulation; but in the varicose ulcers, in addition to these advantages, it is *indispensably necessary*, for the purpose of altering the condition of the structures underneath. In the latter cases, compression is of such absolute and unequalled importance, that without it every thing else will be comparatively ineffectual. For although the chalk ointment may form its crust, by simply being applied and renewed over the surface and edges of the sore, yet this alone will be productive of only the least half of the benefits of the treatment, so long as the subjacent structures remain varicose or swollen. The simple kind of wound, or non-varicose ulcer, will, indeed, commonly heal, and the cicatrix may remain sound without the aid of the roller; but the varicose kind will proceed but slowly, if at all, without its employment; and, even if it should thus get well, is extremely apt to break out again, either spontaneously, or from the most insignificant cause. The advantage of each remedy is greatly increased by the co-operation of the other; it is like some compounds in che-

mistry, endowed with important properties which neither of their elements possessed alone.

"The necessity and advantage of compression in the treatment of the varicose sores being so great, the rapidity and completeness of the cure will very much depend on the manner in which it is employed. *Except it be properly used*, any surgeon who may feel disposed to give the method I am recommending a trial, will probably be disappointed in its result; but then the failure should be fastened neither on me, nor on the plan, but ought to be imputed to the incomplete mode in which the attempt has been made."

The exceptions to the treatment above described are, extremely deep, callous sores, and highly irritable, and specific sores.

In a concluding chapter Mr. Spender combats the commonly-received opinion, that danger is apt to accrue from healing up old ulcers: he has never been able to trace any thing of the kind in more than "about one case in fifty;" and even then, he says, the evil may be avoided by due attention to the bowels in the way of purging. We recommend the volume to attention. The author's views, if not absolutely novel, are at least adduced with an air of originality and freshness, and are calculated to simplify practice, by lessening the mischiefs of "meddlesome surgery."

A History of British Fishes. By WILLIAM YARRELL, F.L.S. Illustrated by Woodcuts of all the Species, and numerous Vignettes. Part I. Those interested in the subject of this work will find it executed in a manner calculated to secure their approbation. The woodcuts are very prettily done, the descriptions good, and the letter-press concise and satisfactory.

The Marriage Almanack; or Ladies' Perpetual Calendar. From the German of Dr. DESBERGER, of Erfurt. with Additions. 32mo.

THIS little lady's-book is quite within our province: it treats of matters, medical and hygienic, principally relating to the pregnant state. Its chief object seems to be to facilitate the calculation of the

time of pregnancy; and, used for this purpose, we imagine it may prove serviceable to many females who make sad blunders in their reckoning, to the great vexation both of themselves and their obstetrical attendants. Accoucheurs could not do better than recommend it to ladies on their lists. It is very beautifully got up; the tables are clear and intelligible, and the short remarks are sufficiently practical. Sir Charles Clarke, we perceive, has permitted the work to be dedicated to him.

MEDICAL GAZETTE.

Saturday, March 28, 1835.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

OPERATIONS FORCIBLY PERFORMED.

RESPONSIBILITY OF SURGEONS.

WE give, in the present number, a report of the trial which took place last week in the Brenchley case. The facts were clearly made out, and no man on perusing them can possibly say that the result ought to be different from what it has been. The surgeon stands convicted of a misdemeanor, and certainly the circumstances strike us as being of an aggravated character. A lad of 15, a pauper in the Brenchley workhouse, is a martyr to stone: he has been operated on ineffectually a year ago by a particular surgeon; and when now he wishes to be treated by other hands, and has made every arrangement for the purpose, with the concurrence of the overseers of the parish, his former attendant, by stratagem and force, seizes him, and performs the operation of lithotomy upon him. Upon the motive of the surgeon who did this we cast no imputation of a criminal kind: he acted, no doubt, with the greatest zeal and anxiety to save his reputation: he

might have even been persuaded that the boy would be safer in his hands than in those of the rival whose interference he dreaded; but we must say that he conducted himself with extreme indiscretion, and with a degree of violence wholly unwarrantable by any law, written or implied. There was novelty in the case, it is true,—force being rendered accessory to the accomplishment of an ostensibly benevolent object; but there could scarcely be two opinions entertained regarding the propriety of *such* means being adopted for the attainment of any end, however good. The judge's view of the matter was clear, and such as must have occurred to any reflecting man—namely, that an *assault* was committed when the surgeon had recourse to a *forcible* operation.

But the view that ought to be taken of this case rests not here. Let us suppose that the operation had terminated fatally: suppose some unfortunate slip of the knife had led to irremediable mischief; or that any of the accidents which not unfrequently attend lithotomy had occurred; what would then have been the awful situation of the surgeon? Would not the charge of manslaughter, or something more serious, have taken the place of simple assault in the indictment? in short, would not the operator's life have been in jeopardy? How narrow, then, has been his escape!

The truth seems to be (and we have over and over again had occasion to proclaim it in this journal, by way of warning), that there are but too many surgeons who are incautious as to the circumstances under which they undertake certain operations. They forget that their profession, though they may have attained it in the most legitimate and honourable mode, does not render them irresponsible: they even go so far as to fancy that they do certain things by right, which, in reality,

they are only allowed to do by sufferance, or the legal penalties for which they perhaps barely escape by connivance. They do not sufficiently consider, that there is no privilege of immunity attached to the practice of surgery or medicine in this country, and that in case of being proceeded against, for any unlucky event that has happened through their means, their good intentions alone are their protection: the law fortunately leaves them this single loop-hole, and, from the highest to the lowest, there is no other general plea available in their behalf.

It is painful to reflect on the catastrophes that have occurred, from time to time, through neglect of these simple considerations. Not so very long ago, we remember that the Cæsarean operation was attempted on a living woman, in a parish workhouse, and in circumstances which called forth the strongest expressions of censure and condemnation from a coroner and his jury, assisted in their judgment by the evidence of respectable professional witnesses. We fear that workhouses generally, in various parts of the country, are the scenes of more unwarrantable experiments than the public or the profession have any adequate idea of. At all events, we more than suspect that the Brenchley case is far from being singular, in any other regard than in its details and its detection.

A notorious contemporary of ours amuses us not a little by his special pleading, on a question of his own raising, and on which any tyro could give him a sufficient answer. His solicitude is to us perfectly intelligible, when he attempts to argue that it is *justifiable*, under certain circumstances, to perform forcible operations; leaving those circumstances amply wide to comprehend the awkward predicaments into which certain friends of his some-

times throw themselves. It would be very convenient, certainly, if it could be proved to be justifiable, now and then to operate on an unwilling patient, in order to display dexterity in supplying a mutilation, or remedying a deformity—such as the want of a nose; but it would be more to the purpose, perhaps, if it could be shewn to be consistent with the law of the land, or even with the respect due to society. Every body knows, save those who are stupidly or wilfully ignorant, that it is *not* justifiable, *in point of law*, to perform a surgical operation on any person against his consent. Where the person is not recognized as capable of giving consent, as in the case of unsoundness of mind, or of minority, the proceeding is, of course, understood to be modified according to the particular circumstances. We are only sorry that our worthy contemporary, before he wrote so zealously about justifiability, did not take a little more pains to get acquainted with the simple *law* of the case: even at the moment of his writing and puzzling his brains about the matter, the learned judge who tried the Brencley question had already decided upon it, but, unluckily, not quite in accordance with the *learned* editor's notions.

One word more in relation to this subject. Some short time since the conscientious journalist just alluded to expressed much virtuous indignation at certain remarks of ours on the case of poisoning with arsenic which was recently investigated at Bristol: we had prejudged the case, forsooth, and had broken through all the rules of propriety and justice. It happened, however, that we had then before us the *evidence*, as given in the said case, and confirmed by the finding of the coroner's jury; we took care, besides, to be most guarded in attributing any culpability

to the accused not warranted by the depositions of the witnesses. Could we have followed a similar course with respect to the Brencley affair, we should have done so; but we had no evidence before us, nothing more authentic than rumours and *ex parte* statements, in which no credit could be reposed. We therefore determined to abstain from any comment on the transaction, and religiously observed our expressed purpose, till now that the report of the trial comes before us in an official shape. Not so our honest contemporary. The exaggerated story of the Brencley proceedings was too tempting a morsel for his appetite; he swallowed it with avidity, and has ever since been chewing the cud upon it with evident satisfaction to himself. All this time, too, be it observed, he could affect a disregard for another morsel equally rich, and of similar flavour,—one which any body else, less partial to such game, might have readily "*nosed*," as Hamlet says; but it was in his friends' dish, and therefore he has considered it sacred. How we do love this *honourable* consistency and nice fastidiousness of taste!

HOMŒOPATHY DISPOSED OF BY THE FRENCH ACADEMY OF MEDICINE.

A short time since we mentioned that a petition which had been presented to the Minister of Public Instruction by certain Hahnemannians in Paris, had been referred by that functionary to the Académie de Médecine. The question was, whether the petitioners should be allowed to open a homœopathic hospital, or dispensary, in the French metropolis; and the answer now given is sufficiently decisive. We extract from the report of the proceedings of the Academy on the 17th instant, the following minutes:—

M. ANDRAL, one of the commission, came forward to give his opinion, and was listened to with deep attention. He said he was decidedly opposed to the

project of allowing the homœopaths a dispensary: humanity should not be trifled with by the experiments of these people. He had given their system a fair trial; he had treated above 130 or 140 patients homœopathically, in presence of the Hahnemannians themselves. M. Guibourt had prepared the medicines; and every requisite care and precaution were duly observed: yet in not one instance was he successful. He had tried various experiments on his own person, and several other professional friends had followed his example, in order to ascertain the actual effects of the homœopathic doses; but the results were not as Hahnemann and his disciples described them. He (M. Audral) had taken quinine in the prescribed globules, but had contracted no intermittent fever; he had taken aconite, but without being affected with symptoms of plethora; sulphur he took, to try if he should catch the itch, but he caught nothing; neither, upon swallowing certain globules of arnica, did he feel pains as if he had suffered contusion: and so with various other substances which he and his friends took, in obedience to the Hahnemannian precepts. With respect to the attempt to cure disease by this method, he said that in every instance he was obliged to return to allopathy, inasmuch as under the homœopathic treatment the symptoms went on from bad to worse. (*Applause.*)

M. PLORRY showed the absurdity of homœopathy, in pretending to overlook the seat of the disorder: for example, in pneumonia, only recognizing spitting of blood, certain pains, &c. Some had said that homœopathy at all events could do no harm, as it might be considered merely as the medicine of expectation; but he begged to remind them, that that method was far from being suited to all cases, nay, in many was absolutely injurious. He suggested that the negative of the Academy should be expressed in strong terms.

M. BALLY said that he had given permission to MM. Curie and Simon to treat patients homœopathically in his wards; they had done so for four or five months; a register was kept, and the result was that *not one* of a large number of patients was cured by the Hahnemannian method. He was of opinion that the refusal of the Academy ought to be strongly expressed.

MM. Adelon, Itard, Double, Rochoux, Bonilland, Desgenettes, and other members, spoke to the same effect; and the discussion closed by the unanimous adoption of a decided reply to the Minister in the negative. "*Repos aux homœopathes!*" as M. Desgenettes said, in concluding his pithy remarks.

CONCOURS AT MONTPELLIER.

THE interesting concours for the Chair of Legal Medicine at Montpellier has just closed, by the appointment of M. le Dr. René to the office. There were eleven candidates altogether; and the display is said to have been unusually brilliant.

CHARTER TO LONDON UNIVERSITY.

MR. TOOKE's motion for an address from the House of Commons, praying his Majesty to bestow a charter on the London University, was last night carried by a large majority. The charter is *not* to convey the power of conferring degrees in medicine. Even the most strenuous advocates of the establishment have had the good sense to yield to the force of argument brought against them on this point. Lord John Russell, in answer to Sir Robert Peel and Mr. Baring, observed—"The Right Honourable Baronet and the Honourable Gentleman, the President of the Board of Trade, had both referred to what had taken place on this subject before the Privy Council. Now he was one of those who sat on the occasion in the Council, and he had heard the arguments on both sides. Grave objections, he confessed, were urged against granting *medical* degrees,—not so much, however, by the universities as by the medical schools of London, on whose part it was proved that there were several that could confer medical degrees as well—if not better—than the London University; and he thought that the other schools of London would be entitled to confer medical degrees, if that power was given to the University of London; and he (Lord John Russell) was not of opinion that the University of London should be allowed to confer medical degrees."

PROSECUTION AND CONVICTION
FOR FORCIBLE SURGERY.

Maidstone Assizes, Wednesday, March 18.
(Before Mr. Justice GASELEE.)

THE KING v. MONCKTON.

This was an indictment against Jonathan Monckton, a surgeon at Brenehley, and the Rev. Nathaniel Harpur Arthy, charging them with committing an assault upon James Roberts, a pauper in Brenehley workhouse, about 15 years old. Mr. Arthy traversed the indictment until next assizes, but Mr. Monckton pleaded and took his trial. The assault complained of was the performance of an operation upon Roberts by the defendant Monckton, who was the surgeon of the workhouse, contrary to the will of Roberts, of his parents, and of the overseers.

Mr. Serjeant Andrews stated the case, and called

James Roberts, who was examined by Mr. Walsh.—Witness had been afflicted with stone for more than five years. About a year ago he had been operated upon by Mr. Monckton, but he was not cured. He grew worse in the beginning of this year. Mr. Russell, the master of the workhouse, took him to Mr. Hargrave, a surgeon at Tunbridge Wells, on Friday, the 6th of February last. Hargrave saw him, examined him, and gave him some medicines, and appointed him to come again the following Friday, when an operation was to be performed. Witness agreed to do so. The next day he met the defendant Monckton, who was on horseback. Monckton asked what Hargrave had done to him? Witness told him, that he was to go again on Friday. Monckton asked why witness did not let him do it. Witness answered he was afraid Monckton would do it, as he had done it before. Monckton said he would have made a man of witness, if he had come before. On the following Thursday (the day before the intended operation by Hargrave) witness was in the kitchen in the poorhouse, when Russell told him that Arthy wanted him in the committee-room. Arthy was a resident in, but not the clergyman of, the parish. Witness went to the door of the room, and saw both Monckton and Arthy, and the table out in the middle of the room with instruments upon it. On this he stepped back, but Monckton caught hold of him and pulled him in, although he held by the door-post. Witness told him “he was not to do it, he did not dare do it; Mr. Joy (the overseer) had said he was not to do it. His own father had said he was not to do it; he was to go the next day to Mr. Hargrave.” Mr. Russell, who was in the

room, said he would have no more to do with it. Monckton said he did not wish him to stay, but he desired him to go to the surgery, for he had got four men there to help him. Monckton then told witness to pull off his shoes, but he refused. Four men, servants of Monckton and Arthy, came in; witness resisted them, but they took off his shoes and trousers, and laid him on the table, one man holding each leg, and one man holding each arm. Witness made what resistance he could, and cried and lamented very much, but did not holloa out. (Witness then detailed the operation.)

Cross-examined by Mr. Bodkin.—He had been five years labouring under the disease, which was very painful, and prevented his working. Monckton attended his family when they were ill with the typhus fever. He had heard there was a new plan of extracting the stone without cutting, which Mr. Hargrave practised, and which did not cause so much pain. No surgeon had examined him since. A little piece of a stone about the size of a pea was got out, and the wound was quite healed in a fortnight.

Mr. Russell, the master of the workhouse, said he went with the boy to Mr. Hargrave, by order of Joy and Venness, the overseers. The boy agreed to go again on the next Friday, to have the operation performed by Hargrave. When Monckton came to the workhouse on the Thursday, the boy stood at the door crying, and said, “You are not to do it, but Mr. Hargrave.” Witness also told Monckton that the boy was to go on the morrow to Mr. Hargrave. Monckton made no reply, but caught hold of the boy and pulled him into the room. They desired witness to call the four men.

Joseph Moon, a pauper.—Heard Roberts cry out, “You must not do it; you shall not do it; Mr. Joy says you are not to do it; Mr. Hargrave is to do it.”

George Joy, the overseer, said the boy was getting worse, and his mother had expressed a wish that some other doctor should do the operation, and he promised to attend to her request. Witness and his brother overseer sent the boy to Mr. Hargrave’s.

Cross-examined by Mr. Deedes.—Monckton manifested great anxiety about the boy. After the first operation, he said he should never be happy until he had taken away the stone. It was Monckton’s duty to attend all sick and diseased persons in the workhouse.

Mr. Bodkin desired his Lordship’s opinion upon the law of the case.

Mr. Justice Gaselee said it was a new case, but he had no doubt about it; the

persisting to perform the operation against consent, was unassaulted.

Mr. Bodkin then addressed the jury for the defendant, and called Mr. John Price and Mr. Richard Webb, surgeons, who gave the defendant a most excellent character for skill, humanity, and benevolence. Mr. Parton, a miller, whose family the defendant had attended, and the officiating clergyman of Brenchley, also spoke in the highest terms of the defendant, and of his great feeling towards the poor. The latter gentleman stated, that the defendant had been vilely calumniated and slandered.

Mr. Justice Gaselee said, whatever verdict the jury might give, no gentleman could go out of court with a better character for skill and humanity. The question was, whether the operation was performed without the consent of the overseers, without the consent of the boy, and without the consent of his father. The father had not been called. It was an important case, and he was not aware that the question had ever before arisen. If the defendant had mistaken the law, his character and honour would not suffer.

The jury immediately found the defendant *Guilty*.

Mr. Walsh said there was no desire to press for punishment, and, after some discussion, the defendant was allowed to depart, upon entering into his own recognizance to appear when called upon to receive judgment.

STATISTICAL SOCIETY.

Monday, March 16, 1835.

Anniversary Meeting.

THE anniversary meeting, numerously attended, took place this day; the Marquis of Lansdowne, President, in the chair. From the report of the Council, it appears that the number of Fellows at present belonging to the society is 398; and perhaps no other scientific body could exhibit so large a list in the first year of its formation. The death of Mr. Malthus was mentioned in the report, as an event deeply to be regretted: this gentleman having been one of the principal founders of the society, and whose name it was hoped would long confer a distinguished lustre upon it. No foreign associates, with the exception of M. Quetelet, have yet been elected; nor is it intended to admit any until the state of the society shall have been further matured. Various provincial statistical societies have either been formed, or are on the point of formation, in different parts of the kingdom. The financial affairs are in a very flourishing condition: up to the 31st of December last there was a clear balance in the hands of the treasurer (all expenses paid) of

715*l.* 19*s.* 2*d.*, which, with the outstanding subscriptions on account of 1834, would leave the assets, at the close of last year, 867*l.* 3*s.* 2*d.*

Mr. Drinkwater proposed three or four changes in the regulations of the society, chiefly affecting the mode of admission, which were carried; after which a vote of thanks to the noble President being acknowledged in a neat speech, the meeting adjourned.

Statistics of Spain.

In the evening one of the ordinary monthly meetings was held,—Lieut. Col. Sykes, Vice President, in the chair,—when an abstract from a new work, by M. Moreau de Jonnes, on the *Statistics of Spain*, was read. From this elaborate document we learn that the population of Spain, together with the Balearic isles, amounts to 11,660,000—that is, 850 inhabitants to the square league: including the colonies, (namely, the Canary and Phillipine islands, Cuba, Porto Rico, and the settlements on the African coast), the number of subjects of the King of Spain should be 18,245,000, or 500 to the square league. Spain, in 1723, contained only about seven millions and a half of inhabitants; so that it has nearly doubled itself since. The rate of increase, however, of late years, seems to be much higher: from 1803 to 1826, a period of 23 years, the increase has amounted to 3,361,000 souls, showing an advance of 30 per cent. on the previous population; according to which rate the period of doubling would not exceed 60 years. The agricultural returns show that Spain has latterly been prospering very conspicuously.

With regard to the mode of living of the people of Spain, one fact may be mentioned. The annual consumption of meat throughout that kingdom is not more than 22 lbs. for each inhabitant. Now in France, be it observed, the consumption of meat is 36 lbs. for each individual, and in Paris 86 lbs.; while in Great Britain the annual consumption is 92 lbs., and in London 113 lbs. for each inhabitant—that is to say, above six times as much meat is used by a Londoner as by a native of Spain!

Public instruction is more neglected in Spain than in any other European country—Russia alone excepted. The census of 1823 gave only 29,900 students for the whole kingdom, which is but 1 for every 346 of the inhabitants; and if the same ratio be still preserved, it follows that there are in Spain only 40,000 children receiving instruction, while there are a million and a half of souls of an age to require it; in other words, only 1 child in every 35 in that country receives the benefit of an early education.

THE BAPTISMS AND BURIALS,

In the Parish of SAINT LUKE, CHELSEA, during the Year 1834.

BAPTISMS.

At St. Luke's Church.

Males, 360; Females, 112.—Total, 772.

At Trinity Church.

Males, 77; Females, 78.—Total, 155.

Comparison with the preceding Year :—

NEW MEDICAL WORKS.

Jornal Medico-Cirurgico e Pharmaceutico de Lisboa, pp. 56. 8vo. [This is the first number of a Portuguese medical journal, brought out last month at Lisbon, under the editorship of Dr. Vianna de Rezende. We shall be glad to hear of its success.]

Table of Medical Botany, for the Use of Students. By J. Barnes.

WEEKLY ACCOUNT OF BURIALS,*From BILLS OF MORTALITY, March 24, 1835.*

Abcess	1	Gout	4
Age and Debility ..	54	Heart, diseased ..	3
Apoplexy	8	Hooping Cough ..	23
Asthma	37	Inflammation ..	58
Cancer	1	Bowels & Stomach ..	5
Childbirth	12	Brain	3
Consumption	80	Lungs and Pleura ..	6
Constipation of the		Liver, diseased ..	22
Bowels	1	Measles	10
Convulsions	47	Mortification ..	1
Dentition or Teething	5	Paralysis	3
Diarrhoea	3	Small-Pox	4
Dropsy	19	Sore Throat and	
Dropsy on the Brain ..	6	Quinsey	1
Dropsy on the Chest ..	1	Thrush	1
Fever	9	Tumor	1
Fever, Intermittent,		Unknown Causes ..	17
or Ague	1		
Fever, Scarlet	11		
Fever, Typhus	1		

Increase of Burials, as compared with }
 the preceding week } 99

METEOROLOGICAL JOURNAL.

*Kept at EDMONTON, Latitude 51° 37' 32" N.
 Longitude 0° 3' 51" W. of Greenwich.*

<i>March, 1835.</i>	<i>THERMOMETER.</i>	<i>BAROMETER.</i>
Thursday . 19	from 32 to 43	30.11 to 30.17
Friday . 20	28 45	30.21 30.23
Saturday . 21	38 48	30.24 30.21
Sunday . 22	39 47	30.21 Stat.
Monday . 23	37 47	30.21 30.19
Tuesday . 24	35 48	30.20 30.29
Wednesday 25	30 46	30.40 30.47

Wind variable, N.E. prevailing.
 Except the 25th, generally cloudy; rain at
 times on the 21st, 23d, and 24th.
 Rain fallen, .375 of an inch.

CHARLES HENRY ADAMS.

NOTICES.

Mr. Beamish, of Ramsgate.—The paper on Medical Reform, as we have already said, is unsuited to our pages; and we have only to add, that the author is greatly mistaken if he thinks we could be induced to publish it through any such motive as that by which he attempts to influence us.

We have to apologize to several correspondents whose papers remain over till next week; when we shall commence a new volume.

WILSON & SON, Printers, 57, Skinner-St. London.

INDEX to VOL. XV.

(VOL. I. FOR THE SESSION 1834-35.)

A.

- ABORTION**, Dr. Churchill on a case of, in the sixth month, with epileptic convulsions, 109.
- extraordinary—fœtus vomited by a boy, 384.
- Accoucheurs and nurses**—pouddage system, 255.
- Acetum opii sedativum**, Mr. Horne on a new preparation of the, 573.
- Acid, pyroligneous**, Dr. Babington on the employment of, in cases of ring-worm, 549.
- Adams, Mr.** account by, of a case of fractured skull, with rupture of the spinous artery, successfully trephined, 730.
- Address to his Majesty**, from the Royal Medical and Chirurgical Society, 812.
- Advertisement extraordinary**, 564.
- Air passages**, Dr. Davies on inflammation of the mucous membrane of the, 178.
- Albin Gras**, account by, of a case of hanging, unattended by any of the usual characteristic lesions, 837.
- Aldis, Dr.** on the exudation of salt from the skin, 18; on percussion, as a mode of discriminating certain abdominal swellings, 552.
- Alexander, Dr.** on a case of congenital malformation, 270.
- Allnatt, Dr.** on a case of cough resulting from diaphragmatic spasm, 340; on the pathology of the second stage of fever, 659.
- All prime ministers** "one faculty men," according to the *Lancet*, 377.
- Amaurosis, saturnine**, M. Duplay on, 287.
- Amenorrhœa**, case of, speedily cured by leeches to the groin, 251; remarks, *ib.*
- Amputation**, clinical lecture on, by Sir C. Bell, 90.
- Mr. Mann on the excision of nerves exposed in, 772.
- Anatomy**, Dr. Quain's elements of, reviewed, 240; ardour evinced for the pursuit of, in Italy, 315.
- Anatomy act**, editorial observations on the imperfect working of the, 341.
- editorial article on the causes of the difficulties in the working of the, 377.
- circular addressed to teachers of, 346.
- encouragement given to, in France, 440.
- the difficulty lately experienced in procuring subjects for the prosecution of the study of, attributable chiefly to a decrease in the number of deaths, 600.
- meeting of the medical students in Edinburgh on the subject of, 811.
- Andrews, Mr.** observations by, on Mr. Stafford's treatment of strictures of the urethra, 75.
- on the changes produced in the blood by repeated bleedings, 592.
- Anderson, Mr. John**, account by, of a case of diabetes mellitus, 654.
- Dr. on the extirpation of fungous tumors of the antrum, 770.
- Mr. on the pathology of phlegmasia dolens, with the history of a case which presented several unusual appearances, 794.
- Anderson's, Mr.** observations on renal dropsy, 855, 903.
- Aneurism, iliac**, case of, in which the *aorta* was tied, by Dr. Murray, 7.
- subclavian, Dr. Gibbs's case of, 150.
- clinical lecture on, by Sir C. Bell, 567; case of, of the arch of the *aorta*, with ulceration into the *œsophagus*, 568; of the external iliac, 569.
- Dr. Davies on, 849.
- Dr. Murray on, and the pathology of secondary aneurismal hæmorrhage, 907.
- Ankle-joint**, Sir C. Bell on a case of fracture into the, 92.
- Arimation, suspended**, Dr. A. P. W. Philip on the nature and treatment of, 318.
- Annual meteorological journal**, 926.
- Antrum, maxillary**, clinical lecture, by Sir B. C. Brodie, on diseases of the, 346;

- case of inflammation of the, independent of local causes, 347; another case dependent on local causes, *ib.*; collection of transparent fluid in the, 349; polypus of of the, 350; malignant tumors of the, *ib.*
- Antruni, Dr. Anderson on the extirpation of fungous tumors of the, 771.
- Anti-psoro-syphilide, account of the composition of the remedy, 320.
- Anus, imperforated, Dr. Dyce on a case of, successfully treated, 226.
- Aorta, ligature of the, in a case of iliac aneurism, 6.
- Sir C. Bell on a case of aneurism of the, 568
- Aorta, Dr. Davies on aneurisms of the, 849.
- Apoplexy, Mr. Robbs on a case of, with delirium tremens, 78.
- Apoplexy and palsy, Dr. Hope on the connexion of, with organic disease of the heart, 776.
- Apoplexia pulmonum, Dr. Davies on, 420.
- Apothecaries' Hall, list of gentlemen who have received certificates, 64, 96, 141, 176, 203, 256, 288, 352, 384, 416, 443, 528, 575, 608, 672, 704, 752, 816, 848, 896, 928.
- Aponeuroses and fasciæ, Professor Mayo on, 445.
- Appointments, French Medical, occasioned by the death of Baron Dupuytren, 810.
- Arrowsmith, Dr. account by, of an unsuccessful case of lithotripsy, 399.
- Arsenic, Mr. Brett on the hydrated oxide of iron as an antidote for, 220.
- reputed antidote for, 447.
- account, by Mr. Holland, of a case of poisoning with, 828.
- supposed antidote for, 847.
- case in which its presence in the stomach was detected fourteen months after interment of the body, 496.
- Artery, femoral, tied by Mr. Bransby Cooper, for the cure of popliteal aneurism, 174.
- case of ligature of the, 573.
- Arteries, wounded, Sir C. Bell on, of the fore-arm, 202.
- Ascites, encysted, Dr. Aldis on the diagnosis of, by percussion, the patient being in the recumbent posture, 552.
- Ashwell's, Dr. letter in reply to Dr. Blundell's pamphlet on the causes of his resignation of the midwifery chair at Guy's hospital, 31.
- Asthma, Dr. Davies on, 449; definition of, *ib.*; various causes and forms of, 450.
- Attendance, gratuitous, of medical men, injustice of the, 831.
- Auricle, case of tumor in the, 670.
- Auscultation, Dr. Davies on, 145; principles on which it depends, *ib.*; instruments employed, *ib.*; position of the patient, *ib.*; application of the stethoscope, 116.
- remarks on, in surgical cases, 689.
- B.
- Babington, Dr. on the treatment of ring-worm by pyroligneous acid, 549.
- Badham, Dr. D. on the nervous circle of Sir C. Bell, 71.
- Dr. John, on a case of exanthema and narcotism, from the external application of hops, 112.
- account by, of two cases of peritonitis, with remarks, 687.
- Badeley, Dr. on opium in delirium tremens, 685.
- Ballingall, Sir George, on a case of rupture of the tendon of the biceps flexor cubiti, 741.
- Barham, Dr. on a new system of weights and measures for the pharmacopœia, 770.
- Barker, Mr. on bronchocele in young females, with remarks on the use of iodine, 230.
- Beaumont, Mr. on a case of laceration of the internal parts without external lesion, 727.
- Bell's, Sir Charles, clinical lectures:—amputation, 90; on wounded arteries of the fore arm, 202; on stricture, with lacerated urethra and distended bladder, 294; on cancer, more especially on carcinoma of the mamma, 423; on dysphagia, 565; on aneurism, 567; on scrofulous diseases of the hip, 698; on diseases of the knee-joint, 896.
- on the functions of some parts of the brain, and on the relations between the brain and nerves of motion and sensation, 614; on the decussation of the posterior columns of the crus cerebri, 626; on the decussation of the posterior cerebral columns, 513.
- Mr. C. W. on the anatomy of the medulla oblongata, 436.
- Bennett's, Mr. extracts from a journal of natural history, 113, 232; wanderings in New South Wales, reviewed, 515.
- Biceps, Sir G. Ballingall on a case of rupture of the tendon of the, 741.
- Bird, Mr. on the modification produced on castor-oil in passing through the bowels, 225; examination of the fatty matter, *ib.*
- Blood, Mr. Andrews on the changes produced in the, by repeated bleedings, 592.
- researches on, by MM. Gmelin and Tiedemann, 605; does it contain urea after the extirpation of the kidneys? 606; no urea, or sugar of milk, in healthy blood, 607.
- Blood-vessels, the large, Dr. Davies on diseases of the, 849.
- Bloxam, Mr. on a case of malformation of the heart, 435.
- Body, Dr. Wilson Philip on the causes of the growth of the, 662.
- Bone, Professor Mayo on hypertrophy and atrophy of, 153; on inflammatory enlargement of, abscess, and necrosis, 183;

- caries of, 244; on malignant tumors of, 262; absorption of, 265; anormal growth of, 266; Mr. Phillips on the union of, being the substance of an essay which obtained the Jacksonian prize, 779.
- Bone soup, complete success of, at the hospital St. Louis, Paris, 447.
- Books, analyses and notices of:—Dr. Belden on somnambulism, 52; Guerin-de-Varry's *nouveaux élémens de chimie, theorie et pratique*, ib.; *ossa humana*, ib.; Dr. Philip on sleep and death, 30; second notice, 662; Dr. Kilgour on the ordinary agents of life, 126; Venables' aphorisms in chemistry, 128; Meade's compendium of pharmacy, ib.; Dr. Good's study of medicine, 236; Dr. Forbes on diseases of the chest, and on mediate auscultation, 238; Dr. Quain's elements of anatomy, 240; Dr. Cutler's surgeon's guide in dressing, &c. ib.; Steggall's manual for students preparing for examination at Apothecaries' Hall, 240; Mr. Everest's popular view of homœopathy, ib.; Dr. Clark on pulmonary consumption, 303; Mr. Foote's medical pocket-book, 310; Mr. Walker's principles of ophthalmic surgery, 311; Mr. Eden's outlines of a new system of philosophy, 374; Cloquet's *anatomie descriptive*, 375; Dr. Thomson's elements of *materia medica* and therapeutics, 403; *cours complet d'histoire naturelle médicale et pharmaceutique*, 438; *des diverses méthodes pour l'obliteration des artères*, par Lisfranc, &c. &c. ib.; Dr. Turner's elements of chemistry, 479; *memoirs and essays on subjects connected with medicine*, &c., 515; Bennett's *Wanderings in New South Wales*, ib.; *Dublin university calendar*, 560; *Velpéau's traité complet de l'art d'accouchemens*, 561; Dr. Jacobi on the structure and arrangement of lunatic asylums, 660; Dr. Philip on sleep and death (second notice), 662; Mr. Duffin on deformity of the spine, 736; Mr. Pritchard's list of microscopic objects, 737; Dr. Grant's outlines of comparative anatomy, 808; Dr. Green on diseases of the skin, 838; Dr. Bostock's history of medicine, 839; Dr. Hodgkin on the means of preserving health, ib.; Royle's illustrations of the Flora of Cashmere, 877; Wight and Arnott's *Prodromus*, ib.; Wight's contributions to the botany of India, ib.; M. Louis on phthisis, 879; Spender on ulcerous diseases of the leg, 915; Yarrell's *British fishes*, 918; marriage almanack, ib.
- Bostock, Dr. outlines of a plan proposed by, for the future regulation of the medical profession, 15.
- 's, Dr. history of medicine, reviewed, 839.
- Botany, prizes for, proposed and adjudged by the Society of Apothecaries, 382.
- Brain, Sir C. Bell on the functions of some parts of the, and the relations between it and the nerves of motion and sensation, 611; of the striated septa in the medulla oblongata and pons varolii, 616; the posterior tract, 617; decussation of the posterior or sensitive part, 618; the origin of the posterior roots of the spinal nerves, and their relation to the decussation of the posterior column, ib.; the origin of the sensitive root of the fifth nerve, and its relation to the spinal marrow, ib.; further examination of the relation between the brain and spinal marrow, 620.
- Brain and spinal cord, Professor Mayo on the, 438; of the cerebral tissue, ib.; inflammation of the cerebral substance, 439; abscess, 490; of softening less evidently dependent on inflammation, ib.; of hardening, ib.; of the pia mater, ib.; of the arachnoid membrane, ib.; of the dura mater, ib.; inflammation of the substance of the cord, 527; inflammation of the membranes of the cord, ib.; serous effusion of the spinal cord, 537; spinal apoplexy, ib.; deposits between the membranes of the cord, ib.; of tumors exterior to the theca, 538; of malignant disease of the spinal cord, ib.
- , Mr. Sweatman on a case of premature development of the, 594.
- Brett, Mr. on the hydrated oxide of iron as an antidote for arsenic, 220.
- on the action of iodine upon guaiacum, 831.
- Breschet, M. operation for the radical cure of varicocele, Mr. Walshe on, 367.
- Bright, Dr. on a diagnostic symptom in peritonitis, 697.
- Brodie, Sir B. C. clinical lectures by: on encysted tumors, 25; on diseases of the maxillary antrum, 346; on diseases of the rectum—hemorrhoids, 742, 842; prolapsus of the rectum, 845; excrescences of the rectum, 846.
- Bronchophony, Dr. Davies on, 529.
- Bronchocele in young females, Mr. Barker on, with remarks on the use of iodine, 230.
- Bronchial tubes, Dr. Davies on dilatation of the, 292.
- Buehner, M. note by, on kreosote, 607.
- Ball, Mr. account by, of a case of cholera in a mare, 30.
- Bulletin, a Portuguese, 608.
- Bursa mucosa, Professor Mayo on, 413.
- Burton, Dr. notice of the appointment of, as physician to St. Thomas's Hospital, 32.
- Burke, Dr. on a case of chronic rheumatism successfully treated by tartar emetic, 50.
- Bury, Mr. on aqueous discharge after parturition, 17.
- Barials, weekly account of, 32, 64, 96, 114, 176, 203, 256, 288, 320, 384, 416, 448, 496, 528, 576, 606, 672, 704, 752, 784, 816, 848, 896, 928.

Burials, annual report of, 928.

Bu-*ck*, Mr. accou-*t* by, of a case in which lithotri-*ty* was unsuccessfully attempted, 590.

C.

Calculus, case of, passing from the kidney, 302.

Calculi in the lachrymal ducts, singular instance of, 623.

Cancer, clinical lecture on, by Sir C. Bell, more especially on carcinoma of the mammae, 423; treatment of, by the paste of chloruret of zinc, 608.

Cantharides, case of poisoning with, 320.

Castel, M. on the comparative irritability of the right and left portions of the heart, 383.

Caswall, Mr. on the treatment of gonorrhoeal and syphilitic affections with iodine, 192.

Castor oil, Mr. Bird on the modification produced on, in passing through the bowels, 223.

Catarrh, Dr. Davies on, 209; chronic mucous, 212, 258.

Cazentre, Dr. on congenital deformity of the iris, 671.

Cerebellum, case of disease of the, giving rise to a singular disturbance of the muscular powers, 113.

Charities, medical, as places of instruction, 874.

Charter of the Royal Medical and Chirurgical Society, copy of the, 272.

Chelsea report of burials, 927.

Chemistry, Dr. Venables' manual of aphorisms in, reviewed, 123; Dr. Turner's elements of, reviewed, 479.

Chest, Dr. Davies' lectures on diseases of the, and on the practice of percussion and auscultation:—DISEASES OF THE LUNGS: 1; theory of the signs of disease of the lungs, 2; theory of dyspnoea, 3; mechanism of the chest, 33; its position and form, *ib.*; its structure, *ib.*; sternum, *ib.*; direction of the ribs, 34; external surface of the chest, *ib.*; its superior and inferior circumference, *ib.*; its functions, *ib.*; movement of inspiration, 35; varieties of dyspnoea, 36; movement of expiration, *ib.*; forced expiration—cough, 37; contraction of the glottis, *ib.*—PERCUSSION, 65; principle upon which it depends, 66; position of the patient, *ib.*; mode of percussing, *ib.*; variations in sound at different ages, and in different temperaments, 67; variations according to situation, 67; regions of the chest, *ib.*; nature of sound elicited in the various regions, *ib.*; inferences arising from the preceding observations, *ib.*; examination of the size, movements, &c., of the chest, 97; examination by the hand, *ib.*; movements of the chest, 98; its dimensions, *ib.*; dilatation and contraction, 99; abdominal pressure, 100; pneumometry, *ib.*; auscultation, 145; principles on which founded, *ib.*; instruments em-

ployed, *ib.*; position of the patient, *ib.*; application of the stethoscope, 146; auscultation of the voice, *ib.*; pectoriloquy, 147; voice in trachea and larynx, 148; voice in bronchial tubes—bronchophony, 148; voice in pulmonary tissue, *ib.*; respiratory murmur, *ib.*; respiratory murmur in pulmonary tissue, *ib.*; in trachea and bronchial tubes, 149; in excavations, or cavernous respirations, *ib.*; bronchial respiration, *ib.*; blowing respiration, *ib.*; souffle voilé, *ib.*; bourdonnement amphorique, 150; rhoncus, *ib.*; ægophony, 151; metallic tinkling, 152; frottement ascendant and descendant, *ib.*; diseases of the ærian passages, 177; inflammation of the mucous membrane of the air passages, 178; mucous catarrh, *ib.*; inflammation of the Schneiderian membrane, or coryza, 179; of the mucous membrane of the fauces, or cyanche pharynge and tonsillaris, *ib.*; of the mucous membrane of the larynx, or laryngitis, 180; of the mucous membrane of the bronchial tubes, 181; rhoncus sibilans, or sibilating wheezing, 182; rhoncus sonorus gravis, or deep sonorous wheezing, 182; rhoncus mucosus, or mucous rattle, 182; catarrh, 209; causes, *ib.*; influenza, 210; treatment, 211; chronic mucous catarrh, 212.—DISEASES OF THE ÆRIAN PASSAGES: pituitous catarrh, 257; chronic pituitous catarrh, 258; whooping cough, *ib.*; catarrhus siccus, or dry catarrh, 260; hysterical cough, 262; croup, 289; dilatation of the bronchial tubes, 292; bronchial hæmorrhage, 294; bronchial polypi, *ib.*—DISEASES OF THE PARENCHYMATOUS STRUCTURE OF THE LUNGS:—Primary disease of the pulmonary tissue, 321; peripneumonia, *ib.*; signs of engorgement, 353; percussion, *ib.*; local signs of the resolution of pneumonia, 354; functional signs, 355; treatment, *ib.*; emphysema pulmonum, 385; vesicular emphysema, *ib.*; symptoms of, 387; interlobular emphysema, 388; œdema pulmonum, 417; apoplexia pulmonum, or hæmoptysis, 420; asthma, 419; asthma, or intermittent dyspnoea, 430; chronic mucous catarrh, *ib.*; chronic dry catarrh, *ib.*; chronic pituitous catarrh, 451; humid asthma, *ib.*; asthma from increased necessity for respiration, or with puerile respiration, *ib.*; spasmodic asthma, 452; stethoscopic proofs of spasm of the bronchial tubes, 453; symptoms of spasmodic asthma, *ib.*; asthma from combinations of organic and nervous causes, 454; remote causes of asthma, *ib.*; asthma, or intermittent difficulty of breathing, *ib.*; asthma from nervous causes, 456; combined forms of asthma, *ib.*; adventitious deposits, 497; definition, *ib.*; inorganic and organic, *ib.*; tubercular deposit, *ib.*; miliary tubercles, 498; tubercular granulations, *ib.*; encysted tubercles, *ib.*; gray

tubercular infiltration, *ib.*; gelatiniform tubercular infiltration, *ib.*; softening of the tubercular matter, 499; tubercular excavation, *ib.*; tubercular fistula, *ib.*; tubercular cicatrix, 500; table of the duration of phthisis before death was produced in 200 cases, 501; phthisis pulmonalis, 529; of the accumulation of gray or crude tubercles, *ib.*; bronchophony, *ib.*; percussion, *ib.*; softening of the tubercular mass, *ib.*; cavernous cough and respiration, *ib.*; pectoriloquy, 530; dyspnoea, 531; general signs, 532; causes, 534; treatment, 535; cartilaginous and osseous adventitious deposits, 577; cysts, 578; hydatids, or acephalocysts, 579; medullary sarcoma, *ib.*; melanosis, 581.—**DISEASES OF THE LUNGS:** pleuritis, 609; conversion of false membranes into cellular tissue, or fibro-cartilage, 611; signs of pleurisy, 611; ægophony, 612; signs arising from the pressure of the fluid upon the surrounding parts, *ib.*; immobility of the ribs, 613; position of the patient, *ib.*; signs of formation of cellular tissue, or fibro-cartilage, or of decrease of effusion, *ib.*; signs of effusion, 614; causes of pleurisy, *ib.*; treatment, *ib.*; paracentesis thoracis, 645; hydrothorax, 673; pneumothorax, *ib.*; signs of, with effusion, 675; hippocratic fluctuation, *ib.*; tintement métallique, *ib.*; bourdonnement amphorique, *ib.*; pleuro-peripneumonia, 677; peripneumonia, combined with slight pleurisy, *ib.*; pleurisy, with slight peripneumonia, *ib.*; pleuritis and peripneumonia of equal intensity, *ib.*; accidental productions deposited in the pleura, 678; diaphragmatic intestinal hernia, 678.—**DISEASES OF THE HEART:** percussion, 706; auscultation, *ib.*; extent of pulsation, *ib.*; impulsion, 707; rhythm of the beatings of the heart, 708; of the sounds produced by the movements of the heart, 709; of certain anomalous sounds produced by the action of the heart and arteries, 710; proximate causes of the sounds produced by the movements of the heart and arteries, *ib.*; frémissement caténaire, 711; of the beatings of the heart heard at some distance from the chest, 712; tabular view of the diseases of the substance of the heart, 753; hypertrophy of the substance of the heart, *ib.*; hypertrophy of the ventricles, 754; dilatation of the ventricles, *ib.*; hypertrophy, with dilatation of the ventricles, *ib.*; hypertrophy, with dilatation of the auricles, 755; diseases of the valves, *ib.*; cartilaginous deposit in the mitral valves, 756; ossific deposit in the mitral valves, *ib.*; ossific deposit in the semilunar valves of the aorta, *ib.*; vegetations formed on the valves and parietes of the cavities of the heart, *ib.*; causes of hypertrophy and dilatation of the heart, 757; obstruction from a con-

tracted or dilated aorta, 758; simple hypertrophy of the ventricles, 785; hypertrophy, with dilatation of the ventricles, 786; signs of hypertrophy and dilatation of auricles, 787; signs of diseased valves, *ib.*; signs of diseased mitral and aortic valves, 788; general signs of diseases of the heart, *ib.*; treatment of diseases of the heart, *ib.*; carditis, 794; ulcers of the heart, *ib.*; rupture of the heart, *ib.*; hardness of the substance of the heart, 792; softening of the substance of the heart, *ib.*; of surcharge of fat, and of fatty degeneration of the heart, 793; of cartilaginous or ossific deposits in the muscular texture of the heart, 793; other accidental deposits in the substance of the heart, *ib.*—**DISEASES OF THE PERICARDIUM:** pericarditis, 817; acute pericarditis, *ib.*; chronic pericarditis, 818; hydro-pericarditis, 821; pneumo-pericarditis, *ib.*; polypi, *ib.*; diseases of the large blood-vessels, 822; pseudo-membranous exudation from the internal surface of the heart and arteries, 823; ulceration of the membrane lining the heart and arteries, *ib.*; osseous, calcareous, and cartilaginous incrustations of the aorta, *ib.*—**DISEASES OF THE LARGE BLOOD-VESSELS:** 849; aneurism of the aorta, *ib.*; true aneurism, *ib.*; false consecutive aneurism, 850; concretions of blood in aneurismal sacs, 851; the effects of aneurisms upon the surrounding organs, 852; general signs of aneurism of the aorta, 853; local signs, *ib.*; treatment of aneurisms, 854; diseases of the pulmonary arteries, and of the coronary vessels, 855.—**NERVOUS DISORDERS OF THE HEART AND ARTERIES:** 897; angina pectoris, *ib.*; treatment of angina pectoris, 898; nervous palpitations of the heart, 899; spasm of the heart, accompanied by bruit de soufflet and frémissement caténaire, *ib.*; nervous affections of the arteries, *ib.*; neuralgia of the arteries, *ib.*; augmentation of arterial impulsion, *ib.*; spasm of the arteries, combined with bruit de soufflet, 900; treatment of neuralgia of the arteries, *ib.*; displacements of the heart, 904; in deconformation of the heart and great blood-vessels, *ib.*; single hearts, *ib.*; imperfect double hearts, 902; imperfect septum of auricles, *ib.*

Chest, Dr. Forbes' treatise on diseases of the, reviewed, 253.

— contributions, by Mr. Robbs, to the pathology of the, 429.

Chevalier, Mr. on the cure of polypi in the meatus auditorius externus with sulphate of zinc, 50.

Chil-murder, editorial observations on an inquest in a case of, 406.

Chomel, M. clinical lecture by, on typhoid fever, 56.

Chorea, case of, terminating fatally, with

- an account of the appearances on dissection, 638.
- Cholera, demonstration of the gradual decrease of, during the last three years, 23; Mr. Bull on a case of, in a mare, 30; poetical description of, 142; notice of a paper on, by Dr. Vetch, read before the College of Physicians, 779.
- Christison, Dr. on paralysis of individual nerves of the face, 59.
- Churchill, Dr. report by, of cases of convulsions occurring in puerperal women, 107; report by, of cases in which ergot of rye was used, with its effects, 223.
- Cicatrix, tubercular, Dr. Davies on, 500.
- Civis Medicus on medical reform, 372, 692.
- Clarke, Mr. on the venereal disease, 37, 68.
- Clark's, Dr. treatise on pulmonary consumption, reviewed, 503.
- Clark, Mr. Wellington, on the pathology of phlegmasia dolens, 370.
- Clendinning, Dr. on the curative properties of hydriodate of potass in periostitis and chronic articular rheumatism, 833, 866.
- Cloquet's, M. anatomie descriptive, critical notice of, 374.
- Club-feet, Dr. Lyons on, 468, 541.
- Cock, Mr. on the anatomy of congenital deafness, 416.
- College of Physicians, papers read at the:—Sir Henry Hallford on the deaths of some eminent persons of modern times, 634; Dr. Hope on the connexion of apoplexy and palsy with organic disease of the heart, 776; Dr. Vetch on cholera, 779, — editorial observations on the proposed changes in the, 485, 561, 664; prospects of reform in—whether is it better to repair or rebuild, 692; editorial remarks on the reform proceedings in the, 694; on internal reform in the, 773.
- list of officers appointed for the year, 32.
- Surgeons, list of gentlemen admitted members in September 1834, 32; notice to hospital surgeons, 176; to surgical students, *ib.*; new regulations of, 197; list of gentlemen admitted members in October 1834, 203; circular addressed to teachers of anatomy, 346; list of gentlemen admitted members, 352, 672, 816.
- Colds and coughs, formula for pastilles for, 446.
- Colon, Mr. Rowe on a case of intro-susception of the, into the rectum, 119.
- Collins, Dr. on the mal-administration of certain provincial hospitals, more especially in Liverpool, 121.
- Concours at Montpellier, for the chair of médecine legale, 741, 921.
- Consumption, pulmonary, Dr. Clark's treatise on, reviewed, 303.
- Convulsions, puerperal, Dr. Churchill's reports of cases of:—hysterical convulsions, 107; epileptic convulsions, *ib.*; epileptic convulsions after delivery, 103; abortion in the sixth month, with epileptic convulsions, 109; apoplectic convulsions, 110; remarks, 111.
- Condyloma, Dr. Peregrine on cases of syphilitic sore resembling, 337.
- Corpora striata, function of the, 346.
- Contradiction, official, to the misstatements in the *Lancet* respecting the school of physic in Ireland, 448.
- Cough, Dr. Allnatt on a case of, resulting from diaphragmatic spasm, 340.
- Corbaux, Mr. on population and mortality, 699; on the fecundity of marriages, 735.
- Coroners' inquests, editorial remarks on, and on a case of apparent death, 696.
- Cornea, Mr. Middlemore on the anterior membrane of the, 547.
- Coryza, Dr. Davies on, 179.
- Cough, hysterical, Dr. Davies on, 262.
- Croup, Dr. Davies on, 289.
- Crus cerebri, Sir C. Bell on the decussation of the posterior columns of the, 626.
- Crystallino-capsulitis, two cases of, 248.
- Cummin, Dr. on medico-legal disinterments in France and England, 187.
- Cumming's, Mr. ossa humana, reviewed, 52.
- Curiosities, literary, 141.
- Cynanche pharyngea, Dr. Davies on, 179.
- Cysts, Dr. Davies on the various kinds of, 578.
- Cutler's, Dr. surgeon's guide in dressing, &c. reviewed, 240.
- Currents, electric, Dr. Faraday on the indication of, 747.

D.

- Davies, Dr. lectures on diseases of the chest, and on the practice of percussion and auscultation: see "Chest, Dr. Davies' lectures on," &c.
- Deafness, congenital, Mr. Cock on the anatomy of, 446.
- Deficiency, congenital, of both the upper and lower extremities, Dr. Hardy on a case of, 235.
- Degrees, editorial observations on the proposed traffic in, 839.
- Delirium tremens, Mr. Parsons on a case of, 160; Dr. Badeley on the employment of opium in, 685.
- Deposits, adventitious, Dr. Davies on, 497; tubercular, *ib.*; cartilaginous and osseous, 577.
- Diabetes mellitus, Dr. Lefevre on, 300; Mr. Anderson on a case of, 654; Dr. Watson on the efficacy of the vapour-bath in, 395.
- Dickinson, Mr. on a case of inversion of the uterus successfully treated, 551.
- Difficulties, anatomical, of the season, 288.
- Disease cured by "command," 23.
- Disinterments, medico-legal, in France and England, 187; case in which the pre-

- sence of arsenic in the stomach was detected fourteen months after burial, 496.
 Dispensaries, editorial observations on the evil of, and how it may be checked, 311.
 Donation, munificent, 256.
 Dropsy, ovarian, Dr. Aldis on the diagnosis of, by percussion, the patient being in the recumbent posture, 553.
 Dropsy, case of, from diseased kidneys, 894.
 Dropsy, renal, Mr. Anderson on, 855, 903.
 Dublin University calendar, critical notice of, 560.
 Duffin, Mr. on the effects of an overdose of stramonium, 195; his inquiry into the nature and causes of deformity of the spine, reviewed, 736.
 Duplay, M. on saturnine amaurosis, 287.
 Dupuytren, Baron, clinical observations by, on fracture of the patella, 135; notice of the state of his health, 208; his decease, 697; biography of, 737; account of the post-mortem examination of the body, 775; his pomatum for preventing the fall of the hair, 818; his munificent donation, 346.
 Dyce, Dr. on a case of imperforate anus successfully treated, 226.
 Dyspnoea, Dr. Davis on the theory of, 3; on the causes and treatment of, 555.
 Dysphagia, clinical lecture on, by Sir C. Bell, 565.

E.

- Eden's, Mr. outlines of a new system of philosophy, reviewed, 374.
 EDITORIAL ARTICLES:—Medical responsibility—affaire of M. Thouret Noroy, 19, 36; demonstration of the gradual decrease of cholera during the last three years, 23; disease cured by command, *ib.*; Portuguese medicine—a royal post-mortem, 52; treatment of the propensity to suicide, 129; providential preservation of the medical evidence, and blasting of the diabolical hopes of the corruptionists, 166; new regulations of the College of Surgeons, 197; St. Bartholomew's midwifery lectures, 198; medical provision for the poorer classes, 241; controversy at St. George's Hospital, 243; medical organization in Austria, 274; evil of dispensaries, and how it may be checked, 311; imperfect working of the anatomy act, 341; present policy of the colleges—what ought it to be? 375; inquest in a case of child-murder, 406; alleged neglect at hospitals, 439; facts and inferences from the population returns, 484; poisoning, and its proofs after a lengthened interment, 516; reform in the College of Physicians, 561; facts and inferences from the population returns, 596; English and French hospital system, 631;

- proposed changes in the College of Physicians, 664, 694; biography of the late Baron Dupuytren, 737, 775; internal reform in the College of Physicians, 773; the joint-stock *University*, 809; proposed traffic in degrees, 839; the "scheme" of dealing in medical degrees abandoned, 882; operations forcibly performed—responsibility of surgeons, 919.
 Education, medical, account of the present state of, and the arrangement of the medical profession in the Austrian states, 277.

- Hanging, death by, without any of the usual characteristic lesions, by M. Albin Gras, 837.
- Hardy, Dr. account by, of a case of congenital deficiency of both the upper and lower extremities, 255.
- Hawkins, Mr. on a case of disease of the hip-joint resembling fracture of the cervix, 835.
- Heart, case of rheumatism of the, with paralysis, 173; Dr. Davies on Diseases of the, 706, 753, 785; symmetrical division of the, 256; Mr. Leppington on a case of mal or transposition of the, with complete obliteration of the gall-bladder, 228; M. Castel on the comparative irritability of the right and left portions of the, 333; Mr. Bloxam on a case of malformation of the, 435; case of disorganization of part of the, with mortification of the lower extremities, 749.
- Hæmipathy, Mr. evidence regarding the morbid appearances in a case of suspected poisoning at Bristol, 321.
- Heat, radiant, account by Professor Faraday, of M. Melloni's experiments on, 637.
- Hernia, inguinal, account by Mr. Robinson of two cases of, 169; strangulated femoral, operation for, 249; diaphragmatic intestinal, Dr. Davies on, 678; strangulated femoral, case of, 749.
- Hill, Mr. on the early employment of the catheter in cases of retention of urine, 896.
- Hip, Sir Charles Bell on serofulous disease of the, 693; treatment, 703.
- Histoire, naturelle, cours complet d', reviewed, 433.
- Hodgkin's, Dr. lectures on the means of promoting and preserving health, reviewed, 859.
- Holland, Mr. account by, of a case of poisoning with arsenic, 823.
- Homœopathy, commission appointed, by the Academy of Medicine in Paris, to inquire into the nature of, 697.
- Homœopathy disposed of, by the French Academy of Medicine, 921.
- Hope, Dr. on the connexion of apoplexy and palsy with organic disease of the heart, 776.

Horne, Mr. on a new preparation of the acetum opii sedativum, 573.

Hospitals, provincial, Dr. Collins on the mal-administration of, more especially in Liverpool, 121.

— small, superiority of, according to the professors of the London University, 378.

— editorial observations on the alleged neglect at, 439.

— morale of mixed patients in, 732.

— system, English and French, editorial observations on the, 631.

Hughes, Dr. on the paralysis produced by lead, 723, 727.

Humerus, Mr. Lonsdale on the treatment of fractures of the, 829.

Hutchison, Mr. A. C. on the treatment of nasal polypi, 17.

Hydrophobia, case of, communicated by a cow, 31.

Hydrocele, various cases of, related by Mr. Robinson, with the treatment employed, and remarks, 169.

Hydrothorax and heart disease, Mr. Jones on a case of, as connected with rheumatic affection, 112; Dr. Davies on, 673.

Hydatids, or acephalo-cysts, Dr. Davies on, 579.

Hypogastrium, Dr. Gibbes on a case of violent contusion of the, 44.

Hysteria, acute, case of, simulating peritonitis, 250; remarks, *ib.*; Mr. Robertson on the origin and nature of, 437, 503; violent, in a man, successfully treated, 603.

I.

Ilium, case of fracture of the, with dislocation and rupture of the ligaments of the knee, 250.

Iliac, external, Sir C. Bell on a case of aneurism of the, 569; full report of the case, 571.

Illusions, mental, M. Esquirol on certain cases of, 174.

Infiltration, tubercular, Dr. Davies on, 498.

Influenza, Dr. Davies on, 210.

Ingham, Dr. on a case of phlebitis, without apparent organic disease, terminating fatally, 102; another case, with organic mischief in the chest, which terminated favourably, 104.

Iodine, Mr. Caswall on the treatment of gonorrhœa and syphilitic affections with, 192; Mr. Barker on the use of, in the treatment of brnchocœle, 230; Mr. Stedman on the effects of, on the epidermis and hair, 447; Mr. Brett on the action of, upon guaiacum, 831.

Iris, case of congenital deficiency of the, 671; Mr. Willisford on a case of congenital deficiency of the, 729.

Iron, hydrated oxide of, Mr. Brett on the, as an antidote for arsenic, 220.

Itch insect, account of the, 29.

J.

Joints, Professor Mayo on diseases of, 379; Mr. Key on ulceration of the, 573.

Jones, Mr. on a case of hydrothorax and heart disease, as connected with rheumatic affection, 112.

K.

Key, Mr. on ulceration of the joints, 573.

Kidgell, Mr. account by, of the birth of a double fœtus, 371.

Kiernan, Mr. on the anatomy and physiology of the liver, 324, 359, 389; method of injecting the minute vessels of the, 395; concise and popular view of the author's researches, 481.

Kilgour's, Dr. lectures on the ordinary agents of life, reviewed, 126.

Kingdon, Mr. on Mr. Stafford's method of treating strictures of the urethra, 191.

Knee-joint, notice of a case of ulcerative disease of the, in a child, for which the lower extremity was amputated, 573.

Knee-joint, Sir C. Bell on diseases of the, 883.

Kreosote, note on, by A. Buchner, of Munich, 607; Dr. Elliotson on the medicinal properties of, 812; effects of, 847.

L.

Labour, difficult, Dr. Montgomery on, when caused by transverse malposition of the head, 266; instrumental, Mr. Reid on a case of, 465.

Laceration, Mr. Beaumont on a case of, of the internal parts without external lesion, 727.

Laennec, biography of, 100.

Lancet, refutation of certain falsehoods published in the, respecting St. George's hospital, 55; its first lie for 1835, 486.

Larynx, Dr. Davies on inflammation of the mucous membrane of the, 180.

Lawrance, Mr. account by, of a successful case of lithotripsy, 553.

Lead, Dr. Hughes on the paralysis produced by, 723, 727.

Lectures, introductory, price of puffing, 24.

Lecturers, a hint to. 25.

Lee, Dr. on phlebotomy, or calculi in the veins, and conversion of the coats of the veins into calcareous matter, 304; on fibrous tumors of the uterus, 751.

Lee, Dr. on the functions of the fetal kidney, 884.

- Lefevre, Dr. observations by, on diabetes mellitus, 300; case of calculus passing from the kidney, 302; on the origin and nature of the disease called *plica polonica*, 333, 337.
- Leg, Dr. Gibbes on a case of compound fracture of the, 47; Sir C. Bell on a case of compound fracture of the, 92; case of compound fracture of the, for which amputation was performed, 231.
- Leppington, Mr. on a case of mal- or transposition of the heart, with complete obliteration of the gall-bladder, 228.
- Ley, Dr. Hugh, on the pathology of nerves, 474, 508, 555, 582, 621, 646, 679, 713, 759, 799, 824.
- Life, Dr. Kilgour's lectures on the ordinary agents of, reviewed, 126.
- Liston, Mr. notice of the appointment of, as operating surgeon at the London University hospital, 89.
- Light, Dr. Ritchie on the Newtonian and undulatory theories of, 747.
- Lightning, effects of—Russian treatment, 575.
- Lisfranc, M. sur les diverses méthodes pour l'obliteration des artères, reviewed, 438.
- Lithotripsy, account, by Mr. Lawrance, of a successful case of, 553.
- Lithotrity, account, by Dr. Arrowsmith, of an unsuccessful case of, 399; account, by Mr. Busk, of an unsuccessful case of, 591.
- Lithotomy, case of, 573; case of, removal of four calculi by Mr. Tuson, 748; two cases of, by Mr. B. B. Cooper, 749.
- Liver, Mr. Kiernan on the anatomy and physiology of the:—Of the lobules, 324; of the surfaces, 326; of the portal canals, 327; of the vaginal portion of Glisson's capsule, and of its vessels, 328; of the hepatic veins, and of the hepatic venous canals, 359; of the structure of the lobules, 361; of the lobular venous plexuses, 363; of the lobular arteries, 389; of the red and yellow substances of Ferrein, and of the appearances produced in the liver by congestion, 390; method of injecting employed, 395; concise and popular view of the minute anatomy of the, 430; corrigendum in, 528.
- Lobstein, M. notice of the death of, 834.
- London University, notice of a meeting of the students of the, on the subject of recent regulations of the College of Surgeons, 315.
- Lonsdale, Mr. on the treatment of fractures of the humerus, 829.
- Louis', M. pathological researches on phthisis, reviewed, 879.
- Lumbago, intermittent, case of, cured by quina, 173.
- Lunacy, Dr. Seymour on the use of morphia in, 446.
- Lungs, Mr. Robbs on ulceration of the, 429.
- Lyons, Dr. on club-foot, 468, 511.
- M.
- McCrae, Mr. account by, of a preparation in the museum at Chatham, displaying a singular malposition in the chest, 372.
- Malformation, congenital, Dr. Alexander on a case of, 271.

- Murray, Dr. account by, of a case of iliac aneurism, and ligature of the aorta, 6; on variola and varicella, 117.
- Murray, Dr. on femoral aneurism, and the pathology of secondary aneurismal hæmorrhage, 907.
- Muscles, voluntary, Professor Mayo on the, 441.
- N.
- Nævus, subcutaneous, Mr. Fawdington on the cure of, by the seton, 157; large, of the cheek, method of cure for, proposed by Mr. Hawkins, 815.
- Natural history, extracts from a journal of, kept by Mr. G. Bennett, 113, 232.
- Negri, Dr. on the comparative merits of Dr. Bellinger's and Sir C. Bell's writings and opinions on the functions of the fifth and seventh pairs of nerves:—on the physiology of the seventh pair of cerebral nerves, 41; concluding remarks, 160; of the fifth pair, or trifacial nerve, 162; of the greater portion of the fifth nerve, 163; of the lesser portion of the fifth, *ib.*
- Nerves, Dr. Hugh Ley on the pathology of, 474; the principal effects of injury or disease of, will be observed at their remote extremities, 476; all the branches proceeding from a common trunk will have a similar disturbance of their function from the same injurious impression, 508; morbid excitement of nerves, 554; defective nervous energy, 557; excitement may be the result of mechanical impulse, of vascular congestion or irritation, of structural disease, or mere functional disorder, 582; symptoms of inflammation, 587; structural changes consequent on inflammation, 621; causes of inflammation of nerves, 646, 679, 713; diminished agency generally the result of extraneous pressure upon a healthy nerve, or of such disorganization of the nerve itself, as to destroy the continuity of the medullary filaments, 759, 799, 824.
- Dr. Negri on the physiology of the seventh pair of, 41; concluding remarks, 160; of the fifth pair, or trifacial nerve, 162; of the greater portion of the fifth nerve, 163; of the lesser portion of the fifth, *ib.*
- Dr. Badham on the offices of the, 74.
- spinal, of the turtle, Mr. Swan on the, 228.
- Professor Mayo on the physiology of the, 271.
- Mr. Mann on the excision of, when exposed in amputation, 772.
- Noble, Mr. account by, of some experiments relative to the sense of taste, 120.
- O.
- Oedema pulmonum, Dr. Davies on, 417.
- Operations at Guy's, inconveniences occasioned by the small size of the theatre, 255.
- Operation, extraordinary, 600.
- Operations forcibly performed—responsibility of surgeons, 919.
- Organization, medical, in Austria, editorial observations on the, 274.
- Opium, account of Mr. Horne's new preparation of, 600.
- Ornithorynchus paradoxus, mammiferous organization of the, 447.
- P.
- Pains, neuralgic, after amputation, Sir C. Bell on, 93.
- Palsy, Dr. Christison on a case of, of the third nerve, recovered from under free venesection and mercurial salivation, 59; of the portio dura of the seventh nerve, on

- both sides, 60; on one side only, *ib.*; of the optic nerve (?) 61.
- Paralysis from lead, Dr. Hughes on, 723, 765.
- of the nerves of the face, Dr. Christison on, 59.
- Parasites, insect, 447.
- Parsons, Mr. on a case of delirium tremens, 160.
- Parturition, Mr. Bury on aqueous discharge after, 47.
- Pastilles, for colds and coughs, formula for, 446.
- Paupers and parish surgeons, 201; note from Mr. Hooper, 287.
- Patella, clinical lecture, by M. Dupuytren, on fracture of the, 135; account of the examination of a limb soon after this accident, 137; diagnosis, 138; treatment, *ib.*; danger of tight bandaging, 139.
- Paterson, Mr. observations by, on intermittent fever, 269.
- Pectoriloquy, Dr. Davies on the occurrence of, 530.
- Pelvis, fractured, case of, with hæmorrhage and suppuration, 669.
- Penis, case of amputation of the, by Mr. Morgan, 64.
- Peritonitis, account, by Dr. John Badham, of two cases of, with remarks, 687; Dr. Bright on a diagnostic symptom in, 697.
- Peripneumonia, Dr. Davies on, 321, 334.
- Peregrine, Dr. on cases of syphilitic sore resembling condyloma, 337.
- Pericardium, Dr. Davies on diseases of the, 817.
- Pericarditis, case of, with remarks, 252.
- Periostitis, Dr. Clendinning on the curative properties of hydriodate of potass in, and chronic articular rheumatism, 833, 866.
- Percussion, Dr. Davies on, 65, 529; principle on which it depends, 66; position of the patient, *ib.*; mode of percussing, *ib.*; variations in sound at different ages, and in different temperaments, 67; variations according to situation, *ib.*; nature of the sound elicited in the various regions, *ib.*; inferences, *ib.*
- — Dr. Aldis on, as a mode of discriminating certain abdominal swellings, 552.
- Pharmacy, Mr. Meade's compendium of, reviewed, 128.
- Pharmacopœia, Dr. Barham on a new system of weights and measures for the, 770; on the same, by B. Y., 833.
- Philip's, Dr. A. P. W. inquiry into the nature of sleep and death, reviewed, 80, 662.
- — on the nature and treatment of suspended animation, 318; on the sympathics, 446, 494; on the causes of the growth of the body, 662.
- Phillips, Mr. B. prize awarded to, by the Institute of France, for an essay on a mode of curing aneurismal tumors without ligature or the knife, 575; on the union of bone, being the substance of an essay which obtained the Jacksonian prize, 779.
- Phlegmasia dolens, Mr. Anderson on the pathology of, with the history of a case which presented several unusual appearances, 794.
- Phlegmasia dolens, Mr. Clark on the pathology of, 870.
- Phlebitis, account, by Dr. Ingham, of two cases of, the one terminating favourably, the other fatally, with remarks, 102.
- Phlebolites, or calculi in the veins, Dr. Lee on, and conversion of the coats of veins into calcareous matter, 304; Mr. Reid on, 772.
- Phrenology, the last news of, 667.
- Phthisis pulmonalis, Dr. Davies on, 529; Sir C. Scudamore on the treatment of, by inhalation, 718; table of the duration of, before death, in 200 cases, 501.
- Phthisis, M. Louis' pathological researches on, reviewed, 879.
- Pineal gland (?), case of disease of the, with remarks, 62; result of an analysis of the gritty matter found in the, 238.
- Pleurisy, Dr. Davies on, 609; morbid anatomy, *ib.*; conversion of false membrane into cellular tissue, or fibro-cartilage, 611; chronic pleurisy, 612; gangrenous pleurisy, 613; signs of the disorder, 641; causes of, 644; treatment of, *ib.*
- Pleura, Dr. Davies on accidental productions deposited in the, 678.
- Pleuro-peripneumonia, Dr. Davies on, 677.
- Plica polonica, Dr. Lefevre on the nature and origin of, 333, 337.
- Pneumo-thorax, Dr. Davies on, 673; signs of, with effusion, 675.
- Pneumonia, Dr. Davies on, combined with slight pleurisy, 677.
- Poisoning, and its proofs after a lengthened interment, 515.
- Polypi, Mr. A. C. Hutchison on the treatment of, 17; Mr. Chevalier on the same, 50.
- , bronchial, Dr. Davies on, 294.
- Polypus, Sir B. C. Brodie on a case of, of the antrum, 350.
- Pomatum, Baron Dupuytren's, for preventing the fall of the hair, 848.
- Population, editorial observations on the facts and inferences to be drawn from the returns of the, 486; facts and inferences from the returns of the, 596.
- Population and mortality, Mr. Corboux on, 629.
- Potass, hydriodate of, Dr. Clendinning on its curative properties in peritonitis and chronic articular rheumatism, 833, 866.
- Pregnancy, Mr. Thomas on the stethoscopic signs of, 346.
- Prescribing, fatal inadvertence in, 441.
- Pritchard's, Mr. list of microscopic objects, critical notice of, 737.
- Prolapsus recti, Mr. Robinson on a case of, cured by tonic and astringent injections,

140 ; another case, with inflammation and deposit of false membrane, cured by antiphlogistic means, *ib.* ; remarks, *ib.*
 Provision, medical, for the poorer classes in the metropolis, editorial observations on, 241.

Pyramids, posterior, Mr. Mayo on Sir C. Bell's discovery of the decussation of the, 402.

Q.

Quain's, Dr. elements of anatomy, reviewed, 240.

Quina, case of intermittent lumbago cured by, 173 ; remarks, 174.

R.

Rectum, Sir B. C. Brodie on diseases of the, 742, 842.

Reform, medical, Dr. Postock on, 15 ; *Civis Medicus* on, 372, 692 ; editorial article on, 375 ; changes most necessary in the College of Physicians, 561 ; remarks on the changes proposed, 664, 694, 773.

Reid, Mr. observations by, on phlebolites, 772 ; account by, of the results of injections of the vessels of the fœtus, to show some of the peculiarities of the circulation, 803.

Reports, medico-legal, by M. Marc, on a case of suspected infanticide, 875.

Responsibility, medical, editorial observations on, suggested by the affaire of M. Thouret-Noroy, 19, 86.

Rheumatism, chronic, Dr. Burke on a case of, successfully treated by tartar emetic, 50 ; case of, of the heart, with paralysis, 173.

Rickman, Mr. on the mortality of the manufacturing districts of England, 588, 652.

Rigby, Dr. on soda in tooth-ache, and some forms of neuralgia, 730.

Riley's, Dr. evidence regarding the morbid appearances in a case of suspected poisoning at Bristol, 519.

Ringworm, Dr. Babington on the treatment of, with pyroligneous acid, 549.

Ritchie, Dr. on the Newtonian and undulatory theories of light, 747.

Robbs, Mr. on a case of apoplexy, with delirium tremens, 78 ; on ulceration of the lungs, 429.

Robertson, Mr. on the origin and nature of hysteria, 467, 503 ; on infant mortality in Manchester and some other parts of Lancashire, 733.

Robinson's, Mr. surgical reports, 140, 168, 253, 282.

Rognetta, M. account by, of a case of rupture of viscera in the cavities of the body without external appearances, 668.

Roux, M. account by, of a professional tour in Italy, with an account of the universities, hospitals, &c. of that country, 306.

Rowe, Mr. remarkable case related by, of intussusception of the colon into the rectum, 119.

Royal Medical and Chirurgical Society : the new charter, 248. Papers read : Dr. Philip on the sympathies, 446 ; Mr. Cock on the anatomy of congenital deafness, 446 ; Dr. Seymour on the use of morphia in lunacy, *ib.* ; Dr. Wilson Philip on the sympathies of the more perfect animals, 494 ; Dr. Seymour on the acetate of morphia in cases of mental derangement, 496 ; Mr. Key on ulceration of the joints, 573 ; Mr. Horne's new preparation of opium, 600 ; Dr. Bright on a diagnostic symptom in peritonitis, 697 ; Dr. Elliotson on the medicinal properties of kreosote, 812 ; address to his Majesty by the society, 812 ; Dr. Lee on the functions of the fœtal kidney, 884 ; Mr. Cæsar Hawkins on a case of disease of the hip-joint resembling fracture of the cervix, 885.

Royal Institution, substance of the lectures delivered at the :—Professor Faraday on Melloni's experiments on radiant heat, 637 ; Dr. Ritchie on the Newtonian and undulatory theories of light, 747 ; Dr. Faraday on the induction of electric currents, *ib.*

Royle's, Mr. illustrations of the botany, &c. of Cashmere, reviewed, 877.

Rye, ergot of, Dr. Churchill on the effects of, 223.

S.

Salt, Dr. Aldis on the exudation of, from the skin, 18.

St. George's Hospital election ; letter of the physicians and surgeons, 199 ; Sir B. Brodie's letter, 200.

St. George's Hospital reports, 62, 173, 250, 573, 603, 669, 749, 814, 892.

St. Bartholomew's Hospital report, 284.

St. Marylebone Infirmary, state of the poll at the close of the election for physician to the, 416.

Sarcoma, medullary, Dr. Davies on, 579.

Scalp, lacerated, Sir C. Bell on a case of, 207.

"Scientific surgeon," description of a, 564 ; contrast presented by the "knivesman," *ib.*
 Seudamore, Sir Charles, on inhalation in chest diseases, 718.

Seymour, Dr. on the use of morphia in lunacy, 446 ; on the treatment of cases of mental derangement by the acetate of morphia, 496.

Semple, Mr. on the occurrence of menstruation at advanced periods of life, 467.

Sheffield medical school, account of the destruction of the, by the populace, 640.

Skin, memoir, by Dr. Fohmann, on the lymphatics of the, and of the serous membranes of the nervous and muscular tissue, 255.

Skull, fractured, Mr. Adams on a case of, with rupture of the spinous artery, successfully trephined, 730.

Sleep and death, Dr. Philip's inquiry into the nature of, reviewed, 80.

Soda, carbonate of, M. Gay Lussac on the purification of, 319.

— Mr. Gaskoin on the relief to be derived from, in cases of toothache, 659; Dr. Rigby on the same, 730.

Somnambulism, Dr. Belden on, 52.

Sore, syphilitic, Dr. Peregrine on cases of, resembling condyloma, 337.

Sphygmometer, description of the, 29.

Spender, Mr. on ulcerous diseases of the leg, reviewed, 918.

Spine, Mr. Duffin's inquiry into the nature and causes of deformity of the, reviewed, 736.

Statistics, Austrian, 704.

Statistical society, notice of a paper read at the first meeting for the season, on the character and condition of the Irish labourer, 286; report of the proceedings at the anniversary meeting, 923.

Stethoscope, Dr. Davies on the application of the, 146.

Stedman, M. on the effects of iodine on the epidermis of the hair, 447.

Steggall's, Dr. manual for examination at Apothecaries'-hall, reviewed, 240.

Strictures, Mr. Andrews on Mr. Stafford's treatment of, 75.

Stricture, with lacerated urethra and distended bladder, Sir C. Bell on, 295; case of, with lacerated urethra, and the operation, *ib.*

Stramonium, Mr. Duffin on the effects of an over-dose of, 194.

Surgery, forcible, 812; further notice of the case, 841; report of the trial of the parties, 922.

Students, medical, number of, in Paris, 384.

Stumps, Sir C. Bell on the condition of, after amputation, 93.

Suicide, editorial remarks on the propensity to, 129; remarkable case of, by the inhalation of carbonic acid gas, 601.

Subjects, the supply of, improved, 519.

Surgeon assassinated by his patient, 847.

Swan, Mr. on the spinal nerves of the turtle, 228.

Sweatman, Mr. on a case of premature development of the brain, 594.

Sympathies, Dr. A. P. W. Philip on the, 446, 494.

T.

Tænia, case in which portions of, have been, and continue to be, voided from the bladder, 236.

Tartar emetic, case of chronic rheumatism successfully treated by, 50.

Taste, account by Mr. Noble of some experiments relative to the sense of, 120.

Talicotian operation, 573.

Tendons, Professor Mayo on, 442.

Thigh, case of amputation at the, performed by Mr. B. Cooper, 64.

Thomson's, Dr. A. T. elements of materia medica and therapeutics, reviewed, 403.

Thomas, Mr. on the stethoscopic indications of pregnancy, 340.

Tibia, Sir C. Bell on a case of compound fracture of the, 93.

Tissue, filamentous, Professor Mayo on, 443; adipose, 445.

Toothache, Mr. Gaskoin on the relief to be obtained from soda in cases of, 659.

— Dr. Rigby on the use of soda as a remedy in, and some forms of neuralgia, 730.

Tubercles, miliary, Dr. Davies on, 498; encysted, *ib.*

Tumor, notice of the removal of a, from the shoulder, by Mr. C. A. Key, 64; from the back, by Mr. Morgan, *ib.*; case of, in the left auricle, 671.

Tumors, encysted, clinical lecture on, by Sir B. C. Brodie, 25; fibrous, of the uterus, Dr. Ley on, 751; malignant, of the antrum, Sir B. C. Brodie on, 350.

Tumors, aneurismal, Mr. Phillips on a new method for the cure of, 870.

Turnbull, Dr. on the internal administration of pure veratria, 190.

Turner's, Dr. elements of chemistry, reviewed, 479.

Turner, Dr. letter from, respecting a case of alleged poisoning and child-murder, 487.

Turtle, Mr. Swan on the spinal nerves of the, 228.

Twins, sympathy between, with respect to diseases, 142.

U.

University hospital, puffing of the, 514.

University, the joint-stock, editorial observations on the financial affairs of the, 809; proposal to grant a monopoly to the, 810.

Universities of Prussia, statistical statement respecting the, 315.

Urethra, strictures of, Mr. Kingdon on the treatment of, with the lancetted stilette, 191.

Urine, retention of, remedy in cases of, where the catheter cannot be applied, 672.

Uterus, Mr. Robinson on a case of malig-

nant ulceration of the neck of the, in which a communication formed between the bladder and the vagina, 234; Mr. Reid on a case resembling rupture of the, 463; inverted, Mr. Dickinson on a case of, successfully treated, 551; Dr. Lee on fibrous tumors of the, 751.

V.

- Vapour bath, Dr. Watson on the efficacy of, in cases of diabetes, 395.
 Variola and varicella, Dr. Murray on, 117.
 Varicocele, Mr. Walshe on M. Breschet's operation for the radical cure of, 369.
 Velpeau's *traité complet de l'art d'accouchemens*, reviewed, 561.
 Venereal disease, Mr. Clarke on the, 37, 68.
 Venables', Dr. aphorisms in chemistry, reviewed, 128.
 Veratria, pure, Dr. Turnbull on the internal administration of, 190.
 Vetch, Dr. notice of a paper by, on cholera, read before the College of Physicians, 779.
 Villermé, M. reply by, to Mr. Rickman's remarks on the infant mortality in manufacturing towns, 301.
 Viper bite, curious case of, giving rise to alarming symptoms, recovered from, 317.
 Viscera, case of rupture of, in the cavities of the body, without external appearances of lesion, 668; Mr. Elwin on a case of rupture of the, without external appearances, 728.

W.

Walker's, Mr. letter to the governors of St. George's hospital, respecting the election of a second assistant surgeon, 247; prin-

ciples of ophthalmic surgery, reviewed, 341.

Walshe, Mr. on M. Breschet's operation for the radical cure of varicocele, 369.

Wakley an M.P., 519.

Wakley's, Mr. *debut* in parliament, 311.

Watson, Dr. on the efficacy of the vapour bath in cases of diabetes, 395.

Weber's, Dr. anatomical atlas, critical notice of, 438.

Weights and measures for the new Pharmacopœia, Dr. Barham on a new system of, 770; remarks on the same subject, by B. Y., 833.

Westminster Medical Society, subjects for discussion, 113.

Westminster hospital report, 894.

Wigan, Mr. on the treatment of ring-worm, with pyroligneous acid, 550.

Wilde, Mr. note from, on the subject of small hospitals, 415.

Whooping-cough, Dr. Davies on, 258.

Wilson's, Dr. letter respecting the election of assistant surgeon at St. George's hospital, 245.

Willisford, Mr. on a case of congenital deficiency of the iris, 729.

Wrist, Sir C. Bell on a case of fracture of the, with compound dislocation and mortification, 91.

Writings, falsification of, 96.

Y.

Yarrell's British fishes, critical notice of the first number of, 913.

Z.

Zinc, sulphate of, Mr. Chevalier on its use in the treatment of nasal polypi, 50.

— the paste of the chloruret of, recommended in the treatment of cancerous affections, 603.
